animal's value warrants the expense. The sicker or more immature the neonate, the more complications it is likely to develop during the course of treatment. It is much better to refer a sick neonate early in the course of disease, rather than as a last resort before death.

If a decision is made to refer the animal, the method of transport is extremely important to the outcome of the case. If the foal is recumbent and is showing signs of hypothermia and/or respiratory distress, consider shipping

the foal ahead of the mare in a heated vehicle. The mare can be stripped of colostrum and then sedated. Colostrum can be sent with the foal. The mare can be sent later, once the foal's condition has been evaluated and stabilized at the referral clinic. Save and send the placenta with all compromised foals. Recumbent foals can be restrained in SUVs and cars by wrapping them in a sleeping bag or blanket. Ideally, an attendant should travel with any weak, recumbent, or potentially recumbent foal.

Cold foals can be warmed during transport by increasing the inside temperature of the vehicle and by placing water bottles or heat packs beside the foal. Body temperature, blood glucose, and oxygenation must be maintained during the trip. In the hypoglycemic patient, a continuous glucose infusion during the trip is far better than a glucose bolus given before departure.

If the foal is dyspneic, administer intranasal oxygen at 3 to 6 L/min using an indwelling intranasal cannula. Portable oxygen tanks can be rented from home care pharmacies with a veterinarian's prescription. A recumbent foal should be kept sternal and turned every 2 hours to minimize dependent lung atelectasis. If the foal is apneic or demonstrating an unusually slow respiratory rate, consider a loading dose of caffeine (10 mg/kg) given PO or per rectum before transport.

20 Chapter 20 Manifestations and Management of Disease in Neonatal Ruminants

John K. House

Alison A. Gunn

20.1 WEAKNESS AND/OR DEPRESSED MENTATION

John K. House

If weakness has been present since birth, in utero acquired bacterial or viral infections, birth asphyxia and trauma, chronic placental problems, and congenital anomalies should be considered on the list of differential diagnoses. A number of congenital bacterial, fungal, and viral infections that cause abortions and stillbirths may result in the birth of a live, weak neonate. In cattle, brucellosis, salmonellosis, leptospirosis, listeriosis, *Escherichia coli*, *Corynebacterium* species, and *Aspergillus* species may cause placentitis and disease in the newborn. In sheep, in utero infection with chlamydia, *Campylobacter, Coxiella,* bluetongue virus, and border disease may cause disease in the newborn. Congenital viral infections of neonates are listed in Box 20-1. Clinical manifestations of fetal infections depend on the age of the fetus and the virulence and trophism of the infecting agent (see individual diseases).

Neonatal calves with storage diseases primarily affecting the nervous system may appear reasonably normal for a short period after birth and then show progressive signs of neurologic dysfunction, including tremors, spasms, depression, recumbency, and coma. Differential diagnoses for weakness and depressed mentation after a period of apparently normal strength and mentation include sepsis, electrolyte and acid-base disturbances, hypoglycemia, and hypothermia. A complete history is obtained, including a detailed description of the delivery process, and complete physical and neurologic examinations are performed. Any signs of trauma, infection, or congenital malformations should be noted. Evaluation of hematologic data and immunoglobulin G (IgG) status, combined with historical and physical examination parameters, results in an assessment of the likelihood of sepsis. Blood glucose, blood gas, and serum electrolyte concentrations should be determined promptly. Blood cultures and cerebrospinal fluid (CSF) analysis are useful for verifying central nervous system (CNS) involvement and targeting antimicrobial therapy.

For collection of fluid from the lumbosacral space, a 20-gauge, 1- to 2-inch needle with a clear hub may be used. A change in resistance is felt when the needle penetrates the dural membranes, and CSF appears in the plastic hub as soon as the subarachnoid space is entered. Approximately 5 to 10 mL of fluid may be removed safely. Urinary reagent strips can be used to rapidly obtain general information on the fluid. If blood is detected, the sample should be spun down after the cytologic examination. Red blood cells contaminating the sample will settle, and the supernatant should be colorless. If hemorrhage occurred before the procedure, the sample remains xanthochromic (yellow). Glucose should be present in “trace” or “+” amounts in the normal sample. Negative values in the adult suggest severe meningitis, but in the neonate may also be caused by profound hypoglycemia. CSF analysis is most useful in determining the presence of septic meningitis. Elevation of the total protein level (>150 mg/dL) and neutrophil count in addition to a positive Gram stain and bacterial culture results in a straightforward diagnosis of bacterial meningitis, and the prognosis is considered poor for the animal.[1] Infection in the CNS, however, can be difficult to detect until the process becomes generalized; the lack of positive cultures and Gram stain does not rule out CNS infection. An elevated albumin quotient suggests increased blood-brain permeability and can be seen in both hypoxic-ischemic brain injury and meningitis, but an elevated IgG index indicates increased intrathecal IgG production and is more compatible with a diagnosis of meningitis.

20.2 MENINGITIS

Depressed mentation is a common presenting sign in neonates with sepsis. Although bacterial meningitis may occur as a primary entity, it more commonly is a result of generalized septicemia in neonates with failure of passive transfer (FPT). Agents that cause meningitis are the same agents that cause septicemia, most commonly the gram-negative enteric bacteria such as *E. coli, Enterobacter* species, and *Salmonella* species. In a review of 32 cases of meningitis in calves by Green and Smith,[1] the clinical signs of CNS disturbance observed were lethargy, recumbency, anorexia, loss of suckle reflex, coma, opisthotonos, convulsions, tremor, and hyperesthesia. Leukocytosis and a left shift were evident in 11 of 15 calves (73%). Concurrent metabolic problems were common and included hyperkalemia, respiratory acidosis, hypernatremia, hyponatremia, hypomagnesemia, and hypoglycemia. Analysis of CSF revealed pleocytosis, xanthochromia, turbidity, and high total protein concentration. Cytologically, neutrophils predominated in the CSF in calves with acute disease. Mononuclear cells dominated in calves with chronic disease. Microscopically, bacteria were evident in 10 of 22 (45%) of the antemortem CSF samples, and bacteria were isolated from slightly more than half (11 of 19). All of the calves in this review died.[1] In my experience treating calves in a hospital environment, the mortality rate is high; however, aggressive early treatment can be successful. The economics and welfare implications of treating commercial calves in a field setting are questionable. Empiric antimicrobial therapy for meningitis in neonatal calves should include a gram-negative and positive spectrum. Antibiotics enter the CSF predominantly via passive diffusion down a concentration gradient. The major determinant of CSF penetration is lipid solubility. Lipophilic agents diffuse via transcellular pathways; peak concentrations in CSF occur relatively rapidly, and entry into CSF is affected minimally by the presence of inflammation. In contrast, hydrophilic agents enter the CSF through paracellular pathways; their transport depends on the opening of tight junctions, and peak concentrations are relatively delayed.[2] Only one report documents the pharmacokinetics of an antimicrobial agent in CSF in calves. Table 20-1 lists CSF-to-blood concentration ratios (penetration) derived from multiple species for a handful of antimicrobial drugs available for use in cattle.

20.2.1 Box 20-1 Differential Diagnoses for the Weak or Depressed Large-Animal Neonate

20.2.1.1 Bacterial Infection: in Utero or Postnatally Acquired

Septicemia

Joint and bone

Enteritis

Pneumonia

Meningitis

Peritonitis (primary or secondary)

20.2.1.2 Congenital Viral Infection

Bovine virus diarrhea virus (B)

Bluetongue virus (B, O)

Infectious bovine rhinotracheitis virus (B)

Akabane virus (B)

Parainfluenza (B)

Caprine herpes (C)

Border disease virus (O)

Equine herpesvirus (E)

Equine viral arteritis (E)

20.2.1.3 Prematurity/Postmaturity

Weak calf syndrome

Bacterial or fungal placentitis

Insufficient fetoplacental matching (twin foals)

20.2.1.4 Birth Asphyxia

Placentitis

Dystocia

Cesarean section

Premature placental separation

Induced parturition

20.2.1.5 Birth trauma

Brachial plexus injuries

Fractured rib, pneumothorax, hemothorax

Ruptured bladder

20.2.1.6 Congenital Malformations

Cardiac malformations

Central nervous system malformations (e.g., hydrocephalus, hydranencephaly)

Angular limb deformities

Arthrogryposis

20.2.1.7 Metabolic Derangements

Hypoglycemia

Hyponatremia

Hypokalemia or hyperkalemia

Hypocalcemia

Acidosis (respiratory or metabolic)

Uroperitoneum (with electrolyte abnormalities)

Renal failure

20.2.1.8 Severe Anemia

Blood loss

Neonatal isoerythrolysis

20.2.1.9 Brain Disease

Hemorrhage

Ischemia, edema, necrosis

Traumatic injury

Meningitis

Malformations

Narcolepsy-cataplexy syndrome (intermittent weakness)

20.2.1.10 Spinal Cord Disease

Spinal cord hemorrhage

Vertebral malformation (e.g., atlantooccipital)

Vertebral abscessation or osteomyelitis

Vertebral fracture or other trauma to spinal cord

20.2.1.11 Peripheral Nerve and Muscle Disease

White muscle disease

Tetanus

Congenital myopathy, polymyositis

Neuropathy of spinal roots or peripheral nerves

Botulism (foal)

Collagen disorder

Aminoglycoside-induced neuromuscular blockade

20.2.1.12 Liver Disease

Hepatitis

Severe hypoxic insult

Tyzzer's disease (foals >2 weeks old)

Toxin (iron fumarate given to foals)

20.2.1.13 Storage Disorders

Maple syrup urine disease

Citrullinemia

Shaker calf syndrome (neurofilament accumulation)

GM1 gangliosidosis

20.2.1.14 Ingestion of Drugs or Toxins

Transplacental transfer of anesthetics and sedatives

Inadvertent oversedation of neonate

20.2.1.15 Gastrointestinal Disease

Gastrointestinal ulceration

Necrotizing enterocolitis

B, Bovine; *C,* caprine; *O,* ovine.

Table 20-1 Cerebrospinal Fluid—to-Blood Concentration Ratios (Penetration) of Antibiotics Available for Treatment of Meningitis in Calves[2,3]

	Concentration CSF/Concentration Serum (%)	
Antimicrobial*	**Human**	**Animals**
Ampicillin	13–14	8–12
Florfenicol		46 (calves)
Gentamicin	0–30	21–25
Penicillin	5–10	5–6
Trimethoprim-sulfamethoxazole	<41	35–39

CSF, Cerebrospinal fluid.

*The list is not conclusive, reflecting the paucity of available data.

In a CSF pharmacokinetic study of florfenicol in calves the maximum concentration of florfenicol attained in CSF was 4.67 ± 1.51 μg/mL following a single intravenous dose of 20 mg/kg. The levels remained above the minimum inhibitory concentration (MIC) for *Haemophilus somnus* over a 20-hour period.[3] This concentration is below the MIC_{90} for *E. coli*. Bacteriocidal antibiotics are proposed to be more effective for treatment of meningitis in humans, and it is recommended that the concentration of antibiotic in the CSF should be maintained at 10 times the MIC of the target pathogen.[2] Ceftiofur may be used to treat meningitis in calves. In one calf, I measured the concentration of ceftiofur in CSF 28 hours after initiation of treatment with 10 mg/kg twice per day (bid). The concentration of ceftiofur in CSF at this time was 1.27 μg/mL, which happened to be five times the MIC of the *E. coli* isolated from the CSF of the calf. Unfortunately, owing to the lack of CSF pharmacokinetic data in cattle, antimicrobial treatment of meningitis is an inexact science.

20.3 METABOLIC ACIDOSIS

Profound weakness associated with metabolic acidosis is commonly observed in calves with diarrhea and sporadically in kids ("floppy kid syndrome") and calves without other clinical signs of disease.[4,5] Correction of the acidosis by intravenous administration of bicarbonate produces a rapid recovery. An improvement in mentation and strength should be observed within 12 hours; persistent depression is likely to reflect incomplete correction of acidosis, sepsis, hypoglycemia, hypernatremia, or hyponatremia.

20.4 HYPOGLYCEMIA

Hypoglycemia is a common sequela to withdrawal of milk for more than 48 hours, especially in cold weather. Affected calves are weak or recumbent but appear to be normally hydrated or minimally dehydrated.[6] They are often emaciated and can occasionally have neurologic signs including facial twitches, convulsions, opisthotonus, and coma. They will respond to infusion of 5% glucose, but often this response is temporary, especially in calves with severe malabsorptive disease. It is important to rapidly restore adequate energy intake to ensure resolution of these cases. Starvation and hypothermia resulting from mismothering are common causes of weakness in neonatal lambs. Similarly, weakness, poor body condition, and increased susceptibility to infectious diseases are observed with protein-calorie malnutrition induced by feeding poor-quality or incorrectly mixed milk replacers.[7]

20.5 HYPONATREMIA

Hyponatremia occurs when loss of isotonic fluid through the gastrointestinal tract is replaced by free water or hypotonic solutions. The latter often occurs when too much water is added when making up an oral electrolyte solution. Hyponatremia may also occur when isotonic oral electrolyte solutions are administered to calves with compromised sodium absorption capacity. This may be a result of severe pathologic changes or an inadequate level of agents that facilitate sodium cotransport within the oral electrolyte solution. Hyponatremia results in a fluid shift from the extracellular space to the intracellular compartment along the osmotic gradient, and the resultant swelling of the cells can result in neurologic disturbances, depression, disorientation, and even convulsions.[8] Hyponatremia should be considered in calves with serum sodium <132 mmol/L; calves with serum sodium <120 mmol/L have severe hyponatremia.

The goal of therapy is to restore serum sodium levels to >125 mmol/L over the first 6 hours and then to restore to normal levels over 24 hours.[8] In hypovolemic calves the initial treatment should be achieved using normal saline, and in normovolemic calves hypertonic saline should be used for the initial treatment, as the administration of large fluid volumes will exacerbate cerebral edema. If the calves are also suspected to be acidotic, this should be corrected with sodium bicarbonate solutions of appropriate tonicity.

The amount of sodium required in the first 6 hours to raise the sodium level to 125 mmol/L can be calculated as follows[8]:

$$\text{Sodium } \backslash(\text{mmol}) = (125 - \text{Measured serum sodium } \backslash[\text{mmol} / \text{L}]) \times \backslash(0.6 \times \text{Body weight } \backslash\ \backslash[\text{kg}])$$

Calves should then be maintained on a sodium-containing isotonic fluid, such as normal saline or lactated Ringer's, and treated with oral electrolyte solution as appropriate. The sodium level should be monitored frequently in the first 24 hours because of unknown losses through the gastrointestinal tract as well as unknown kidney function in a severely dehydrated patient.

20.6 HYPERNATREMIA

Hypernatremia is defined as a serum sodium concentration over 152 mmol/L (although only levels greater than 170 mmol/L have been associated with nervous dysfunction[9]). Hypernatremia occurs secondary to improper mixing of oral electrolyte solutions[8] or from the use of high—sodium-content milk replacer when there is limited access to

fresh water; consequently it is often farm-specific. Rapid development of hypernatremia results in fluid moving from cells into the extracellular fluid and produces cellular dehydration. Neurologic signs include lethargy, weakness, depression, coma, and death. Treatment of hypernatremia involves fluid therapy with a stepwise reduction in serum sodium concentration. A gradual reduction of serum sodium is indicated, as a rapid drop in serum sodium promotes a fluid flux into the brain, exacerbating cerebral edema and resulting in death.[8] Intravenous fluids are adjusted to contain concentrations of sodium approximately equal to the patient's sodium plasma concentration.[10] The goal is to reduce plasma sodium by less than 5 mEq/L/day over the first 48 hours by slow excretion through the kidneys. The volume given should be that to provide rehydration and cover maintenance and ongoing losses. The solution may include sodium bicarbonate if the calf is acidotic. Sodium should be added to any oral fluids (e.g., milk replacer) until plasma sodium levels approach normal so that the concentration is approximately equal to the intravenous fluids. Seizures may be observed if the drop in plasma sodium is too rapid. Cerebral edema may be treated with 25% solution of mannitol at 1 g/kg given intravenously (IV) over 30 minutes or an oral solution of glycerin given at 1 g/kg diluted 1:1 with water.

335

336

20.7 NEUROMUSCULAR AND MUSCULOSKELETAL DISEASE

Primary neuromuscular or musculoskeletal disease should be considered when weakness is not associated with depressed mentation. Weakness associated with micronutrient deficiencies results from myodegeneration (white muscle disease, selenium, and vitamin E) or demyelination (copper, enzootic ataxia). If weakness is detected in one or more limbs immediately after birth, peripheral nerve and muscle damage associated with birth trauma should be ruled out (see Box 20-1). Femoral nerve paralysis may be observed in calves after a “hip lock” dystocia.[11] A condition resembling congenital myasthenia gravis has also been described in Brahman calves.[12]

Nutritional myodegeneration associated with selenium or vitamin E deficiency may produce paresis that is localized (dysphagia) or generalized. Neonatal small ruminants appear to be particularly susceptible. Affected lambs may be unable to rise. Others can stand but may be unable to nurse because they are unable to raise their heads. Diagnosis is based on clinical signs, increased serum creatinine kinase concentration, and reduced whole blood glutathione peroxidase and/or selenium concentrations. (See Chapter 42.) Vitamin E deficiency is observed when pregnant ewes are fed stored forage low in vitamin E; the clinical signs in affected lambs are identical to those of selenium deficiency, but selenium status is adequate. As vitamin E is labile, serum should be harvested quickly after blood collection, frozen, wrapped in aluminum foil, and sent via express mail on ice.

Paraplegia and tetraplegia are commonly associated with spinal cord compression. Compression of the spinal cord in neonates most commonly results from vertebral body malformations, osteomyelitis, or fractures. Generally, vertebral body malformations occur sporadically; genetic, nutritional, and environmental factors have been implicated.[13,14] In older calves, underlying metabolic bone disease (copper, vitamin D, or phosphorous deficiency) may increase the propensity for fractures to occur. Osteomyelitis and vertebral body abscess may be sequelae to bacteremia after neonatal septicemia[15] or pneumonia.[15] The frequent isolation of *Arcanobacterium (Actinomyces) pyogenes* from vertebral body abscesses in ruminants suggests that chronic respiratory infections is more frequently the source in these species.[16,17] Vertebral body abscesses in lambs are occasionally a sequela to infected docking wounds. Leukocytosis and hyperfibrinogenemia are commonly observed in neonates with vertebral body abscesses. In most instances vertebral abscesses do not infiltrate the pachymeninges, so the CSF either is normal or has a mild elevation of protein and/or a mild pleocytosis.[15,16]

Differential diagnoses for paresis in goat kids include caprine arthritis-encephalitis virus (CAEV) and enzootic ataxia. Enzootic ataxia is also common in lambs. Progressive ataxia and paresis or paralysis is a feature of both

diseases. There are two forms of enzootic ataxia (swayback): the neonatal and the delayed types. In the neonatal condition animals are affected at birth; in the delayed type, signs of incoordination appear at 14 to 30 days of age.[18] Most affected neonates are afebrile, bright, and alert and will continue to eat if it is physically possible. Enzootic ataxia is associated with low liver copper content and, occasionally, low serum copper concentration.[19] It has been proposed that reduction in the activity of the copper-dependent enzyme cytochrome oxidase impairs phospholipid synthesis and subsequently myelin production. Microcytic anemia and increased fragility of bones may be observed in more chronic cases.[20] The copper, molybdenum, and sulfur content of the maternal diet should be evaluated and adjustments made for copper deficiency or molybdenum or sulfur excess. (See Chapter 41.)

Goat kids with the neurologic form of CAEV will have mild to moderate fevers and evidence of cerebral involvement. Cerebral signs commonly identified include depression, head tilt, torticollis, and circling.[21] Evidence for CAEV would include CSF pleocytosis and increased CSF protein and a positive CAEV (agar gel immunodiffusion [AGID]) test or enzyme-linked immunosorbent assay (ELISA). Both the neurologic form of CAEV and enzootic ataxia carry a poor prognosis.

A complete neurologic examination is an important component of the workup of the weak neonate. In particular, it should be noted whether the weakness is accompanied by signs of depression and diffuse cerebral disease. It should be remembered that strength is preserved if ataxia is caused by cerebellar disease. Limb reflexes should be tested to establish whether components of the spinal reflex pathways are involved in the disease process (sensory nerve, lower motor neuron, neuromuscular junction, muscle). Animals with other types of spinal cord disease (e.g., trauma, vertebral malformations, enzootic ataxia) may also show weakness and ataxia yet appear clinically to have normal cerebral function. Virtually any severe systemic disease such as generalized infection can cause both profound depression and weakness in a neonate without the presence of actual brain pathology. Intermittent signs of severe weakness and depression may be caused by the narcolepsy-cataplexy syndrome. (See Chapter 33.)

20.8 RESPIRATORY CONDITIONS

20.8.1 EXAMINATION AND ANCILLARY DIAGNOSTICS

Assessment of the pattern and effort of breathing is a very important part of the examination of the respiratory system. Any obvious abnormal noises associated with respiration should be noted. Inspiratory stridor is often a feature of extrathoracic airway obstruction, and increased abdominal effort on expiration often indicates pulmonary disease causing reduced lung compliance. Absence of cyanosis is not a reliable indicator of adequacy of oxygenation in the neonate, because the partial pressure of oxygen may reach very low levels (<35 to 40 mm Hg) before cyanosis is observed. Fever, cough, and nasal discharge are usually absent in the early stages of pneumonia in the neonate.

Diagnosis of most upper airway disorders can usually be made with a careful physical examination in combination with radiography and/or endoscopy (Box 20-2). An integral part of the diagnostic approach to the neonate with suspected upper airway obstruction is assessment of the lungs for aspiration pneumonia. If the primary upper respiratory problem is not corrected and normal nursing allowed, the pneumonic process will likely persist and become chronic.

20.8.1.1.3

Lung Parenchymal Diseases

Pneumonia (bacterial or viral)

Atelectasis

Hyaline membrane disease

Pulmonary edema, congestion

Aspiration syndromes

Air leaks (e.g., pneumothorax)

Pulmonary hemorrhage

Transient tachypnea syndromes

20.8.1.1.4

Nonpulmonary Causes

Congestive heart failure

Central nervous system lesions

Metabolic derangements (e.g., acidosis, hypoglycemia)

Severe anemia

Hypovolemia

Persistent pulmonary hypertension

Birth asphyxia

Pain, abdominal crisis

Fever, high environmental temperatures

Excitement

Pleural effusion (e.g., pleuritis)

Endotoxemia and gram-negative sepsis

Thoracic radiographs are helpful in diagnosing the presence of respiratory disease and in determining the type and extent of pulmonary involvement. Shortly after birth the smaller vessels posterior to the heart and in the caudodorsal lung fields should be clear. The heart, posterior vena cava, and aorta should be clearly defined. When the radiographic appearance of the lung fields is evaluated, the type of infiltrate (interstitial, nodular, alveolar, mixed), severity, and location (diffuse, cranioventral, caudodorsal) should be noted. Other soft-tissue structures (including the heart, vessels, and diaphragm) and bones (ribs, vertebrae, long bones) should also be evaluated. Thoracic radiographs are routinely taken in the standing or recumbent lateral position in calves. Cranioventral consolidation is a common feature of infectious pneumonia in calves. Radiographic changes may either follow or precede changes in clinical condition, and sometimes major changes can occur surprisingly rapidly. Clinical signs of pneumonia frequently resolve much earlier than chest radiographs and hemograms return to normal.

Table 20-2 Normal Blood Gas Values for Calves

Age-Group	O_2 (mm Hg)	CO_2 (mm Hg)	pH	HCO^-_3 (mEq/L)
1 hour	58.43 ± 11.61	50.40 ± 5.27	7.30 ± 0.05	23.52 ± 2.78
4 hours	62.30 ± 9.27	47.92 ± 3.97	7.34 ± 0.03	24.49 ± 2.35
12 hours	67.23 ± 9.32	45.36 ± 3.97	7.38 ± 0.03	25.74 ± 2.37
24 hours	70.53 ± 11.47	44.04 ± 3.45	7.40 ± 0.03	26.44 ± 1.87
48 hours	63.85 ± 10.82	45.25 ± 3.69	7.42 ± 0.01	27.98 ± 1.91

Ultrasonographic evaluation of the thorax is useful for identification of pleural effusion, pulmonary consolidation, pleuritis, and chest wall abscesses and for detecting congenital heart defects.

Arterial blood gas concentrations provide a measure of respiratory function. The optimal site for collection of arterial blood samples from neonatal calves is the brachial artery.[22] The calf is placed in lateral recumbency, with one hand on the neck and the other pulling the upper leg caudally. The brachial artery is located on the proximomedial aspect of the elbow of the lower limb. The area over the artery is thoroughly scrubbed and the artery stabilized by placing the index and second fingers of one hand above and below the proposed site of puncture. The arterial blood sample is collected using a 25- or 27-gauge ¾-inch needle and a 3-mL syringe.[22] Normal arterial blood gas values for neonates of different postnatal and gestational ages are presented in Table 20-2.

Several factors can interfere with accurate interpretation of blood gases in the neonate. First, significant inaccuracies can occur if the blood sample is collected, handled, or measured improperly. The most common artifact is the introduction of room air into the sample, with an artificially increased Pa_{O_2}, decreased Pa_{CO_2}, and more alkaline pH resulting. The position of the patient and amount of struggling during sample collection cay also potentially cause transient changes in all blood gas values. The inspired oxygen concentration should also be considered when analyzing arterial blood gas values. With supplemental oxygen, Pa_{O_2} is increased variably, depending on the inspired oxygen concentration (Fi_{O_2}), the amount of pathology present, particularly the extent of right-to-left shunting, and the respiratory rate and tidal volume.

Common patterns of derangement include hypoxemia (Pa_{O_2} <70 mm Hg) with low or normal Pa_{CO_2} and hypoxemia with hypercapnia (Pa_{CO_2} >50 mm Hg). If there is hypercapnia and resulting respiratory acidosis, ventilation is inadequate or pulmonary pathology is severe, impairing diffusion of CO_2. Hypoventilation may reflect lack of surfactant in the premature neonate, compromised muscle function (white muscle disease), or neurologic dysfunction with altered chemosensitivity resulting in inappropriate ventilatory responses to changes in blood gas values. Clinical signs must be evaluated along with blood gas analysis if the most appropriate therapy is to be chosen.

Interpretation of blood gas values of venous blood can be very deceptive and should be restricted to evaluation of metabolic conditions (e.g., metabolic acidosis) and not pulmonary gas exchange. To avoid problems associated with regional blood sampling, peripheral venous blood should be taken from a free-flowing jugular vein, because the metabolic status of the head is usually stable.

Transtracheal aspiration provides a sample for both cytologic and microbiologic analysis. (See Chapter 31 for specific details on technique and interpretation.) If the neonate is in respiratory distress, this technique can further compromise the patient. When mycoplasma or chlamydia infection is suspected, the laboratory needs to be notified, as specific media and growth conditions are required to isolate these pathogens. Viral infections are diagnosed directly by viral isolation (cell culture) or indirectly by demonstrating the presence of a virus (polymerase chain reaction [PCR] and fluorescent antibody techniques) or an immunologic response to a virus (seroconversion). Specific tests available for respiratory viral pathogens are discussed in Chapter 31.

20.8.2 UPPER RESPIRATORY TRACT DISORDERS

Conditions that affect pharyngeal and laryngeal function are important, as they predispose to aspiration pneumonia. Dyspneic neonates also have difficulty nursing and are subsequently likely to become malnourished. Congenital defects of the upper respiratory tract include collapsed trachea, stenotic nares, choanal atresia, and epiglottal cyst. Impaired pharyngeal and laryngeal function may result from physical deformation or neuromuscular disorders. Sporadic outbreaks of pharyngeal and laryngeal injuries are often associated with improper application or use of damaged feeding tubes and/oral medication equipment. Compression of the larynx by a retropharyngeal abscess or mass tends to cause inspiratory dyspnea. Edema and necrosis of the larynx may be observed with infectious bovine rhinotracheitis virus infections in neonatal calves.[23,24] *Fusobacterium necrophorum* typically causes necrotic laryngitis in weaned calves but sporadically infects neonates after pharyngeal trauma.[25] Partial occlusion of the upper airway induces turbulent airflow and subsequently mucosal edema. Placement of a tracheostomy tube provides an alternate, sometimes lifesaving, airway and rests the inflamed mucosa.

Nutritional myodegeneration and botulism may induce laryngeal paresis. Dysphagia and subsequent aspiration pneumonia are common sequelae of pharyngeal and laryngeal dysfunction. Collapsed trachea is a rare congenital or acquired condition. Clinical signs include an intermittent honking cough, stridor, and dyspnea with mild exercise. There is no stenosis of the trachea; rather a dynamic dorsoventral collapse during inspiration. The caudal cervical and cranial thoracic sections of the trachea in the area of the thoracic inlet are most frequently affected. Acquired tracheal collapse is commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by the subsequent bony callus. Treatment of collapsed trachea in the calf by surgical reconstruction has been attempted, but the prognosis is poor.[26–29]

20.8.3 RESPIRATORY INFECTION

A number of respiratory disease syndromes may be observed in neonatal calves. Pneumonia in calves less than 3 days of age typically reflects aspiration of milk subsequent to inappropriate feeding practices or pharyngeal dysfunction (white muscle disease). A mixture of gram-positive, gram-negative, and anaerobic bacteria may be introduced into the lungs, inciting a severe inflammatory response necessitating broad-spectrum antimicrobial and antiinflammatory therapy.

Mannheimia hemolytica and *Pasteurella multocida* infrequently cause pneumonia in calves less than 2 weeks of age. Outbreaks of respiratory disease in this age group may be associated with mixed infections with *Mycoplasma bovis* or may be secondary to bovine virus diarrhea (BVD) infection. Respiratory disease is most common in calves more than 4 weeks of age, with the peak incidence observed after weaning in intensive calf rearing operations. Bovine respiratory syncytial virus, infectious bovine rhinotracheitis virus, BVD virus, *Mycoplasma* species infection, and bovine coronavirus may all produce respiratory disease in neonatal calves.

Viral infections increase the risk of opportunistic bacterial infections by their immunosuppressive effects and damage to the respiratory epithelium and pulmonary clearance mechanisms. Pleuritis is an uncommon feature of most neonatal respiratory infections but may be a manifestation of a generalized polyserositis with specific pathogens such as mycoplasma infections of ruminant neonates[30] and occasionally *Pasteurella* infections in lambs.[31]

Environmental risk factors include extremes of temperature, poor ventilation, dust, ammonia, and overcrowding. A number of pathogens capable of causing respiratory disease are shed in milk. These include *Mycoplasma* species,[30,32,33] CAEV,[34,35] and *Salmonella* Dublin. The practice of feeding mastitic milk (hospital milk) to neonates increases the risk of disease transmission. Rapid growth of salmonella in warm milk quickly produces a lethal challenge. *Salmonella* Dublin is an invasive salmonella serotype host adapted to cattle; calves commonly develop septicemia, and respiratory disease may be the predominant clinical manifestation. *Mycoplasma* species infection typically produces acute polyserositis; goat kids infected with *Mycoplasma mycoides* subsp. *mycoides* (large colony type) are often in pain, febrile, and reluctant to stand and have multiple hot, swollen joints. Approximately 50% of kids develop pneumonia or pleuropneumonia manifested by an increase in respiratory rate and auscultable lung sounds.[30] Pasteurizing goat milk at 56° C for 1 hour kills *Mycoplasma* species and CAEV. Outbreaks of *Mycoplasma* pneumonia in calves are usually caused by feeding waste milk contaminated with *M. bovis*. Clinical signs include increased rate and effort of breathing associated with pneumonia, joint and tendon sheath distention reflecting polyserositis and auricular discharge, and a head tilt reflecting otitis media interna.[32] *Mycoplasma* organisms are susceptible to antimicrobial agents that affect DNA, RNA, protein synthesis, or the integrity of the cell membrane. *Mycoplasma* organisms are not susceptible to agents that interfere with synthesis of folic acid or that act on the cell wall. Tylosin, tetracyclines, erythromycin, tilmicosin, florfenicol, aminoglycosides, and fluoroquinolones have been shown to have activity against one or more *Mycoplasma* species.[36] However, the efficacy of antimicrobial therapy in eliminating the organism is limited, and although animals may recover, chronic infections may persist. Numerous antimicrobials are labeled for the treatment of respiratory disease caused by *Pasteurella, Mannheimia,* and *Hemophilus* in cattle. Treatment protocols are reviewed in Chapter 31.

CAEV produces a number of disease syndromes in goats including mastitis, arthritis, encephalitis, and pneumonia. Encephalitis and subclinical respiratory disease typically occur in kids 2 to 4 months of age and occasionally in kids as young as 1 month of age.[34,37]

20.8.4 NEONATAL APNEA AND IRREGULAR BREATHING PATTERNS

Periods of apnea in the neonate are commonly associated with nonrespiratory factors, including infection, CNS disorders, hypothermia, and metabolic conditions such as hypoglycemia. Seizure activity may be expressed by changes in breathing rate and pattern, and neonatal asphyxia may induce respiratory depression, whether or not cerebral lesions are present.[38] Neonatal respiratory distress may also cause apnea resulting from respiratory center depression or diaphragmatic fatigue. There are two mechanisms of apnea: central apnea, resulting from cessation of diaphragmatic activity, and obstructive apnea, resulting from obstruction of the airway, usually at the pharyngeal level.

338
339

20.9 ABDOMINAL DISTENTION

20.9.1 RUMINAL BLOAT

Ruminal bloat is uncommon in calves less than 5 weeks of age because of the relatively undeveloped state of the neonatal rumen. Causes of ruminal bloat in calves include ruminal putrefaction, obstruction of the cardia or esophagus, and vagal indigestion (Box 20-3).

If milk arrives in the rumen in greater quantities than normal by escaping the esophageal groove, it can be subjected to putrefactive decomposition by proteolytic bacteria. Normally the rumen of neonatal calves has a stable aerobic bacterial population. Anaerobic conditions are rapidly established when appreciable amounts of fermentable substances enter the rumen.[39] Clinical signs include diarrhea, poor development, rough haircoat, and recurrent bloat. Reducing the volume of milk fed per feeding, feeding from nipples rather than buckets, and introducing calf starter to promote ruminal development help prevent the condition. A course of oral antibiotics (500 mg oxytetracycline) once daily for 3 or 4 days may help affected calves by killing the putrefactive gut flora.

Bloat is occasionally observed as a complication of severe bronchopneumonia in calves as a consequence of swollenmediastinal lymph nodes compressing the esophagus or compression or inflammation of the vagus.[40] Relief of ruminal distention is important for return of ruminal function. Chronic ruminal bloat may be relieved by placement of a ruminal fistula (Buff's screw trocar). Correct placement of the screw, as described by Dirksen and colleagues,[41] reduces the risk of inducing peritonitis. The rumen must be bloated so that it lies firmly against the body wall as the trocar is screwed into place. The site for the trocar is shaved and scrubbed, a small skin incision is made, and the trocar is quickly and forcefully screwed into the belly wall and rumen. After removal of the stylet, the outer rim of the trocar is kept under constant outward tension so that the ruminal wall is held tightly against the parietal peritoneum by the last ridge of the screw. To fix the trocar in this position, gauze soaked in antibiotic should be wrapped around the stem of the trocar between the outer rim and the body wall.[41]

20.9.1.1 Box 20-3 Causes of Abdominal Distention

20.9.1.1.1 Obstruction

Hemoperitoneum

Ruptured umbilical vessels

Ruptured spleen or liver

Congenital tumor

20.9.1.1.6 Ascites

Severe liver or renal failure

Severe hypoproteinemia

20.9.2 ABOMASAL ULCERS

Abomasal ulcers are usually asymptomatic in young calves, but if perforation occurs peritonitis and shock rapidly develop. Clinical signs of abomasal ulcers in calves include abdominal distention, pain on abdominal palpation, expiratory grunt, drooling saliva, bruxism, and melena. Less commonly a syndrome of chronic abdominal pain is observed after abomasal perforation.[42] Absence of inflammatory changes suggest the gut is unlikely to be perforated or necrotic. Severe hypoproteinemia is common with diffuse peritonitis presumably because of the combination of poor colostral uptake and loss of protein into the abdominal exudate. Obtaining peritoneal fluid from normal calves is difficult; if peritonitis is suspected, collection of abdominal fluid is facilitated by locating pockets of peritoneal fluid via abdominal ultrasound.

Clinically more abomasal ulcers seem to appear during or shortly after a period of weather-induced stress.[43] Lilly proposes that this may be associated with higher endogenous cortisol secretion.[44] Perforating abomasal ulcers in calves have also been associated with *Clostridium perfringens* abomasitis,[45] copper deficiency, dietary changes, mycotic infections, and abomasal bezoars.

Perforated abomasal ulcers are repaired surgically by a right paracostal approach. The ulcers are commonly located on the midpart of the fundus, on the greater curvature of the abomasum. Prognosis is guarded (40%).[43]

20.9.3 ABOMASAL DISPLACEMENT

Abomasal displacement is rare in neonatal ruminants. Clinical signs include reduced appetite, poor weight gain, recurrent tympany (left side), and diarrhea. An association of left-sided abomasal displacement with pneumonia in calves suggests that altered vagal function may be involved in the pathogenesis of the condition.[46,47] Typically, left-sided abomasal displacement in calves occurs between 6 and 14 weeks of age, but younger calves may be affected. Displacement of the abomasum is diagnosed by auscultation and percussion; affected animals may have a hypochloremic metabolic alkalosis. Correction can be attempted by rolling the calf on its back or via surgery.

20.9.4 ABOMASAL TYMPANY

Acute abdominal distention, colic, depression, and sudden death have been reported in neonatal calves with abomasal ulcers, abomasitis, and abomasal tympany. Possible sequelae to abomasal dilation include abomasal torsion, perforation, and rupture. Numerous causes have been postulated, including dietary changes, in particular the addition of coarse roughage feeds; abomasal bezoars; copper deficiency; and various microorganisms. Roeder and co-workers isolated *C. perfringens* type A from a group of eight calves affected by this syndrome[45] and subsequently experimentally reproduced the disease by intraruminal inoculation of the organism.[48] *Campylobacter* species have been incriminated in other studies. Histopathologic evaluation of abomasums from 38 affected calves at necropsy revealed that 31 contained abundant gram-positive bacteria associated with the damaged abomasal mucosa.[49] *Campylobacter*-like organisms were demonstrated in nine and *C. perfringens* in 14 of the 38 cases.[49] Studies of range cattle in west central Nebraska and Wyoming suggest subclinical trace

mineral deficiencies of copper and/or selenium may be involved in the pathogenesis of the condition in this region.[44]

Onset of clinical signs is rapid; affected animals become anorectic, depressed, or occasionally restless. Signs of abdominal discomfort including treading on the spot and kicking at the abdomen are observed in approximately half of the cases. On physical examination splashing and metallic sounds are heard on succussion of the distended abdomen, and passage of a stomach tube fails to relieve the distention. Fecal output is reduced, and occasionally melena is observed. Early in the clinical course calves are likely to have a marked metabolic alkalosis; however, rapid deterioration and onset of shock are common and accompanied by metabolic acidosis. Observation of metabolic acidosis carries a poor prognosis.

Management of abomasal tympany requires rapid relief of the abomasal distention. Paracentesis through the right flank often fails to completely drain the abomasum and carries a high risk of inducing peritonitis.[50] Kumper[51] describes good results with paracentesis using a 14 gauge, 50-mm needle when the calf is turned upside down and the abomasum is deflated by inserting a needle in the highest point of the distended abdominal wall between the umbilicus and xiphoid. Twenty of 21 calves with abomasal tympany were successfully managed without complications using this technique. Repeated paracentesis carries a high risk of inducing peritonitis; if after paracentesis the calf's condition deteriorates or tympany recurs, a right flank laparotomy is performed to correct a possibly torsed abomasum.[51] Intravenous fluids are administered to correct dehydration, electrolyte, and metabolic derangements.

A decreased prevalence of abomasal tympany and ulceration were reported in neonatal calves from herds having a history of these problems after implementation of a *C. perfringens* vaccination program.[44,52]

Abomasal bloat is a significant problem in artificially raised lambs. Feeding systems that allow lambs to drink large quantities of milk replacer at infrequent intervals and housing lambs on litter are predisposing factors.[53,54] Proliferation of lactobacilli, *E. coli*, and *C. perfringens* has been implicated in the disease process.[54,55] Fermentation of sugars contained in milk replacer produces carbon dioxide, distending the abomasum.[56] Lambs may die within hours from acute abdominal tympany compromising vascular return and respiration. Early treatment of bloated lambs with oral doses of antibiotics is sometimes an effective treatment. Addition of 0.1% formalin (37% formaldehyde) to milk replacer reduces the incidence of the condition.[55]

20.9.5 INTESTINAL ATRESIA

Intestinal atresia is the most common cause of abdominal distention in calves in the first week of life.[42] Typically calves are born normally but develop progressive abdominal distention shortly after birth. Signs of mild colic are occasionally observed. The spiral loop of the ascending colon is usually the site of atresia.[57] Other congenital abnormalities may be present (18% of cases).[57] Pregnancy diagnosis by palpating the amniotic sac before 40 days of gestation may cause colonic atresia in cattle[58]; however, an autosomal recessive inheritance in Holstein cattle has recently been proposed.[59] Surgical repair by resection of the distended proximal blind end and anastomosis of the proximal segment of intestine to the descending colon has been described, but breeding affected animals is not recommended.[57] Long-term survivors are likely to have loose feces and do not tend to grow well.[57]

20.9.6 INTUSSUSCEPTION

Intussusception occurs most commonly in the jejunum, but the frequency of ileocecal and colon intussusceptions appears higher in calves than in adults.[60] Commonly there is a history of diarrhea. Clinical signs may include intermittent colic, absence of feces, and melena; however, these are inconsistent. The inconsistency of clinical signs and inability to perform a rectal examination makes the diagnosis more difficult in calves than in adults.[60] Abdominal ultrasound may be useful. The prognosis after surgical correction is strongly influenced by the duration of the condition before correction.

Twisting of the intestinal mass around the cranial root of the mesentery is a rare event but occurs more frequently in calves than in adults.[60] Clinically the condition is characterized by a sudden onset of severe colic (kicking at the abdomen, dropping to the ground) that rapidly progresses (abdominal enlargement, tachycardia, tachypnea, reduced or absent fecal passage) to signs of shock and recumbency. Early diagnosis and rapid surgical correction, using either a right paralumbar or ventral midline, together with a supportive fluids approach allow for a good prognosis.

20.10 DIARRHEA

Alison A. Gunn

Jonathan A. Naylor

John K. House

Herd management variables that affect the risk of neonatal death losses in housed calves include efficiency of passive transfer, calf nutrition and environmental management (pathogen exposure), calving area sanitation, and cow vaccination status and health. Successful calf rearing is based on good management. A goal of less than 5% death loss from diarrhea is achievable. With neonatal death losses in pasture or range animals it is important to evaluate the dystocia rate, physical management, and nutritional status of the calving and nursing herds; the cleanliness of the calving and nursing areas; the provision of shelter from wind; and any biosecurity risks.

Rotavirus, *Cryptosporidium,* coronavirus, enterotoxigenic *E. coli* (ETEC), and *Salmonella* are recognized as the major pathogens associated with diarrhea in calves (Table 20-3). Rotavirus, *Cryptosporidium,* coronavirus, and ETEC are common pathogens in beef calves (Fig. 20-1).[61–64] *Salmonella* is more frequently implicated in intensive calf-rearing systems.[63–65] Enteropathogenic strains of *E. coli* are occasionally implicated in calf diarrhea; the true prevalence of disease associated with these strains is unknown because of the lack of routine definitive diagnostic tests. Torovirus has recently been associated with neonatal calf diarrhea in Canada, the United States, and Europe.[66–69] BVD is infrequently associated with diarrhea in young calves.[70,71] Various other agents have been implicated as causes of neonatal diarrhea, but their importance in the field situation is unknown (see Table 20-3). The incidence of the various etiologic agents varies with the age of the calf, and this is useful in establishing the likelihood that a particular agent is involved (Fig. 20-2). It is usually impossible to make a definitive etiologic diagnosis on clinical grounds. It is possible to detect signs of straining or passage of frank blood and mucus that suggest the presence of colitis, implicating possible *Salmonella,* coronavirus, BVD, enteropathogenic *E. coli* (EPEC), or coccidial infection.

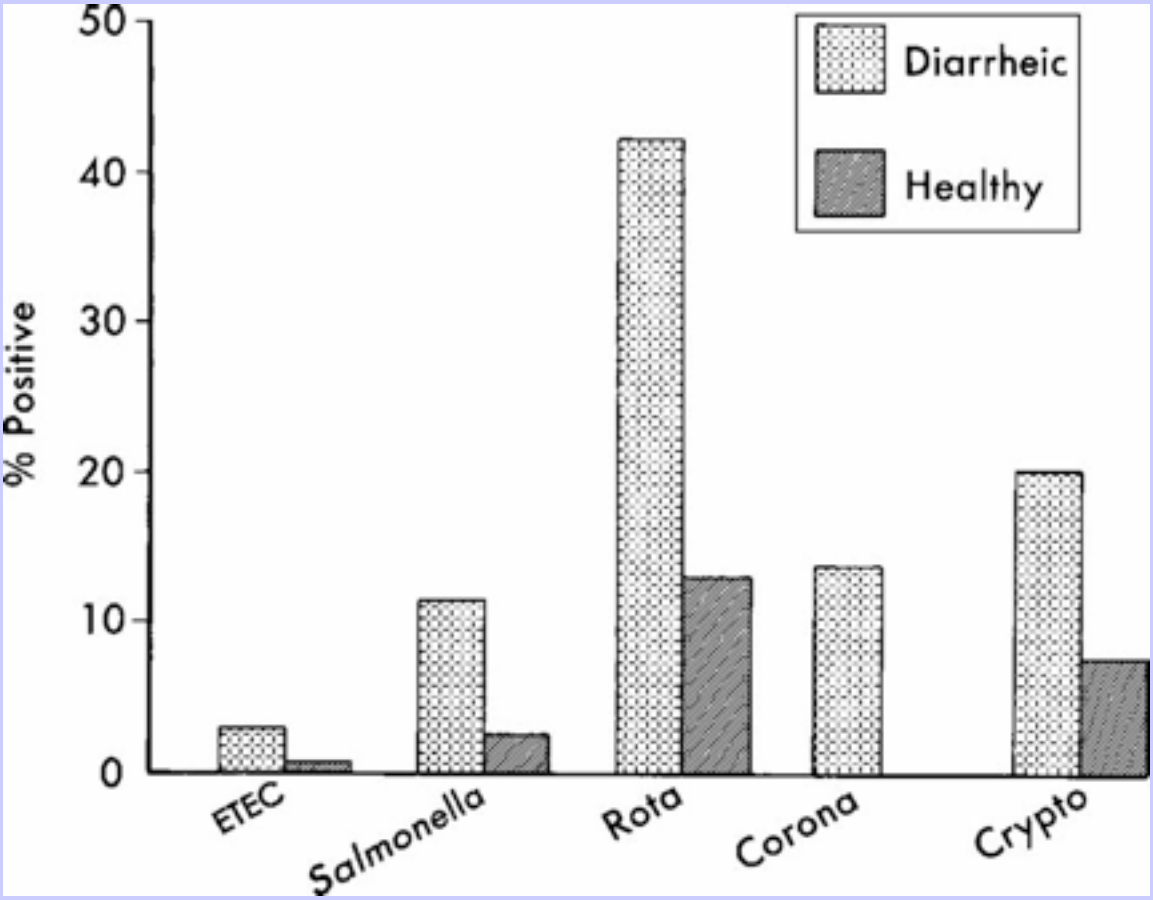
Fig. 20-1 Common enteropathogens in dairy calves. The comparative incidence of isolation from diarrheic and normal calves is shown. From Snodgrass DR, Terzolo HR, Sherwood D, et al: Aetiology of diarrhoea in young calves, *Vet Rec* 119:31, 1986.



20.11 PATHOGENESIS

Diarrhea can be the result of either increased secretion or decreased absorption. Bacteria such as ETEC and, to some extent, *Salmonella* cause neonatal diarrhea by secreting enterotoxins that stimulate increased intestinal secretions.[72,73] These changes are thought to be mediated by cyclic adenosine monophosphate (AMP) or cyclic guanosine monophosphate (GMP), calmodulin, and changes in protein kinase activity.[74,75] The cell's structure is not affected, but the activity of the membrane pumps is altered, and secretion of chloride, sodium, and potassium is

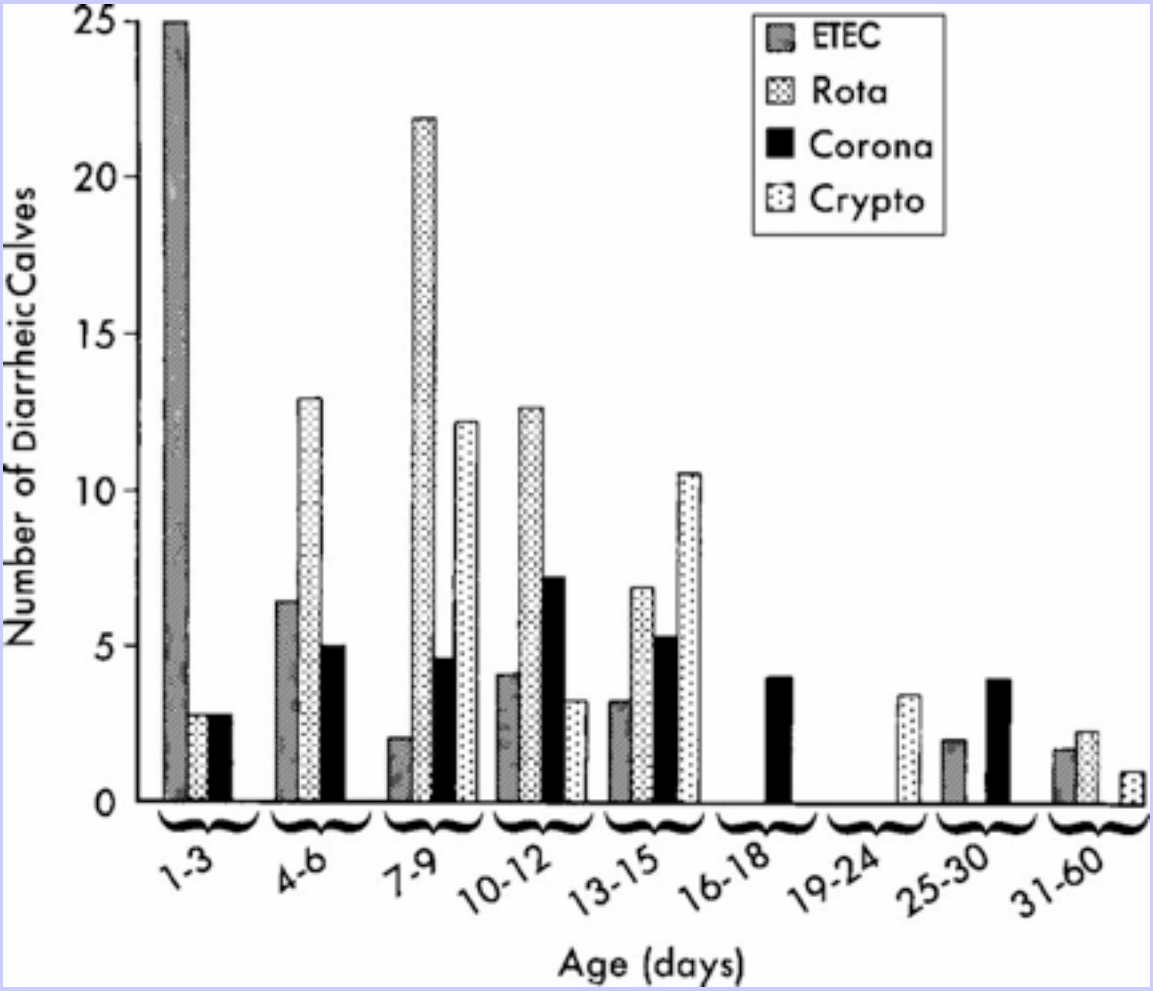
increased.[76] Sodium absorption linked to glucose and amino acid transport across the mucosal epithelium is not affected.[77,78] Bovine ETEC does not stimulate intestinal bicarbonate secretion.[76]

Protozoa and enteric viruses cause neonatal diarrhea as a result of the destruction of the absorptive villous epithelial cells.[79–82] Diarrhea results because intestinal digestive secretions continue while absorption is impaired.[83,84] In rotavirus and coronavirus infections this is further exacerbated by compensatory hyperplasia of the crypt cells. The crypt cells have secretory functions, and their multiplication adds to the secretory load.[83] Rotavirus can also stimulate intestinal secretion both at a cellular level and by stimulation of the enteric nervous system. This is associated with the viral nonstructural protein NSP4.[85,86]

341

342

Fig. 20-2 Age incidence of isolation of different enteropathogens from diarrheic beef calves. The data are based on a retrospective records survey of 245 diarrheic calves admitted to the Western College of Veterinary Medicine over a 2-year period.



Continued feeding may result in more nutrients presented to the small intestine than the damaged villi can absorb.[87,88] Excess nutrients are fermented in the large intestine, promoting bacterial overgrowth[74,89] and generation of organic acids and other deleterious compounds. The osmotic effect of the unabsorbed nutrients drags water into the gut and contributes to the diarrhea.[83] Marked inflammation is a feature of salmonellosis and clostridiosis. This contributes to diarrhea by increasing mucosal pore size and hydraulic pressures within the intestinal wall, by destroying absorptive cells, and by increasing prostaglandin production, which in turn stimulates secretory mechanisms within the enterocytes.[74,83]

On an individual animal basis, diarrhea is significant because of fluid and electrolyte losses. As long as the neonate can compensate for these losses it will remain fairly bright and continue to suck. If the losses exceed intake, systemic effects of dehydration (salt and water loss) or acidosis are seen. Fluid is lost preferentially from the vascular compartment,[90,91] and cardiovascular collapse results. Acidosis has several causes including fecal loss of bicarbonate, endogenous synthesis of L-lactic acid in response to dehydration and poor tissue perfusion, and D-lactic acid production through bacterial fermentation of undigested or malabsorbed milk within the gastrointestinal tract.[92–97] Acidosis contributes to the calf's malaise by increasing vascular resistance and impairing cardiac function by direct effects and by inhibiting the action of catecholamines. Esophageal groove function may be compromised in acidotic calves, promoting ruminal drinking with the consequences of further production of D-lactic acid in the rumen and subsequent ruminal acidosis.[97,98]

The neonate becomes depressed, loses its suck reflex, and becomes weak; if the disease progresses, recumbency and coma may develop. One cause of death is believed to be heart failure as a result of myocardial potassium imbalance caused by the combined effects of potassium losses into the gastrointestinal tract and the redistribution of potassium from the cells to extracellular fluid as a result of acidosis.[99–101] Hypothermia will also contribute to cardiac failure. In cases of ETEC, *Cryptosporidium,* rotavirus, and coronavirus infections, correcting the fluid, electrolyte, and acid-base imbalances restores the neonate's ability to walk and suck. A residual degree of malaise may persist, which can be attributed to inflammation within the gut wall and damage to the integrity of the mucosal barriers, allowing invasion of enteric microbes or their toxins. If malabsorption persists, cachexia can develop—particularly if milk continues to be withheld as part of therapy—and death from malnutrition or hypoglycemia may occur.

Salmonella organisms are invasive and release endotoxins in the systemic circulation. *Clostridium* organisms produce exotoxins. Both endotoxins and exotoxins have profound systemic effects that are often directly responsible for malaise, microcirculatory failure, and cardiovascular collapse. Correcting fluid and electrolyte disturbances in these infections will aid the neonate but will not overcome the effects of toxemia or bacteremia.

20.12 ETIOLOGY

20.12.1 Bacteria

20.12.1.1 ESCHERICHIA COLI

E. coli are part of the normal flora of the bovine gastrointestinal tract. Pathogenic strains of *E. coli* possess virulence attributes that are involved in the pathogenesis of disease. Virulence attributes include adhesins, enterotoxins, and cytotoxins. Pathogenic strains of *E. coli* may be shed by adult cattle with transmission to

neonates by the fecal-oral route. Sick neonates amplify environmental contamination via prolific fecal shedding.

20.12.1.2 ENTEROTOXIGENIC *E. COLI*

ETEC possess two virulence factors: fimbriae (pili) and enterotoxins. F5 (K99) and/or F41 fimbriae mediate adherence, and thermolabile (LT) and thermostable (STa and STb) enterotoxins stimulate a secretory response by intestinal crypt cells. Although some bovine-origin ETEC produces LT, most strains that cause diarrhea in neonatal calves produce STa heat-stable enterotoxin.[102] The STa enterotoxin and F5 antigen are plasmid-mediated virulence factors. Susceptibility to ETEC is age dependent according to the binding specificity of pili antigens to immature enterocytes.[103] Disease is typically observed in calves less than 3 days of age; however, concurrent infection with rotavirus may extend this window to 7 to 14 days of age.[104,105] Intestinal cells of calves older than 2 days of age acquire natural resistance to F5 adhesion.[103] Despite this, F5-positive *E. coli* organisms have been isolated from healthy 4- to 12-week-old calves and F5-positive ETEC organisms are shed in feces for several weeks after experimental infection of newborn calves.[106]

20.12.1.3 ATTACHING AND EFFACING *E. COLI* AND SHIGA TOXIN–PRODUCING *E. COLI*

Attaching and effacing *E. coli* (AEEC) and Shiga toxin—producing *E. coli* (STEC) have been identified as causes of diarrhea and dysentery in calves.[107,108] Disease is mediated by cytotoxic damage to the intestinal mucosa. Lesions may be observed in the ileum, cecum, and colon.[109] AEEC (Vero or HeLa toxin—producing) induces a mucohemorrhagic colitis, with petechial or ecchymotic hemorrhages in the wall of the colon and rectum.[110–112] *E. coli* organisms that carry this toxin often belong to O serogroups 5, 26, 111, and 118.[111,113] Naturally occurring outbreaks have been reported in 2-day- to 4-week-old calves.[114] The most common clinical sign is diarrhea, but dysentery, abdominal pain manifested by bruxism, and dehydration are seen in some cases.

342

343

STEC serotypes associated with dysentery in calves include O5:H–, O26:H11, O111:H–, O113:H21.[115] These serotypes may produce Shiga toxins—those that are immunologically similar to the Shiga toxin produced by *Shigella dysenteriae* (Stx1) and those that are immunologically distinct from *S. dysenteriae* Shiga toxin (Stx2).[116] Bovine STEC produces STx1, STx2, or both.[117] AEEC, which causes disease and does not produce enterotoxins or Shiga toxin, is referred to as *enteropathogenic E. coli* (EPEC).

The prevalence of AEEC and STEC in calves and the incidence of disease caused by these strains are not clearly defined, as most diagnostic laboratories do not routinely screen for AEEC and STEC. In a study aimed at determining the clinical significance and prevalence of AEEC in Swiss cattle, fecal swabs of 93 cattle from two farms with calf diarrhea and of 54 cattle from two similar farms without clinical problems were screened for AEEC by PCR assay and colony-blot hybridization. On average, 21% of all cows were positive for AEEC by PCR, without differences between farms with and without diarrhea problems. By contrast, AEEC was detected by PCR in 60% of animals younger than 2 years from farms with diarrhea problems, whereas only 32% of comparable control animals from farms without clinical problems had AEEC.

20.12.1.4

SALMONELLA

There are over 2200 reported serotypes of *Salmonella*, yet fewer than 2% of these account for approximately 80% of the disease reported in livestock.[118] In cattle, over 95% of *Salmonella* associated with disease is in serogroups B, C, D, and E. *Salmonella* induces a wide spectrum of disease in cattle of all ages ranging from inapparent subclinical infections to acute fulminant bacteremia, endotoxemia, and death. The variable manifestations of disease reflect the tissue trophisms of different *Salmonella* serotypes and the influence of challenge dose and host immunity. Common clinical signs associated with salmonellosis include fever, diarrhea, anorexia, depressed mentation, and dehydration. Many of the clinical signs are associated with endotoxemia. Systemic signs of endotoxemia include, fever, tachypnea, tachycardia, scleral injection, leukopenia or leukocytosis, and weakness. Some serotypes, particularly *Salmonella typhimurium,* have a tendency to induce severe inflammation of the bowel mucosa, resulting in dysentery and passage of fibrin and mucosal casts. Fluid, electrolyte, and protein loss may progress rapidly and become life-threatening if not corrected. With severe disease animals rapidly become emaciated because of the catabolic state induced by release of tumor necrosis factor alpha (TNF-α). Sequelae occasionally observed after invasive *Salmonella* infections in neonates include septic osteoarthritis and meningitis.

Immunity to *Salmonella* changes rapidly during the first 3 months of life. At 2 weeks of age the LD_{50} for some virulent strains is 10^5,[119] at 6 to 7 weeks is 10^7, and at 12 to 14 weeks is $10.^{10}$,[120] In contrast, administration of 10^{10} *Salmonella* to 24- to 28-week-old calves failed to induce clinical signs of disease.[120] The numbers cited reflect the influence of age on immunity but should not be interpreted as absolute. Different age predilections, manifestations of disease, and virulence are observed among *Salmonella* serotypes and among different strains of the same serotype.[121,122] Although adults may serve as carriers and a source of infection of *Salmonella* Dublin infection in neonates, disease in adults is less common in mature cattle compared with calves. In contrast, *S. typhimurium* tends to manifest disease in an epidemic manner, causing illness in all age groups.

Calves on endemically infected farms are commonly exposed to *Salmonella* in the first few days of life.[123] *Salmonella* exposure may occur via contaminated colostrum or milk; surface contamination of teats and udder, personnel, or equipment; or the environment. Chronically infected carriers may shed 2.5×10^8 *Salmonella* organisms in milk per day (25 kg of milk containing 10^5 *Salmonella* per milliliter).[124] Feeding utensils and personnel often play a significant role in transmitting *Salmonella* between calves.[125] Salmonella infects the salivary glands and is shed in saliva and nasal secretions.[126,127] Adequate cleaning and disinfection of feeding and medicating utensils is necessary to remove *Salmonella* contamination. *Salmonella* is sensitive to most disinfectants, but removal of contaminating organic debris is imperative, as the activity of disinfectants is reduced by the presence of organic matter.[128]

20.12.1.5

CLOSTRIDIA

Although clostridia are not commonly considered a major pathogen causing neonatal calf diarrhea, a number of reports associate clostridial infections with enteritis and abomasitis.

C. perfringens is the most important cause of clostridial enteric disease in calves. Some types of *C. perfringens* (mainly type A) are consistently recovered from the intestinal tracts of animals and from the environment, whereas others (types B, C, D, and E) are less common in the intestinal tracts of animals and can

occasionally be found in the environment in areas where disease produced by these organisms is enzootic.[129] Disease is usually precipitated by management factors that lead to the proliferation of the organism within the gastrointestinal tract or attenuated digestion of clostridial toxins within the lumen of the alimentary tract.

C. perfringens type A has been associated with acute hemorrhagic abomasitis in neonatal calves. Clinical signs include acute abdominal distention, colic, depression, and sudden death. Onset of clinical signs is rapid; affected animals become anorectic, depressed, or restless. Signs of abdominal discomfort are observed in approximately half of the cases and include treading on the spot and kicking at the abdomen. On physical examination splashing and metallic sounds are heard on succussion of the distended abdomen; passage of a stomach tube fails to relieve the distention. Fecal output is reduced, and melena may be observed. Gross pathology may include abomasal ulcers, abomasitis, and abomasal tympany.[45,48] Trace mineral deficiencies of copper and/or selenium may also be involved in the pathogenesis of the condition.[44] A decreased prevalence of abomasal tympany and ulceration was reported in neonatal calves from herds having a history of these problems after implementation of a *C. perfringens* vaccination program.[44,52] Enterotoxemia caused by *C. perfringens* type A has been described in 2- to 4-month-old calves, with the condition observed more often in beef calves than in dairy calves.[130] The disease is characterized by a high case fatality rate, sudden deaths, lesions of necrotic and hemorrhagic enteritis of the small intestine, and, most often, an absence of other clinical signs.[131]

C. perfringens type B is not commonly associated with neonatal diarrhea in calves. *C. perfringens* type C infections are most frequently observed in neonates less than 10 days of age.[132] Newborn animals are typically most susceptible, perhaps because of ready colonization of the gut by *C. perfringens* in the absence of well-established normal intestinal flora.[129] Alteration of the flora by sudden dietary changes may also be an inciting factor in type C infections. Vigorous, healthy calves develop hemorrhagic, necrotic enteritis and enterotoxemia, often accompanied by evidence of abdominal pain and neurologic signs that may include frenzied bellowing, aimless running, tetany, and opisthotonus. Death may be peracute, occasionally without other clinical signs, but may also follow a clinical course of several days.

20.12.1.6 CAMPYLOBACTER SPECIES

The clinical significance of *Campylobacter* species in calf scours is inconclusive. *Campylobacter* species are part of the normal intestinal flora. Experimental challenge studies have demonstrated the capacity of *Campylobacter jejuni* to cause enteritis in calves.[99,133–135] However, there is a paucity of convincing reports that demonstrate a causal association in naturally occurring cases.

343

344

20.12.2 Viruses

Intestinal viruses multiply within enterocytes. As the epithelial cells are destroyed, villous atrophy develops. The various agents cannot be readily separated on clinical grounds. Diarrhea can vary in severity from soft to watery feces.

20.12.2.1 ROTAVIRUS

Rotaviruses are the most common cause of neonatal diarrhea in calves.[136,137] Affected calves are generally 5 days to 2 weeks of age, although disease can occur at 24 hours, particularly in colostrum- deprived calves (see

Fig. 20-2).[138,139] This age predilection is thought to occur because many cows secrete antirotavirus antibody in their colostrum, which confers local protection against rotavirus attack until antibody levels in milk decline 48 to 72 hours postpartum.[140,141] Resistance to infection is not age dependant, but age-dependant resistance to clinical disease has been demonstrated.[142] Several possible mechanisms are associated involved in age dependence. Age restriction may be related to immunity, as neutralizing antibodies increase with age and virus exposure. The expression of intestinal mucins and the rate of epithelial cell replacement and fluid absorption are also age dependent and have been shown to affect rotavirus infection and disease expression.[143]

Rotavirus invades small intestinal villous epithelial cells; the attack is usually self-limiting because of destruction of target cells.[82] Enterocytes are lost to the gut faster than they can be replaced from the crypts. The shrunken villi are initially covered by squamous and cuboidal cells from the crypts; the villi gradually regenerate as these differentiate into absorptive columnar epithelium.[82,144] Intestinal secretions are increased owing to the compensatory hyperplasia of crypt cells and enterotoxigenic activity of the viral nonstructural protein NSP4.[85,86] Both increased secretory load and impaired absorption resulting from villous hypoplasia contribute to the diarrhea. It is thought that virulent strains replicate more quickly and infect a larger area of epithelium. Difference in rotavirus replication rates in the gut and age-dependent differences in the rate of enterocyte loss and natural replacement rate may explain the differences in clinical outcome. Concurrent infection with ETEC has also been shown to cause clinical signs at a later age than with a single infection of either agent alone.[145]

Rotavirus of calves, lambs, kids, pigs, foals, mice, and children is morphologically identical. Infections are classified by the antigenic properties and/or sequence of the genes encoding the viral capsid proteins. Viral protein (VP) 6 is used to separate them into seven antigenically distinct serogroups, A through F. Rotaviruses from serogroups A, B, and C have been isolated from cattle, and serogroup A is the most common cause of diarrhea in calves. Group B rotaviruses have been isolated from calves and adult cattle; however, there is less information regarding their significance and prevalence in cattle.[146–150] Group B rotavirus is more common in lambs than in calves.[151] Group C rotavirus has been isolated only from adult cattle.[149] The serotype and/or genotype of capsid proteins VP7 and VP4 are also used to differentiate the viruses into a number of G-types (glycoprotein) and P-types (protease sensitive protien).[152] A range of both serotypic and genotypic diversity and virulence has been reported within serogroup A.[142,153–155] Rotavirus is shed in the feces of infected animals, and transmission is primarily fecal-oral. Clinical signs occur 1 to 3 days after infection and last for 5 to 9 days. Virus excretion commences with the onset of clinical signs and continues for 3 to 7 days.[142,156] Adult cows can be subclinically infected and intermittently shed the virus during pregnancy and especially at parturition.[157–159] It is likely that this is the most common source of infection, with carrier cows infecting their calves and then these calves infecting other calves.[160] Calves from carrier cows have a significantly higher risk of clinical disease, and the birth of calves from known carrier cows has been associated with the beginning of an outbreak. Recovered calves can become reinfected and shed virus.[161]

The environment may be an important source of infection. Rotaviruses can survive in fresh water for more than 2 weeks at 23° C and for months in water or soil <5° C.[162] They are also stable in feces and effluent for up to 9 months and therefore are likely to remain in calving areas from year to year.[163]

20.12.2.2 CORONAVIRUS

Bovine coronavirus commonly causes diarrhea in calves 5 days to 1 month of age.[63,68,164,165] Disease can occur within 24 hours in colostrum-deprived calves and has also been recorded in calves up to 5 months of age.[166] Respiratory infections are common in older calves and may be important in the epizootiology of enteritis.[166]

Calves may be infected with coronavirus by the oral or respiratory route.[156] Fecal shedding commences 3 days after infection and persists for up to a week; nasal shedding can be detected 2 days after infection and persists for 2 weeks. Once infected, calves initially excrete high levels of virus and are potent sources of contamination. Infection persists for weeks in apparently recovered calves, and these excrete low levels of virus for weeks.[167] Subclinical infection is common. Disease is more common in the winter months, and coronavirus survives in the environment from year to year.

Calves may be infected by virus shed by persistently infected cows.[168] Coronavirus has been detected in the feces of more than 70% of clinically normal cows.[159] The rate of virus excretion increases at parturition and in the winter months.[157,169] Calves born to carrier animals are at a significantly increased risk for developing diarrhea.[157]

All BCV isolates are believed to belong to a single serotype.[169a] Differences in hemagglutination-inhibition characteristics have been used to classify strains as types 1 through 3.[169b]

The pathology of coronavirus is often more severe than that of rotavirus, resulting in a mucohemorrhagic enterocolitis. The virus infects both the small and large intestine. In the spiral colon there is widespread destruction of the cells of the colonic ridges.[79,81] Virus replication occurs in the surface epithelium, especially in the distal half of the villi, resulting in stunting and fusion of the villi. Immature cells replace epithelial cells, and in severe infection there can be areas of complete desquamation. Intestinal secretions continue, and absorption is impaired by reduced surface area. Undigested lactose accumulates in the intestinal lumen, often resulting in a secondary bacterial overgrowth, fermentation, lactate production, and an osmotic imbalance that draws fluid into the intestinal lumen. Most infections are self-limiting because the virus rarely attacks crypt epithelial cells.[168] In response to infection the mitotic rate of crypt cells increases, producing immature cells that are more resistant to virus infection and that migrate up the villi to replace the damaged cells.

In experimental challenge studies, diarrhea develops 48 hours after infection. Calves are initially depressed and anorectic for the acute phase and may become dehydrated and pyrexic in a severe infection.[168] Severe infections can result in death from dehydration, acidosis, shock, and cardiac failure. Respiratory signs are generally mild. Rhinitis, sneezing, and coughing may occur. Lesions may be found in the lungs, but clinical signs of pneumonia are rare, except when secondary infection occurs.

344

345

20.12.2.3 BOVINE VIRUS DIARRHEA VIRUS

BVD virus occasionally causes diarrhea and thrombocytopenia in young calves outside the confines of the persistently infected disease model.[70,71] Colostral antibodies generally protect young calves from BVD infection, but disease may occur as a result of FPT or the introduction of novel BVD strains with new cattle or

viral mutation in persistently infected home-grown cattle. BVD is also thought to exacerbate infections caused by other pathogens.[170] It has also been implicated in necrotic enteritis, an acute enteritis of 7- to 12-week-old beef calves reported in the United Kingdom.[171] Affected calves usually show oral ulcerations, particularly on the hard and soft palates. The buccal papillae are often blunted, and the tips may be ulcerated.[172] Some variants of the virus produce intestinal bleeding, petechiation, ecchymosis, or prolonged bleeding from venipuncture sites secondary to thrombocytopenia.[70,173–175] Hematologic findings often include leukopenia and thrombocytopenia. The disease must be differentiated from other causes of enteritis that are complicated by bovine papular stomatitis infection. Bovine papular stomatitis is common in neonatal calves. It produces oral lesions that are hyperemic and red, with a central white area of necrosis and often a raised rim of proliferating epithelial cells. These lesions often involve the mucosa around the molars. They are usually of little consequence, and their importance lies in the fact that they may be confused with BVD. One feature that helps identify BVD ulcers is that they lack the zones of epithelial proliferation seen in bovine papular stomatitis.

20.12.2.4 BOVINE TOROVIRUS (BREDA VIRUS)

Bovine torovirus has been detected worldwide[176–179] and has recently been implicated as an important cause of calf diarrhea.[66,67] Initially known as *Breda virus,* it is part of the Coronaviridae family. It has been relatively infrequently reported because it is difficult to recognize by electron microscopy and it cannot as yet be grown in cell culture, which has precluded the development of routine immunospecific diagnostic tests.[66] Laboratory studies using PCR testing have implicated it as the sole pathogen isolated in 25% to 30% of fecal samples from calves with diarrhea under 6 weeks of age.[66,67] It is also found in the feces and nasal secretions of asymptomatic animals,[66,68] suggesting that the epizootiology is likely to be similar to that of rotavirus and coronavirus, with asymptomatic carriers acting as reservoirs of infection within a herd.[157] It is mainly a disease of calves less than 3 weeks of age, with diarrhea commencing as early as 1 to 3 days after birth,[178,179] but clinical signs have been observed in animals up to 10 months of age.[67,180] Clinically it produces mild to moderate diarrhea in calves under both experimental and field conditions.[179,181] The virus infects the small and large intestines, affecting differentiating epithelial cells in the crypts of the intestinal villi.[179,180] Clinical signs develop 24 to 72 hours after experimental infection.[179] It has also been isolated from the respiratory tract of cattle and associated with respiratory signs in calves at 1 month and 4 to 6 months of age.[182]

20.12.2.5 OTHER VIRUSES

Calicivirus, astrovirus, adenovirus, parvovirus and picobirnavirus have all been associated with neonatal calf diarrhea.[183–187] The pathogenicity and contribution of these viruses to field outbreaks is uncertain.

20.12.3 Protozoa

20.12.3.1 CRYPTOSPORIDIUM

Two species of *Cryptosporidium* have been identified in cattle: *Cryptosporidium parvum* in the intestine and *Cryptosporidium andersoni* in the abomasum.[188] The two species have morphologically distinct oocysts and

differ genetically.[189] *C. andersoni* is a parasite of calves postweaning and has not been associated with neonatal diarrhea.

There are several subgenotypes of *C. parvum,* many of which appear to be host-specific and could represent distinct species.[188,190] These genotypes include type 1, which is found in human sources, and type 2, which is considered to be zoonotic and can be isolated from cattle, sheep, and goats.[190] Calves generally become infected between 1 and 4 weeks of age and display clinical signs for 4 to 14 days. Animals of all ages can be infected, but diarrhea is mainly associated with calves preweaning.[191] Cryptosporidial infections are asymptomatic in cattle older than 4 months of age. *C. parvum* mainly infects the distal small intestine, but lesions are also found in the cecum and colon and occasionally the duodenum.[192] The parasite invades the superficial cells of the mucosa in the intestine but is surrounded by an invagination of the host cell membrane and remains extracytoplasmic. Parasitic invasion of the mucosa leads to epithelial destruction and mild to moderate villous atrophy, with microvillous shortening and destruction. This leads to impaired nutrient digestion and transport and a resulting malabsorption diarrhea.

Affected calves often show no sign other than diarrhea but can show depression, dehydration, and anorexia.[193] Pyrexia and tenesmus have been noted.[194,195] Variable levels of morbidity have been reported, and mortality is generally low.[193,194,196] Other pathogens can be involved and are likely to contribute to the severity of the disease. Affected calves can take 4 to 6 weeks to recover. Cryptosporidiosis occurs less frequently in suckler calves at pasture, but when these calves are affected outbreaks were reported to be more severe than found in dairy calves, with mortality rates up to 30%.[188] High mortality rates have been attributed to lack of herd immunity in seasonal calving herds in which the transmission cycle is broken. Neutralizing antibodies in colostrum and milk reduce infectivity by immobilizing the parasite, blocking invasion, inhibiting adhesion to host cells, or having direct cytotoxicity for *Cryptosporidium* sporozoites.[197] High mortality rates have also been associated with concurrent low levels of selenium, inadequate nutrition, presence of concurrent enteric infections, and specific management practices.[188]

Transmission is fecal-oral, by ingestion of an encysted, sporulated oocyst. Transmission can be direct from host to host, by ingestion of contaminated food or water, and probably mechanically via flies.[198] A study of oocyst shedding in experimentally infected neonatal calves demonstrated prepatent and patent periods ranging from 3 to 6 and 4 to 13 days, respectively.[199] However, oocyst excretion has been described at as early as 2 days of age, which means that calves are susceptible to infection during or shortly after birth.[200] The parasite is capable of autoinfection, sporulating within the intestine and immediately infecting adjacent cells. This can result in protracted clinical illness and relapses. The ability to autoinfect results in huge parasite burdens after very small infective doses. Oocyst excretion has been described at as early as 2 days of age, which means that calves are susceptible to infection during or shortly after birth.[200] Calves aged 1 week to 4 months of age are most likely to be actively shedding significant numbers of oocysts, with peak shedding occurring at 1 to 3 weeks of age.[191,199–201] Infected calves can shed in excess of 10^6 oocysts g^{-1} of feces.[199,202] *C. parvum* oocysts have also been isolated from adult cows, with herd prevalence ranging from 7%–100%.[191,203–205] Mean shedding intensity reported for adult cows has ranged from 3 to 900 oocysts g^{-1} of feces.[205–207] It is likely that carrier cows are a source of infection of young calves.

The most critical factor affecting environmental oocyst survival is the temperature. Drying of oocysts has been shown to dramatically reduce their viability and infectivity in mice.[208,209] Oocysts can enter watercourses and ground water by direct contact with cows or from runoff of rain or irrigation water from pastures and manure

storage areas.[188,210] *Cryptosporidium* oocysts have been shown to survive in water for at least 12 weeks at 4° C.[211] Oocysts are resistant to chlorination of water and most disinfectants.[188] They have also been shown to survive in silage.[212] Wildlife may be a significant reservoir for *C. parvum* and may act as a method of amplification and infection in the environment.[203,213,214]

Cryptosporidia cause diarrhea and sometimes death in 3- to 30-day-old lambs. Protracted infections and mortality are most common in lambs infected in the first few days of life, as age resistance is seen after about 3 weeks of age.[92,215–217] Cryptosporidiosis has also been described in goats; it affected 5- to 20-day-old kids, signs lasted from 3 to 7 days, relapses were not uncommon, and there was a moderate mortality rate.[218] Cryptosporidia are resistant to all commonly available antimicrobial and anticoccidial agents and most disinfectants and can survive for long periods in the environment.

People working with diarrheic neonates should be warned of the risk of zoonotic disease. An outbreak of cryptosporidiosis has been described in caregivers in a veterinary hospital treating diarrheic calves. Affected people suffered from watery diarrhea, cramping, flatulence, and headache.[219] One person became infected as a result of handling soiled clothing.

20.12.3.2 GIARDIA

Giardia is often found in diarrheic calves in association with other pathogens, but its relevance as a pathogen in its own right is unclear. Several authors have documented cases of diarrhea in which *Giardia* infection has been implicated as the causative agent either by itself or in conjunction with *C. parvum* and rotavirus.[220–222] Affected calves are at least 2 weeks old, and often older than 1 month of age, with infection often becoming chronic and lasting for several months.[200,220,223–225] *Giardia* has a prepatent period of 7 to 8 days, and the delayed interval between birth and infection is likely to relate to high levels of colostral protection against *Giardia* but low protective levels in milk.[226] Many calves were shown to have a poor specific immune response to the infection, accounting for the chronicity of the infection.

The significance of *Giardia* as a primary pathogen has been questioned by the observation of similar or lower rates of infection in calves with diarrhea compared with asymptomatic calves.[200,227] Treatment of affected calves with fenbendazole reduces the duration but not the number of diarrhea episodes.[222]

20.12.3.3 COCCIDIOSIS

Thirteen species of *Eimeria* have been reported in cattle.[228] *Eimeria bovis* and *Eimeria zuernii* have historically been the most common pathogenic species; however, there are increasing reports of *Eimeria alabamensis* causing disease.[229–231] Transmission is fecal-oral. Infected animals pass unsporulated oocysts in their feces that sporulate and become infective. The sporulated oocysts are protected from the environment by a double cyst wall.[232] Moist, temperate, cool conditions favor sporulation, and oocysts can survive for several years. Sporulated oocysts can resist freezing to −8° C for several months but are destroyed by high temperatures and dry conditions within a few weeks.[233] Under optimal conditions sporulation can occur within a few days. The prepatent period of the two main pathogenic species is 15 to 20 days, and the patent period is approximately 11 days. *E. alabamensis* has a prepatent period of only 8 days and a patent period of 5 days.

Calves start shedding at about 1 month of age and shed for 3 to 4 months. *E. bovis* and *E. zuernii* schizonts first reproduce in the lower small intestine, then produce second-generation schizonts and gamonts in the cecum and colon, where they attack crypt cells.[228] These latter stages induce both local and more extensive lesions.

Outbreaks of disease in calves and lambs are often related to overcrowded and confined conditions. Up to 95% of infections are subclinical, causing decreased growth rates that are often unnoticed.[234] Clinical disease can be chronic or acute and is generally found in calves aged 3 weeks to 6 months, although animals 2 years of age or older may be affected. In beef cattle the most common reports of clinical disease are associated with weaning stress.[235] Clinical signs may include diarrhea, ill thrift, increased susceptibility to pneumonia, tenesmus, increased mucus in feces, and hematochezia. Pyrexia, dehydration, and anemia may also be observed. The disease is usually self-limiting without reinfection. Chronic disease is often underdiagnosed.[234] Calves appear weak and listless, with pasty feces, drooping eyes, and a staring coat. Fecal oocyst count is low or negligible. Disease results from continual reinfection as a result of a heavily contaminated environment.

20.12.4 Nutritional Diarrhea

Producers often express the opinion that scours is caused by calves consuming too much milk. However, there is no documented research in healthy calves to support this. Calves fed 16% to 20% of body weight per day or allowed ad libitum access to milk have not developed problems with diarrhea.[236,237] However, in studies in which calves are also infected with enteric pathogens, the diarrhea and depression were exacerbated by feeding normal amounts of whole cow's milk in the early stages. Villous atrophy as a result of attack by an enteropathogen reduces the ability of the calf to digest nutrients,[84,88] and this predisposes to gastrointestinal overload with fermentation of milk in the large intestine. Deliberate underfeeding of healthy calves also predisposes to diarrhea.

Studies in Scotland have shown that poor clotting ability of milk is associated with diarrhea and abdominal distention in calves aged 1 to 3 weeks of age in beef suckler herds.[238–240] Milk should clot within 7 minutes when incubated with rennet; the milk from the affected cows took at least 1 hour to clot and in some cases >24 hours. Diarrhea may be a result of the rapid passage of undigested milk through the bowel or secondary to infection by enteric pathogens facilitated by the conditions created in the bowel. Milks with poor clotting ability were shown to have low ultrafilterable calcium levels and low total magnesium levels.[240] Calves responded to treatment with 30 mL of 1 molar solution of CaCl administered three times daily by mouth (PO) and relapsed when this treatment was stopped. The majority of the milk samples clotted when 100 µL of 1 mol/L calcium chloride solution was added before the addition of rennet. The exact cause of the impaired clotting ability was not determined. The diet of one group of affected cows was shown to be low in calcium.[238,239] After a mineral mixture containing additional calcium was added to the diet of these cows, the clotting time was reduced to ≤12 minutes; treatment of the calves was stopped, and there was no recurrence of clinical symptoms.[238]

Calves seem to experience more problems with diarrhea on certain milk replacers. One study showed that calves performed well on milk replacers containing soy protein when healthy but that during an outbreak of salmonellosis there was better weight gain and less mortality in calves fed whole milk.[241]

20.13 ESTABLISHING AN ETIOLOGIC DIAGNOSIS

An etiologic diagnosis is useful in selecting specific diagnostic and preventative regimens for bacterial infections. Establishing an etiologic diagnosis for viral infections will allow establishment of specific control methods and development of an appropriate vaccination strategy. Diagnosis of salmonellosis, cryptosporidiosis, and giardiasis can have public health implications. Once an agent has been identified, one of the major problems is in interpretation of whether or not that agent is responsible for diarrhea in the individual or herd, because most agents can also be found in a percentage of normal calves (see Fig. 20-1).

346

347

20.13.1 Sample Collection

Appropriate selection of diagnostic specimens is required to achieve a meaningful diagnosis. Best results are obtained when fresh samples and specimens are collected from calves early in the course of disease. When possible, a fresh necropsy is informative, as it provides an opportunity to relate the presence of pathogens to a disease process. This is required to establish causality. The quality of the information gathered is to a large extent determined by the quality of the samples submitted to the diagnostic laboratory. Autolysis and bacterial invasion of gut mucosa begin within 5 minutes of death. Autolysis is a common cause of poor tissue sections for histopathology; this may reflect a prolonged postmortem interval or poor tissue preparation, handling, or transport. To avoid autolysis, formalin needs to distribute into the lumen of intestinal sections; therefore intestinal specimens should be no longer than an inch long and the tissue-to-formalin ratio should be no greater than 1 to 10.

20.14 DIAGNOSTIC TESTS

20.14.1 Bacterial Pathogens

20.14.1.1 ESCHERICHIA COLI

E. coli is a normal inhabitant of the gastrointestinal tract. Isolation of *E. coli* from fecal samples or gut contents is therefore of no significance unless the isolates are demonstrated to possess virulent attributes that are consistent with the clinical and/or pathologic presentation. Virulence attributes include adhesins, enterotoxins, and cytotoxins. ETEC adheres to enterocytes in the jejunum and ileum.[242] On gross pathology, ETEC is associated with fluid-distended loops of bowel without enteritis.[243] Calves infected with ETEC have a mild inflammatory reaction in the small intestinal wall and some villous atrophy. In fresh specimens, sheets of gram-negative bacilli can be seen adhering to the small intestinal wall.[242] Definitive diagnosis of enterotoxigenicity rests on demonstration of the ability of the *E. coli* to dilate intestinal loops.[244] ETEC can also be identified by the presence of F5 (K99) using antigen-specific immunoassays including latex agglutination,[245] ELISA,[246] fluorescent antibody,[247] slide agglutination,[247] and rapid dipstick tests. A potential limitation of immunoassays is the specificity of the antibodies used; strains of ETEC using non-F5 fimbriae will not be detected by these tests.[108,248]

AEEC and STEC mediate disease by cytotoxic damage to the intestinal mucosa. Diagnosis of *E. coli* infection may be achieved using phenotypic differentiation of pathogenic strains from nonpathogenic normal flora *E. coli* via bioassays or immunoassays for toxins and fimbriae. Immunoassays have been developed to identify

the presence of Stx1 and Stx2 in feces as a presumptive test for the detection of STEC in cattle feces.[249–251] An alternative approach to identify and differentiate ETEC, AEEC, and STEC is to use PCR to identify virulence-associated genes commonly found in these *E. coli* strains (F5, F41, enterotoxin, intimin, Stx1, and Stx2).[117] The significance of STEC, EPEC, and AEEC in bovine enteritis is unknown because of a lack of appropriate assays for routine detection and because of the widespread presence of verotoxin-producing *E. coli* strains in healthy cattle that complicate the interpretation of detecting fecal shedding in sick animals.[252–254] Demonstration of verotoxin in cultures from bovine enteritis is not sufficient to imply a causative association.

20.14.1.2

CLOSTRIDIUM SPECIES

C. perfringens has been associated with enterotoxemia and hemorrhagic abomasitis in calves.[129,131] *C. perfringens* organisms are normal flora of the gastrointestinal tract; therefore isolation of *C. perfringens* from feces is not in itself diagnostic. Pathogenic strains of *C. perfringens* produce exotoxins; five of these (alpha-, beta-, epsilon-, and iota-toxins and enterotoxin) are involved in the pathogenesis of disease.[129] The complete pathogenesis of enterotoxemia and abomasitis has yet to be completely elucidated. Production of specific toxins can be demonstrated only in a proportion of cases.[255] Isolation of toxin-positive *C. perfringens* from intestinal contents does not confirm a clinical diagnosis of bovine enterotoxemia, because almost as many *C. perfringens* isolates from normal calves produce toxin and because toxin production cannot be demonstrated in as many as 40% of affected calves.[256]

A fresh necropsy is required to definitively diagnose clostridial enteritis. Observing many gram-positive bacilli in the mucosa associated with hemorrhagic enteritis is suggestive of clostridial enterotoxemia. Quantitative bacterial counts of intestinal contents at the site of the lesion have proven to be one of the most reliable methods for diagnosing enterotoxemia.[131] A *C. perfringens* count greater than 10^6/mL of intestinal contents is consistent with a diagnosis of enterotoxemia.[131] Demonstrating the presence of *C. perfringens* toxins or the capacity to produce toxins provides support for the diagnosis. Tests for detecting toxins or the bacteria's capacity to produce toxins include bioassays, immunoassays, western blot, and PCR assay.[257] The basis of the bioassay is to demonstrate protection of mice using antitoxin. *C. perfringens* enterotoxin is produced during sporulation. In vitro detection of enterotoxin-production capacity of a *C. Perfringens* isolate using western blot or immunoassays requires sporulation to occur. In vitro techniques to induce sporulation are not 100% efficient, so detection of enterotoxin using these methods is less sensitive than PCR is at detecting the genes required to produce enterotoxin.[258]

20.14.1.3

SALMONELLA SPECIES

Salmonellae are capable of causing disease in cattle of all ages. Neonatal infections are common. The classic pathologic lesion is fibrinous or fibrinonecrotic to ulcerative enteritis.[259] The severity of lesions is usually greatest in the distal small intestine and proximal large bowel. Hypertrophy of the mesenteric lymph nodes is a common finding.[260] Serosal hemorrhages may be observed in the small and large intestines. Septic infarcts in the kidneys and inflammation of the gall bladder are less common findings. Pneumonia is a common finding with *Salmonella* Dublin infections, and gangrenous necrosis of distal extremities may also be observed.[261] Bacteremia is a feature of neonatal salmonellosis and may manifest as osteomyelitis and/or meningitis.

Isolation of *Salmonella* from feces of calves with diarrhea is consistent with a diagnosis of salmonellosis but in itself does not necessarily establish causality, as *Salmonella* may be isolated from the feces of apparently

healthy calves.[262] Isolation of *Salmonella* from tissues at necropsy is indicative of invasive salmonellosis. A definitive diagnosis of salmonellosis is based on the clinical presentation, pathologic lesions, and isolation of *Salmonella* from tissues at necropsy.

There are numerous methods for isolating and detecting the presence of *Salmonella*. These include direct culture, enrichment cultures, PCR, immunoseparation, and immunoassays.

The process of directly inoculating tissues or other samples onto plating media, except in the case of acute infections, is usually nonproductive. Typically, with subclinical infection the number of salmonellae shed in feces is low relative to the high number of other bacteria. Fecal samples should be inoculated into selective-enrichment media for optimal recovery of *Salmonella*. Selective-enrichment broths are formulated to selectively inhibit other bacteria while allowing *Salmonella* to multiply to levels that may be detected after plating. Internal organs that are normally sterile do not need to be inoculated onto selective media; rather, they should be inoculated onto nonselective (blood agar) or weakly selective (MacConkey agar) media.

347

348

Rapid detection methods have been developed to expedite the detection of salmonella. These methods include electrical conductance and impedance, immunologic techniques, nucleic-acid—based assays, and PCR assay. These methods generally take 24 to 52 hours to screen for or detect and identify salmonella organisms. Most of these tests, and particularly the enzyme-linked immunologic techniques, require 10^5 cells per milliliter for reliable results. Accordingly all these tests involve a preenrichment stage, and some also involve a selective-enrichment culture.[263] When *Salmonella* is causing disease, clinically affected calves may shed 10^9 *Salmonella* organisms per gram of feces.[264] Detection of *Salmonella* in clinical samples when it is the inciting cause of the disease process is not normally difficult when multiple samples are collected from a representative sample of the affected population.

20.14.2 Viral Enteropathogens

Viruses are usually identified by direct examination of the feces, immunoassays, or fluorescent antibody examination of intestinal mucosa. Molecular techniques involving PCR and reverse transcriptase—PCR (RT-PCR) have been described for most pathogens but are not routinely available in all diagnostic laboratories. Electron microscopic examination of feces is not a sensitive means of detecting virus particles, but it has the advantage that many different types of viruses can be detected, including those such as parvovirus that are not recognized as common causes of diarrhea. The recent development of relatively inexpensive immunoassay diagnostic test kits makes these an attractive option; limited test-specific data regarding test sensitivity and specificity limit the application of some of these tests.

20.14.2.1 CORONAVIRUS

Coronavirus replication occurs in the epithelial cells of the distal half of the villi of the lower small intestine and colon. Infected cells die, slough, and are replaced by immature cells. In the small intestine these changes result in stunting and fusion of adjacent villi, and in the large intestine they lead to atrophy of the colonic ridges. On histopathology the tall columnar epithelial cells are replaced by cuboidal and squamous epithelial cells, and in severe infections there may be areas of complete desquamation.[265] Virus is shed in respiratory secretions and feces. There are several methods for detecting bovine coronavirus virus in feces. These include isolation of the virus in cell culture,[266] electron microscopy,[267] immunoelectron microscopy,[166] immunoassays[159,246,268–271] and molecular techniques including dot blot hybridization assays[272] and RT-PCR

assay.[273,274] Isolation of bovine coronavirus using cell culture techniques is not often performed in diagnostic laboratories, as the technique is difficult and requires viable virus (fresh samples or shipped on dry ice).[275] Electron microscopy has been used as a standard diagnostic method for bovine coronavirus. Although the intact virion of bovine coronavirus is fairly characteristic in appearance, it is not uncommon for the identifying surface projections of the virus to be lost during sample preparation or storage, making it difficult to properly identify virus particles by electron microscopy.

Numerous ELISA assays have been described for the detection of BCV antigen in feces. Several companies have developed commercial kits using this technology. The use of monoclonal antibodies rather than polyclonal antibodies is reported to increase the sensitivity and specificity of bovine coronavirus ELISAs.[271] The limit of detection for ELISA assays ranges from 10^4 to 10^7 virions per milliliter of feces.

A one-step RT-PCR assay, targeting a 730-bp fragment of the nucleocapsid gene of bovine coronavirus, and a nested PCR assay, targeting a 407-bp fragment of the nucleocapsid gene have been developed to detect bovine coronavirus. Compared with an antigen capture ELISA, the limit of detection for the RT-PCR and nested PCR assays was 10^5 virions/mL and 10^3 virions/mL, respectively, compared with 10^7 virions/mL for the ELISA.[276,277]

20.14.2.2

ROTAVIRUS

Bovine rotavirus infects enterocytes of the intestinal villus. Infected cells are predominantly in the distal third to half of the villus. The age at the time of infection influences the distribution of the virus in the gastrointestinal tract and the number of virions shed in feces. In experimental challenge studies, infection of day-old calves resulted in a uniform distribution of virus throughout the small intestine.[278] Challenge of 10-day-old calves led to a patchy distribution of the virus with maximal viral load observed in the mid small intestine.[278] Villous stunting is more pronounced in young calves.

Methods for detection of rotavirus include cell culture, fluorescent antibody staining, electron microscopy, immunoelectron microscopy, immunoassays, electrophoretic procedures, and RT-PCR assay.[146–150,245,246,269,279–281] Bovine rotavirus is difficult to isolate in cell cultures because of the cytotoxic nature of feces and fecal filtrates and because the virus is inconsistent in production of cytopathic effects.[280] The fluorescent antibody technique is simple, rapid, and specific; however, rotaviral antigen is usually difficult to detect within 24 to 72 hours after the onset of diarrhea because rotavirus-infected epithelial cells are rapidly shed from the tips of the villi.[282] Comparative studies evaluating methods of detecting rotavirus in feces show comparable test results between antigen capture assays (ELISA, latex agglutination) and electron microscopy.[245,269,280,283] Direct immunofluorescence testing of fecal samples corresponds well (90%) with electron microscopic examination for rotaviruses when samples are collected during the 24 hours after the onset of diarrhea,[284] but have poor agreement (33%) for field specimens submitted to a diagnostic laboratory.[280]

20.14.2.3

BOVINE VIRUS DIARRHEA

BVD virus rarely causes diarrhea in neonatal calves.[71] Sporadic disease may be observed in persistently infected calves. Pathologic lesions include ulceration of the oral cavity, particularly on the hard and soft palates, and blunting of the buccal papillae.[172] Erosions may be observed in the esophagus, and necrosis of Peyer's patches may be observed in the ileum. Thrombocytopenia has been observed with BVD type II

infections. Outbreaks of neonatal disease have been observed with this strain. Petechial and ecchymotic hemorrhages are a feature of this condition.[70,174,175] Hematologic findings often include leukopenia and thrombocytopenia.

Several options are available for the detection of BVD; these include virus isolation,[285,286] RT-PCR assay,[287] immunohistochemistry,[288] and antigen capture ELISA.[289] Assays; the latter two are used in most commercial laboratories. Maternal antibodies reduce the sensitivity of the ELISA assay in young calves.[287]

20.14.2.4 BOVINE TOROVIRUS (BREDA VIRUS)

Bovine torovirus produces cytolytic infections of villi and crypt enterocytes in the small and large intestine.[290] 348
Bovine torovirus does not grow in tissue culture, cell culture, or embryonated eggs.[291] Therefore the large- 349
scale preparation of reference antisera and antigens for the development of diagnostic tests has been precluded. Torovirus is capable of causing diarrhea in cattle, with disease observed most frequently in calves less than 3 weeks of age.[68,179,181,292–294] Like other enteric viruses, bovine torovirus has been detected in feces of normal calves; therefore detection of the virus in feces from diarrheic cattle cannot be interpreted as causal. The lack of diagnostic reagents has limited the study of bovine torovirus, leaving questions about its epidemiology and relative importance in calf diarrhea.[67] Diagnostic methods that have been used to detect bovine torovirus include electron microscopy, immunofluorescence, antigen capture ELISA, and RT-PCR assay.[67,179]

20.14.3 Protozoa

20.14.3.1 EIMERIA SPECIES

Eimeria species are host-specific. *E. bovis* affects primarily the mucosa of the cecum and the proximal part of the large intestine, whereas *E. zuernii* affects the mucosa of the cecum as well as the entire large intestine, including sometimes the rectum.[295] The clinical signs of bovine coccidiosis are associated with the final stages of the eimerian life-cycle and commence shortly before oocyst shedding. Gross lesions in the cecum and large intestine range from having semiliquid contents, little or no blood, and few areas of epithelial sloughing to having extensive hemorrhage and large areas of epithelial sloughing and necrosis of the mucosa.[295] The serosal surface is often reddened opposite the affected mucosal area, and the submucosa and external muscular layers are often thickened by edema.

Oocysts usually can be recovered 2 to 4 days after the onset of diarrhea.[296] Oocysts can be identified microscopically by direct smear, flotation, or centrifugation methods. The oocysts of *E. alabamensis* are smaller and less distinctive than oocysts of other coccidian but are approximately 4 times larger than cryptosporidia. Oocyst counts of 5000 or more per gram of feces are considered significant in cattle.[232] Identification of oocysts in feces is not diagnostic for clinical coccidiosis, because the parasite is frequently detected in small numbers in the feces of healthy cattle.[297] When scour problems are being investigated, multiple samples should be collected for oocyst counts to provide an indication as to the level of infection within the group. The potential for discord between clinical signs and fecal shedding limits the diagnostic utility of a single sample from an individual animal.

20.14.3.2

GIARDIA

Giardia infection is not associated with changes in intestinal villous height or crypt depth. However, transmission electron microscopy has been used to demonstrate a reduction in microvillous surface area.[298] Diagnostic methods for detection of *Giardia* include direct microscopy, immunomagnetic separation, fluorescent antibody staining,[221,299] ELISA,[300] and PCR assay.[301] When direct microscopy is used, fecal samples should be examined within 24 hours of collection. Concentration of trophozoites and cysts via density gradient centrifugation or filtration followed by fluorescent antibody staining is the diagnostic method used in most veterinary epidemiologic studies of *Giardia* in calves.[200,302,303] Other immunoassays and PCR techniques are emerging in human diagnostic laboratories.[300,301]

20.14.3.3

CRYPTOSPORIDIA

C. parvum infections are mainly concentrated in the distal small intestine, but lesions may also be found in the cecum and colon, and occasionally in the duodenum.[304] The pathologic findings associated with *Cryptosporidium* are a mild to moderate villous atrophy, villous fusion, and changes in the surface epithelium with infiltration of mononuclear cells and neutrophils in the lamina propria.[304]

Calves infected with *C. parvum* usually develop diarrhea in 72 to 96 hours; diarrhea is observed for 8 to 23 days,[305] during which oocysts are excreted in feces. Oocysts are stable in feces for many days at room temperature.[306] Laboratory methods for the diagnosis of cryptosporidial infections include microscopic examination of fecal smears or fecal preparations, immunoassays, and PCR assay. Cryptosporidia oocysts are small (4 to 6 μm in diameter) and are easily missed on a fecal smear. Because fecal smears do not concentrate the oocysts, this technique is less sensitive than fecal flotation. Concentration of the protozoa is achieved by salt[307] or sugar flotation. Special stains may be used to facilitate detection of cryptosporidia during microscopic examination. Differential staining techniques are useful to distinguish *Cryptosporidium* oocysts from other fecal components (especially some yeasts) of similar size and shape.[308–311]

A number of immunoassays have been developed for the detection of cryptosporidia. The detection thresholds of the different methods have been reported to be 3×10^5 oocysts/g for a monoclonal antibody—based antigen capture ELISA, compared with 1×10^6 oocysts/g detected by examination of acid-fast stained fecal smears and 1×10^3 oocysts/g detected by indirect immunofluorescence.[312] The detection threshold may be further enhanced by using a combination of immunomagnetic separation coupled with immunofluorescent microscopy. With this combination it is possible to detect as few as 10 oocysts/g.[313] Several dipstick immunoassays have also been developed. The detection threshold for this technology is reported to be 1×10^3 oocysts/g.[314] This technology offers the potential for rapid, cost effective detection of cryptosporidia in fecal specimens.

Molecular techniques have been described for detection and typing of cryptosporidia.[190,315] The capacity to differentiate the different genotypes makes this approach useful for epidemiologic studies of cryptosporidia.[315]

20.15 RISK FACTORS FOR NEONATAL CALF DIARRHEA

It is important to identify risk factors, both to set up effective preventive programs and to initiate control in the face of a disease outbreak. The cause of calf diarrhea is multifactorial; consequently it is common for several factors to contribute to the outbreak and perpetuation of disease in a herd.

20.15.1 Dystocia

Dystocia is associated with neonatal calf diarrhea in more intensive beef and dairy systems[62,316] and is a risk for preweaning mortality, with over 40% of preweaning deaths occurring in calves born to cows with dystocia.[317–319] Dystocia affects the ability of the calf to suckle colostrum, resulting in decreased serum IgG levels; consequently calves that survive dystocia are two to four times more likely to become sick in the first 45 days of life.[320–322] Stocking density of preparturient cows, timing of calving, breed, and cow grouping all influence the risk of dystocia.[323] Calves that experience dystocia are likely to have edema of the head and tongue, making suckling difficult. They are weak, exhausted, and likely to be recumbent for longer, increasing exposure to fecal pathogens.[164] Low- and high-birthweight calves are at greater risk of mortality.[318] Small calves experience greatest mortality at parities greater than one, and large calves at first parity.[324] There is no direct effect of preparturient nutrition on the subsequent incidence of neonatal calf diarrhea. Increased feed intake precalving will increase calf birthweight but does not increase the risk of dystocia unless cattle become obese.[325–327] Weight loss is associated with prolonged labor, increased dystocia, and increased perinatal mortality.[327,328]

349

350

20.15.2 Dam Parity

Calves born to first- and second-parity cows have increased mortality compared with those born to older cows, and the risk of diarrhea in calves born to heifers is 3.9 times greater than in those born to cows.[318,329,330] Heifers have an increased risk of dystocia, lower colostrum quality, and inferior mothering ability.[320,321,330–332] The stocking density of heifers is often increased before calving to facilitate observation, with the consequence of exposing their calves to a greater environmental pathogen load. These factors are all likely to contribute to increased morbidity, and consequently the percentage of heifers in the herd will affect the risk of diarrhea. Calves from carrier heifers shedding rotavirus and bovine coronavirus are more likely to develop clinical disease than calves born to carrier cows.[157] Studies in dairy herds have shown that there is a positive correlation between the number of young stock in the herd, the overall herd size, and herd production with the risk of neonatal calf diarrhea.[333–335]

20.15.3 Colostrum Management

Many studies have shown that FPT results in increased risk of neonatal calf diarrhea in beef and dairy herds.[336–342] Calves are able to absorb immunoglobulins only for a limited time after birth, and the subsequent serum Ig concentration is determined by the perinatal state of the calf, timing of colostrum ingestion, and the mass of immunoglobulin consumed.[343] Colostrum also provides local (enteric) immunity, with the major benefits lasting for approximately 3 to 4 days after birth.[344–346] After this period, milk contains little immunoglobulin and most colostral antibody has been cleared from the intestine. Colostral antibodies protect against rotaviral infections in

the first 4 days of life[140,141]; in contrast, anti-F5 (K99) *E. coli* antibody is present in low amounts in unvaccinated cows,[347] and enteric *E. coli* infections are usually seen in very young calves. After 4 days the protective effects of colostrum are primarily a result of systemic antibodies, and there is evidence that these can leak back into the gut and probably give limited long-term protection against diarrhea.[348]

Colostral quality is affected by colostral volume, genetics, nutrition, parity, and climate. Beef breeds have been shown to have a significantly higher IgG concentration than dairy breeds, and this was attributed to differences in the onset of lactogenesis and colostral volume[349]; however, studies comparing colostral quality between beef breeds or between dairy breeds have not shown a consistent result.[320,321,332,350–355] Beef cows have a significantly smaller prepartum decline in serum IgG compared with dairy cows, but the resulting colostral IgG concentration is higher because of the significantly lower volume produced. However, the combination of low volumes and increased turbidity may limit the calf's ability to take in sufficient immunoglobulin, especially if the calf is weak. Recent studies in beef cattle have shown an increased incidence of FPT in specific genotypes, with different haplotypes determining receptors for neonatal Ig absorption.[356,357] This would indicate that FPT is more prevalent in specific lines of cattle rather than in breeds per se. First- and second-calving beef and dairy cows have a lower colostral immunoglobulin concentration than cows of third parity and above.[352,354,358–360] This is reflected in significantly lower mean serum IgG concentration found in calves born to beef heifers and second-parity cows.[320,321,330–332]

The biggest effect of nutrition on colostral quality is its effect on colostral volume, with increasing volume resulting in dilution of immunoglobulins.[359] Severe nutritional restriction has no effect on IgG levels other than an increased concentration associated with a decrease in colostral volume.[321,361–365] Similarly, nonlactation period length appears to have little effect, although a prolonged dry period may result in increased volume in mature cows.[355,359,366]

Passive transfer is also influenced by climate, with both hot and cold extremes leading to decreased immunoglobulin concentration, intake by the calf, and immunoglobulin absorption.[339,355,367–371]

20.15.4 Beef Cow Herd Management

In beef herds, high stocking rates in the calving area and the use of one calving area are major risks for neonatal calf diarrhea.[372,373] The practice of leaving nursing dams and calves with calving cows further increases stocking rates and promotes disease transmission.[338] The weather at calving affects both pathogen survival and calf comfort; shelter in the nursing area is associated with decreased mortality resulting from neonatal calf diarrhea.[329] Major calf scour pathogens can survive in the environment for months or years in cool, wet conditions, and consequently both the incidence and the mortality from diarrhea increase with prolonged use of the same paddock or a longer calving season, and the incidence of diarrhea increases as the calving season progresses.[319,329,330] Adverse weather conditions cause cows to move to shelter and shade, concentrating cows and calves in small contaminated areas. Calves born into a contaminated environment potentially become infected during or shortly after birth and shed enteropathogens even when they remain clinically normal. This further increases the environmental load of infectious agents, infecting adult cattle as well as calves. The outcome of host-pathogen interactions is largely influenced by the pathogen challenge dose and the age of the animal, with clinical disease becoming more common both in younger neonates exposed to higher pathogen numbers (Fig. 20-3).

Farms that purchase replacement calves aged less than 4 weeks have an increased mortality from neonatal calf diarrhea.[329] Purchased calves may introduce new pathogens, challenging a susceptible population. Stress from transport and arrival at a new location may increase shedding and predispose to clinical disease, increasing the environmental pathogen load. The risk of pathogen introduction increases when introduced calves from multiple properties are commingled before introduction.

350
351

Fig. 20-3 Cow on a farm with a high incidence of neonatal diarrhea. Note that the mud is so deep around the feeders that it covers the cow's hocks. As a result the teats will be contaminated by manure and enteric pathogens.

20.15.5 Intensive Calf-Rearing Systems

Intensively reared calves have an increased risk of diarrhea associated with housing, nutrition, and weaning. Variables that have been observed to increase the risk of scours include feeding milk once versus twice a day within 14 days of birth,[374] placing preweaned heifers in groups of seven or more, using damp versus dry bedding,[374] a male having primary responsibility for the care and feeding of preweaned heifers, calves not receiving hay or other roughages until >20 days old, and feeding mastitic or antibiotic milk versus whole milk.[375] Use of individual calf hutches has been reported to increase the risk of scours but to reduce mortality.[374]

Factors significantly associated with a decreased risk of cryptosporidial infection included ventilation in calf rearing areas, daily addition of bedding, feeding of milk replacer, daily disposal and cleaning of bedding, and use

of antibiotics. Postweaning practices that reduced risk of infection included moving animals after weaning, cleaning soiled bedding, and using antibiotics and ionophores as preventive measures. Maternity management factors that reduced risk of infection included using fresh colostrum to feed calves and having a concrete floor in the calving area. General management factors that influenced risk included the total number of dairy cattle, the total number of other species of agricultural animals on the farm, and the distance of the barn water source from the septic system.[376] It is likely that many of these factors in all categories will also increase the risk of infection with other enteric pathogens.

20.16 HERD STRATEGIES TO PREVENT NEONATAL DIARRHEA

Management practices that reduce the risk of calf scours also promote good health, improve growth rates, and reduce the risk of transmitting other enteric pathogens such as *Mycobacterium paratuberculosis*. The principles of prevention are as follows:

1 Minimize pathogen exposure.

2 Ensure adequate colostral intake.

3 Boost specific and nonspecific immunity.

4 Promote farm biosecurity.

20.16.1 Minimizing Pathogen Exposure

Enteric pathogens may be shed in large numbers by calving cows, scouring calves, and asymptomatic cohorts, especially those up to 4 months of age. All enteric pathogens can survive in the environment for months or years in moist damp conditions. Other sources of infection include people who have treated or handled infected calves; contaminated water; contaminated colostrum, milk, or solid feed; and equipment that has been used to feed or medicate infected calves.*

20.16.1.1 MINIMIZING PATHOGEN EXPOSURE IN DAIRY HERDS

Strategies to prevent disease in dairy calves focus on calving cows in a clean environment, removing calves from cows at birth, feeding adequate good-quality colostrum, placing calves in a clean, dry environment separate from other stock, feeding good-quality milk or milk replacer, providing adequate shelter, and providing access to water and high-quality calf pellets. Microbial contamination is an important determinant in the quality of colostrum and milk. Good sanitary practices are required for the harvest, storage, and feeding of both products. Microbial contamination of colostrum compromises passive transfer and in the case of pathogens such as *Salmonella* may lead to a direct pathogen challenge. Similarly, feeding milk with a high bacteria count increases the risk of diarrhea.

In dairy systems, where calves are reared by hand, the number of young stock on the farm and the incidence of respiratory disease are positive predictors for calf diarrhea.[333] Cleanliness of the calving area is important; bedding should be changed between each calving, and large numbers of cows should not be cycled through a few stalls.[333] Before calving the udder and the perineum of the cow should be cleaned. The calf should receive adequate colostrum.[373] In recent years the use of calf hutches has gained widespread acceptance for managing calves after they have been separated from their dam. This system provides individual isolated housing for

each calf. Cleaning is facilitated because the hutches can be moved to new sites between calves. Keeping preweaned calves in groups larger than six puts them at increased risk for diarrhea.[335]

Cleaning and disinfection after each calf batch plays an important role in reducing contamination in housed calves. The key to decontamination is the physical cleaning. Physical removal of organic contamination through scrubbing is preferred to application of high-pressure sprays, which can aerosolize organisms, allowing dissemination. On smooth, ideal surfaces physical removal of visible contamination by thorough washing with soap and water removes 99% of the microbial load (two logs). However, on typical housing surfaces washing removes only 90% (one log). Application of disinfectant after washing is important to eliminate remaining pathogens and to prevent bacterial pathogens from proliferating. Physical cleaning cannot be replaced by applying disinfectants in larger quantities, as organic material neutralizes most disinfectants. Disinfectant solutions are applied following cleaning. With regard to disinfectants, pathogen elimination is time dependent.[380] Other important variables that influence the effectiveness of disinfectants and rate of pathogen reduction include concentration, temperature, pH, and water hardness.

In addition to cleaning between batches, it is important to clean nipple buckets and other feeding utensils between each feed. Separate equipment should be used to administer oral electrolytes and colostrum. *Salmonella* and coronavirus are shed in saliva and can contaminate equipment used for oral medication. Washing with warm soapy water is required to remove the fat residue left by milk and colostrum handling equipment.

Several microbial characteristics should be considered when disinfecting equipment that comes into contact with calves. Rotavirus is susceptible to sodium hypochlorite but is relatively resistant to many common disinfectants, such as chlorhexidine. Because as a nonenveloped virus it is not affected by soaps, washing with soap alone may actually spread the virus around on the washed surface.[381] Coronavirus is an enveloped single-stranded RNA virus and is not as stable in the environment as rotavirus. Because of their envelope, these viruses retain infectiousness better at lower than at higher relative humidity[382] and are considerably more sensitive to soaps and common disinfectants than are nonenveloped viruses. *Cryptosporidium* can autoinfect the original host; consequently, the infectious dose can be exceedingly small. In the environment, cryptosporidia are extremely resistant to most veterinary disinfectants except 5% ammonia, 6% hydrogen peroxide, or 10% formalin.[208,383,384] They survive very well in water, requiring 4 to 11 weeks to decline by one log.[385] On the other hand, cryptosporidia are susceptible to drying, with oocyst infectivity declining in 1 to 4 days.[209]

351

352

The most readily cleaned surfaces are made of smooth impervious materials such as plastic and varnished wood (Table 20-4). Usually buildings are cleaned and then either disinfected or fumigated.[386] Many disinfectants are inactivated by organic matter; viruses, coccidia, and particularly cryptosporidia may be resistant to their action (Table 20-5). Disinfectants may also be toxic and are best applied by personnel wearing rubber gloves and respirators (if indoors). In general, potent phenolics such as cresol (cresylic acid) are very useful for disinfecting dirty surfaces because they are not inactivated by organic matter and are effective against gram-negative organisms and viruses. The phenolics are highly toxic and leave lingering odors. Hypochlorite solutions (5 g of available chlorine per liter) have a broad spectrum of action but are rapidly inactivated by organic matter. They would be useful as a final disinfectant on previously cleaned surfaces. Because hypochlorite is unstable, it is unlikely to leave toxic residues. Iodophors are not very effective against rotavirus, particularly if organic matter is present. Virkon, a newer disinfectant and cleaner containingpotassium monopersulfate as the active ingredient, is effective for all pathogens except cryptosporidia. Normally a 1% solution is used and is prepared by mixing 10 g of powder with 1 L of water.

Contact time should be a minimum of 10 minutes. Virkon has the advantage of having a detergent action that facilitates cleaning.

Table 20-4 Ability of Bacteria to Persist on Various Types of Surfaces Found in Farm Buildings

	Total Bacterial Count per 100 cm^2	
Material	**Uncleaned**	**Cleaned**

Aldehydes	Formaldehyde*	+	+	+
	Glutaraldehyde	+		
Quaternary ammonium	Benzalkonium chloride	+	+	–
	Cetrimide	+		
Ammonia	Ammonia			+
Oxidizing agent	Potassium monopersulfate	+	+	–

Based on information in references 408, 446–451.

++, Highly effective, not inactivated by organic matter; +, moderately effective, inactivated by organic matter; ±, some effect; –, little effect.

* Requires long contact time—18 hours to kill cryptosporidia.

Formaldehyde is one of the few agents that is effective against cryptosporidia. It requires a long contact time and is highly toxic. It is usually used for terminal fumigation in buildings that can be tightly sealed. Formaldehyde gas is best generated by heating paraformaldehyde (5 g/cubic meter of building) in an electrically heated pan at 204° C. Some manufacturers of paraformaldehyde provide pans specially designed for this purpose. The pans should be placed no more than 30 m apart and arranged so that electricity to the pan can be controlled from outside the building. There must be a safety mechanism to ensure that the pan does not overheat and cause a fire. The building must be sealed for at least 24 hours and cannot be entered until it has been thoroughly ventilated. Formaldehyde gas can also be generated by boiling formalin or by adding potassium permanganate to formalin. The latter method generates a violent chemical reaction and carries risks of explosion. Formalin aerosol generators are ineffective.[387] After cleaning and disinfection one should allow a rest period for the building to ventilate before reintroducing calves. It is very important that cleaning and

disinfection be thorough. Attention should also be given to rodent control because rodents can be a reservoir for *Salmonella*.[388]

20.16.1.2 MINIMIZING PATHOGEN EXPOSURE IN BEEF HERDS

In beef herds, calving areas should be located to take advantage of natural shelter and drainage and rotated from year to year to avoid pathogen buildup.[330,372,389,390] Pregnant cattle are moved into a clean paddock no more than 2 weeks before the start of calving. It is best that cows and heifers are managed separately until their calves are at least 1 month old. This gives the opportunity to provide better feed to the heifers and to minimize infection between the groups. Confined, wet, or muddy areas should be avoided for calving cows, and if they need to be used the stocking rate should be decreased. Feed-out areas should be rotated and separated from watering points to encourage dispersal. When pasture for calved cows is limited, supplementary feed should be fed to dry cows to ensure enough freshpasture for calving and nursing cows. Clean water should be available in a trough that is accessible to cows and calves. Chronically sick animals, weak calves, and cows with no milk should be removed from the calving paddock and kept isolated from the herd.

352

353

Grazing and reproductive management have a significant impact on pathogen load. Where appropriate to grazing management, calving paddocks should be left vacant during the summer. For producers that manage periparturient cows in smaller calving paddocks to facilitate supervision, the emphasis should be on minimizing the stocking density in the calving paddock by removing cows and calves shortly after parturition.[372,389] Alternatively, pregnant cows can be moved away from cows with calves every 1 to 2 weeks or more frequently in large herds. Young calves in the calving paddock will markedly increase the rate of pathogen buildup and the subsequent challenge to newborn calves. Moreover, the increased stocking rate will amplify stress, affecting both transfer of passive immunity and the ability of young calves to rest. Often, calving areas are small because of the perceived need to assist cows with dystocia.[390] Well-grown and appropriately fed heifers mated to suitable sires can minimize this need. Beef cows with calves at foot should be moved from the calving paddock into nursing groups that have a maximum age range of 4 weeks and a low stocking rate. Groups should not be mixed until all calves are at least 4 weeks old.[372,389,390] Reproductive management influences pathogen load by determining the age spread of the calves. Sick calves amplify environmental contamination. A prolonged calving period leads to a buildup of contamination so that calves born later in the calving period experience an increased pathogen challenge. It is desirable to maintain a calving period that is less than 60 days.

20.16.2 Ensure Adequate Colostral Intake

The principles of colostrum feeding and evaluation are discussed in detail elsewhere (see Chapter 53). In general, colostrum deprivation is seen in 25% to 50% of dairy calves[391–393] but is much less common in single suckle beef operations.[394] Colostrum deprivation, poor mothering, and early separation of dam and calf are the major causes of failure of transfer in dairy calves. Beef calves are usually mothered well,[395–397] and volume of colostrum produced, which is strongly influenced by nutrition, is one limiting factor.[361,398,399] Thus adequate colostrum intake is best ensured in dairy calves by assisted sucking of the dam or hand feeding 2 to 3 L of colostrum within 2 to 4 hours of birth. If colostrum is given by stomach tube, 4 L (10% of body weight) should be administered because the efficiency of absorption is reduced. In beef cattle adequate nutrition during late

pregnancy is important. The calving area should be carefully monitored, and any calves that fail to suck within 6 hours of birth should be caught and tubed with colostrum. In herds where both dystocia and neonatal disease is a problem, it may be advisable to administer colostrum after calving to all calves that have an assisted birth.

20.16.3 Boosting Specific and Nonspecific Immunity

20.16.3.1 ENTEROTOXIGENIC *E. COLI*

The protective efficacy of ETEC bacterins is well documented.[400–403] Because ETEC scours occurs during the first 3 days of life, the neonate does not have time to mount a protective immune response to vaccination. Protection is afforded by vaccinating cows in late gestation so as to ensure high concentrations of anti-K99 colostral antibodies. Good maternal management is required to ensure that the calf receives the maternal antibodies. Antipilus antibodies block the adhesion of the pathogen to enterocytes and subsequently prevent disease.[401] In general it is recommended that the vaccines are given 6 and 3 weeks before calving. Studies with some vaccines have shown that the vaccine is still effective if the priming dose is given 18 months before calving and boosting is carried out in the second half of gestation.[404] Clinical experience in beef farms with severe outbreaks of *E. coli* F5 (K99) diarrhea indicates that vaccinating cows that are more than 10 days from parturition can give considerable protection against death from ETEC infection.

Products containing monoclonal antibodies against F5 (K99) antigen have been shown to reduce the severity of diarrhea when calves are experimentally challenged a few hours after receiving the product.[405] In field situations, however, monoclonal products can have a low efficacy, presumably because a single dose provides only a short period of enteric protection. Antibody supplements are expensive, and vaccination of the dam to boost colostral immunity will usually be more cost-effective. On farms experiencing an outbreak of neonatal diarrhea caused by F5(K99) *E. coli,* there may be a place for the use of these products until vaccinated cows begin to calve. However, short-term administration (once a day for first 3 days of life) of an antibiotic to which the *E. coli* is susceptible is also highly effective in preventing diarrhea in herds experiencing outbreaks of ETEC.

20.16.3.2 SALMONELLA

The successful reduction of *Salmonella* prevalence in livestock on a national level via implementation of a *Salmonella* control program emphasizing immunoprophylaxis with modified live and killed *Salmonella* vaccines indicates the potential benefits that can be derived from the application of effective *Salmonella* vaccines.[406] *Salmonella* vaccine studies in cattle have focused on *Salmonella* bacterins and attenuated modified live *Salmonella*.

There are conflicting reports regarding the efficacy of *Salmonella* bacterins. The reported efficacy of *Salmonella* bacterins ranges from good to ineffective.[407–415] The overall consensus of these reports is that vaccination of cattle with *Salmonella* bacterins provides partial protection against *Salmonella* challenge. In the only reported controlled field trial an autogenous *Salmonella* bacterin was not found to have any effectiveness.[415] Anaphylactic reactions are occasionally reported in cattle vaccinated with *Salmonella* bacterins. The cause of these reactions is unknown but has been suggested to be associated with the lipopolysaccharide content of these products. Similar allergic-type reactions in humans caused by *Salmonella* bacterin vaccination during typhoid outbreaks are well documented.[416]

Several naturally occurring and genetically manipulated attenuated *Salmonella* strains have been used to immunize cattle against salmonellosis. The most widely tested genetically altered *Salmonella* mutant vaccines in cattle are the auxotrophic strains. Aromatic amino acid (aro) and purine (pur) auxotrophs of *Salmonella* are attenuated and have decreased virulence.[417–423] Comparative vaccine trials indicate that modified live attenuated *Salmonella* vaccines provide greater protection against virulent *Salmonella* challenge than *Salmonella* bacterins.[413,423,424] Vaccination with modified live *Salmonella* vaccines attenuates the severity of clinical signs and pathologic lesions and reduces *Salmonella* shedding and mortality.[406,419,425]

Calves immunized with modified live *Salmonella* vaccines are protected from homologous and heterologous *Salmonella* serotypes when challenged within 3 weeks of vaccination.[426–428] Live *Salmonella* vaccines induce transitory T-cell independent nonspecific protection that disappears about 1 month after immunization following clearance of the organisms from the reticuloendothelial system. Thereafter, protection against oral challenge is species- and serotype-specific, with recall of immunity presumably involving specific antigen recognition.[429,430]

353

354

The level of passive protection of calves achieved by feeding colostrum from vaccinated cows is questionable. Several reports suggest that immune colostrum provides passive protection, but others report no protective effect. In trials in which protection was achieved, calves were challenged at 1 week of age; trials in which no protection was observed involved challenging calves at 3 weeks of age, suggesting that the duration of passive immunity associated with colostral transfer is relatively short. Considering that many calves are exposed to *Salmonella* in the first week of life, colostral protection may be useful.

20.16.3.3 ROTAVIRUS AND CORONAVIRUS

Bovine coronavirus is associated with several diseases in cattle. All BCV isolates are believed to belong to a single serotype.[169a] Differences in hemagglutination-inhibition characteristics have been used to classify strains as types 1 through 3.[169b] There are seven serogroups of rotavirus, with group A accounting for the majority of pathogenic isolates. Members of the group A rotaviruses are further classified according to antigenic and genetic differences in their outer capsid proteins, G and P. Both of these proteins are involved in neutralization of infectivity in vitro and in vivo.[433] In the United States eight G serotypes and genotypes and four P serotypes and genotypes have been identified in cattle isolates.[153] The genome of rotavirus is composed of 11 gene segments that can be exchanged among isolates when animals are infected by more than one virus at the same time.[434] Genetic reassortment can generate new progeny viruses that can evade what was once a protective immune response, thus allowing persistence of rotavirus in susceptible populations.[433]

Two approaches have been taken with immunoprophylaxis against rotavirus and coronavirus infections in calves. The first approach involves oral vaccination of neonatal calves with a modified live vaccine. Calves begin producing detectable levels of local secretory IgM within 4 to 6 days of vaccination.[435] Calves are resistant to challenge from the initial appearance of local IgM antibodies.[435] In order to consistently elicit an effective immune response, the vaccine must be administered orally, immediately after birth, and before the calf has nursed because the colostrum of most cows contains virus-neutralizing antibodies that interfere with the vaccine.[436] There are conflicting reports of efficacy with these type of vaccines. In double-blind field studies that include vaccinated and nonvaccinated calves the vaccine was not shown to be effective.[437]

Conversely, when all calves were either vaccinated or not vaccinated in sequential comparisons, morbidity and mortality were significantly reduced.[437]

The second approach involves intramuscular vaccination of pregnant cows with either modified live vaccine or inactivated viral vaccines to stimulate high levels of specific viral neutralizing antibodies in colostrum and milk during the first several days of the calf's life. Infectious viral particles are neutralized within the gut lumen, preventing infection of intestinal villous enterocytes. One advantage of passive immunization is the fact that cross-protection between serotypes is less of a problem. This is because vaccination of a mature cow that has had natural rotavirus exposure leads to cross-serotype stimulation of heterotypic antibodies.[438] Single serotype vaccination therefore stimulates antibody production to a wide range of rotavirus serotypes, negating the need for multivalent rotavirus vaccines. Passively absorbed anti-bovine rotavirus IgG1 antibodies are transferred to the small intestinal lumen, where they protect against experimental challenge.[439] Antigen sensitized maternal lymphocytes also confer partial protection against challenge with virulent bovine rotavirus.[440] Colostrum and milk with a high virus-neutralizing antibody titer are highly protective while being consumed by the calf. For example, administering 400 mL of immune colostrum daily to calves from days 2 to 12 reduced the incidence of diarrhea from 41% to 3% in one study.[441] The concentration of rotavirus- and coronavirus-neutralizing antibodies in milk of vaccinated cows falls below protective levels by 3 to 7 days after parturition.[442–444] Rather than complete protection, the manifestations of passive immunity to bovine rotavirus that are often noted are (1) a delay of a few days in the onset of clinical signs, (2)a reduced severity of clinical signs, and/or (3) a reduction in the length of the period of viral shedding associated with infection.[445] Although there are reports of successful field trials involving bovine rotavirus— and bovine rotavirus-coronavirus—vaccinated cows,[402,446,447] negative esults have also been reported.[448] A common problem with commercial vaccines on the market in the United States and Europe is a lack of vaccine-specific data supporting efficacy claims. Protection correlates with serum titers; independent studies have sometimes failed to demonstrate effective seroconversion with some products.[449]

20.16.4 Nonspecific Immunity

20.16.4.1 DIET

The microbial quality of the diet is an important factor in preventing diarrhea. Calves that are fed milk from mastitic quarters or antibiotic-containing milk are at increased risk for diarrhea.[335] After fresh colostrum feeding, young calves have less diarrhea if placed on whole cow's milk rather than on other diets. Pasteurizing surplus colostrum and waste milk reduces the incidence of diarrhea in animals on these diets.[450] It is also important to offer a good-quality calf starter from approximately 2 to 3 days of age; at first little will be ingested, so offer small amounts and keep it fresh.

Some producers routinely administer vitamin A to neonatal calves. Many, but not all, studies in children indicate that supplementation can reduce the incidence of diarrhea in areas in which clinical and subclinical vitamin A deficiency is endemic.[451] In cattle, vitamin A deficiency is most likely when a diet of unsupplemented straw and grain is fed. Calves born to cows fed good-quality green forage or cattle receiving a vitamin A supplement should not require supplementation—particularly if they received adequate colostrum. Enteric absorption of vitamin A is diminished in calves with cryptosporidiosis, so the systemic route should be used in calves with this type of infection.[452]

20.16.4.2 BIOSECURITY

Infectious diseases are often purchased with brought-in stock. Operations that buy calves for rearing purposes should be encouraged to buy from as few sources as possible. Direct purchase from one farm is best; assembling collections of calves through auction markets should be avoided if possible.

20.16.5 TREATMENT OF INDIVIDUAL CALVES

20.16.5.1 Examination

Physical examination of the diarrheic calf is the first step in establishing therapeutic needs. It is important to determine the presence of any intercurrent disease. Treatment of uncomplicated cases of diarrhea depends on the estimation of dehydration, severity of acidosis, likelihood of intercurrent infection, presence or absence of hypothermia, and hypoglycemia. The severity of dehydration is gauged from the eyeball position and skin tent (Table 20-6). In acute diarrhea the degree of enophthalmus is the most reliable indicator of dehydration, but because the position of the eye within the orbit is also dependent on body fat stores, the skin tent in the cervical region may be the most reliable in calves with chronic diarrhea or cachexia.[453] Skin tent can be measured over the eyelids and neck. Best results are obtained when the neck is held straight and the skin of the midneck is tented in the direction of the long axis of the neck to avoid the natural skinfolds that run across the neck. Some have claimed a relationship exists between severity of dehydration and acidosis. However, this has not been borne out in studies of diarrheic calves.[454] Instead, acidosis can be gauged from the calf's sucking or drinking drive, the degree of weakness, and the age of the calf (Fig. 20-4).[454,455] Estimation of severity of acidosis either from laboratory or physical findings is very important to the successful therapy of severely depressed calves. Rectal temperature measurement will determine whether or not the calf is hypothermic.

354
355

Heart rate is variable in diarrheic calves. Bradycardia (<90 beats/min) is clinically important and may indicate the presence of hypothermia, hypoglycemia, or hyperkalemia. Cardiac arrhythmias occur[455] and are usually a result of severe hyperkalemia (K^+ above 8 mEq/L) (Fig. 20-5). Hyperkalemic arrhythmia can usually be differentiated from arrhythmia resulting from cardiomyopathy (selenium deficiency) because the heart rate is not elevated. The presence of bradycardia or arrhythmia indicates the need for immediate fluid therapy with bicarbonate-containing solutions to prevent death.

Body condition is usually good at the start of an attack of diarrhea. Poor condition often indicates chronic infection, mismothering, or poor feeding programs, which may be exacerbated by milk withdrawal for therapeutic purposes.

It is important to check for intercurrent infections, which are easily missed even with careful examination. The lungs should be examined for signs of pneumonia; the navel palpated for pain, swelling, and wetness; and the joints checked for signs of distention and lameness. The boundary between calves in which the primary insult is septicemia with a secondary diarrhea and those in which primary diarrhea is complicated by septicemia is blurred. Calves that are recumbent, under a week of age, have lost their suck reflex, or have evidence of intercurrent infection are more likely to be septicemic and require concurrent antibiotic therapy.[456] Calves in which septicemia has progressed to produce signs of meningitis (e.g., extended neck with reluctance to flex neck), joint involvement, or ophthalmic signs (congested scleral vessels withhypopyon or iridospasm) have a

poor to very poor prognosis. It is best to identify these cases before instituting therapy so that the owner can decide whether treatment is economically feasible.

Table 20-6 Guidelines for Assessing Dehydration in Neonatal Calves

% Dehydration	Eyeball Sunkenness	Neck Skin Tent (Seconds)	Mucous Membranes
0	None	<1	Moist
1–5	None to slight	1–4	Moist
6–8	Slight separation of eyeball and globe	5–10	Tacky
9–10	Gap, <0.5 cm, between eyeball and orbit	11–15	Tacky to dry
11–12	Gap, 0.5 to 1 cm, between eyeball and orbit	16–45	Dry

The laboratory is useful for quantifying metabolic disturbances in diarrheic calves. Blood gas analysis will accurately determine the degree of metabolic acidosis. This is not routinely available to most practitioners. However, it may be worthwhile to make special efforts to get measurements when setting up a fluid therapy protocol for your area or when dealing with cases that fail to respond to treatment. Blood can be collected into a heparinized syringe and the syringe capped, placed in a Styrofoam cup surrounded by ice, and transported 4 hours or more to a laboratory. Alternately, the practice laboratory may have a total CO_2 (Harleco) analyzer or access to serum bicarbonate estimation as part of the serum chemistry profile. Total CO_2 or bicarbonate is a useful index of the severity of metabolic acidosis. Blood glucose can be readily determined using a hand-held Glucometer.

20.16.5.2

Fluid Therapy

The most common causes of death in diarrheic calves are dehydration and acidosis.[457] The immediate objective in treating depressed diarrheic calves is to restore them to a normal systemic state. In some calves it may also be necessary to correct hypoglycemia or hypothermia, restrict milk intake, or give antibiotics.

The estimated severity of dehydration can be combined with estimates of losses through diarrhea and for the maintenance of essential functions to give the total daily fluid requirement (see Table 20-6). The hydration status of the calf can be estimated from the degree of enophthalmus, the degree of skin tent on the neck, and evaluation of the mucous membranes (see Table 20-6). The volume (L) required to replace the deficit is determined as follows:

$$\text{Volume}\,(\text{L}) = \%\ \text{Dehydration} \times \text{Calf body weight}\,(\text{kg})$$

The ongoing losses through diarrhea should be estimated from the nature and volume of the diarrhea. Fecal losses can range from 1 to 6 L in diarrheic calves.[458] Maintenance requirements have been estimated at 50 to 100 mL/kg/day.[6,458] The degree of hydration and the volume of feces passed should be reassessed daily, and the treatment adjusted accordingly. Only 60% to 80% of oral fluids are absorbed, and this needs to be accounted for in the calculation.[459]

Bicarbonate requirements can be calculated from base deficit values (based on blood gas measurements or estimated from physical findings) as follows:

$$\text{Bicarbonate}\,(\text{mmol}) = \text{Body weight}\,(\text{kg}) \times \text{Base deficit}\,(\text{mmol}/\text{L}) \times 0.5$$

A chart of bicarbonate requirements for various body weights and base deficit values is available (Table 20-7).

Measurements of serum total carbon dioxide content or bicarbonate are also reliable estimates of bicarbonate requirements.[460] Bicarbonate requirements are as follows:

$$\text{Bicarbonate}\,(\text{mmol}) = \text{Body weight}\,(\text{kg}) \times (30 - \text{TCO}_2) \times 0.6$$

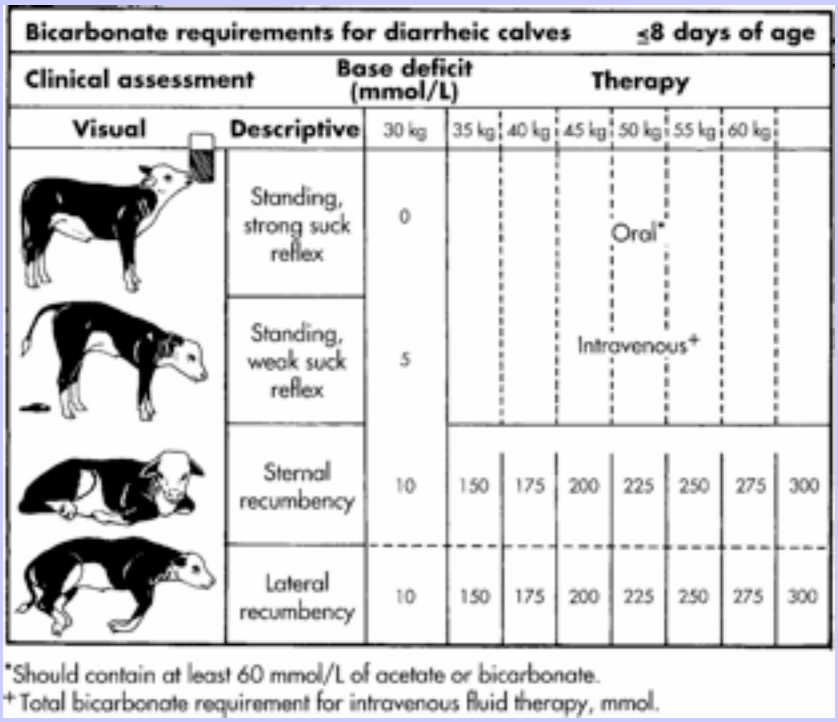
For example a 40-kg calf has a serum bicarbonate or TCO_2 of 10 mmol/L. The calf has a bicarbonate deficit of 30 mmol/L – 10 mmol/L = 20 mmol/L, so 40 kg × 20 mmol/L × 0.5 = 400 mmol bicarbonate required to replace existing deficits. Ongoing diarrhea may require additional bicarbonate.

Calves that are unwilling to suck and that are severely depressed are best treated with intravenous fluids. Calves that are only moderately depressed may also be treated with intravenous fluids if the condition is worsening rapidly. Catheterization is easier if a No. 15 scalpel blade is used to nick the skin. If it proves very difficult to catheterize the calf, it can be suspended upside down so that blood will pool and distend the jugular veins. The calf's neck should be clipped and prepared before inversion, and the calf laid flat as soon as the catheter is placed. It should be possible to place a catheter in less than a minute even in severely dehydrated calves using this technique. Once the catheter is placed, fluids can be administered. If the calf is hypothermic the fluids should be warmed before administration because cold fluids can decrease cardiac output and may kill a critically ill calf. Fluids can be warmed by a number of methods; one convenient technique is to run the fluids through a coil of tubing immersed in a bucket of hot water (check the temperature regularly) on the way to the calf.

355

356

Fig. 20-4 Prediction of severity of metabolic acidosis from body position, strength of suck reflex, and age.



Bicarbonate requirements for diarrheic calves ≤8 days of age

Clinical assessment		Base deficit (mmol/L)	Therapy						
Visual	Descriptive	30 kg	35 kg	40 kg	45 kg	50 kg	55 kg	60 kg
	Standing, strong suck reflex	0	Oral*						
	Standing, weak suck reflex	5	Intravenous+

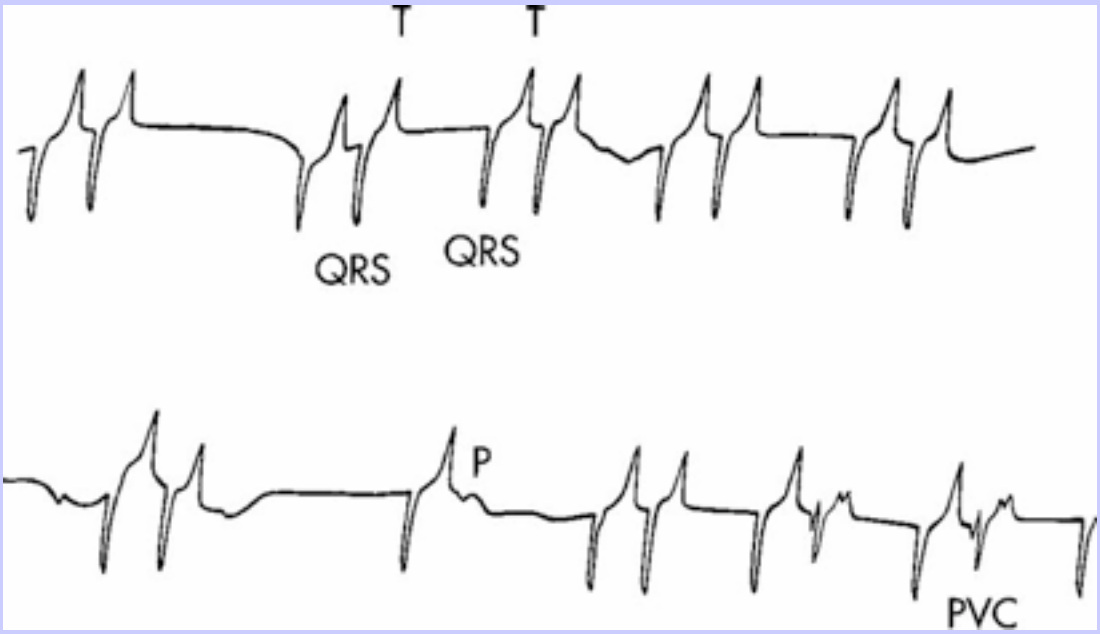
	Lateral recumbency	20	300	350	400	450	500	550	600

*Should contain at least 60 mmol/L of acetate or bicarbonate.
+Total bicarbonate requirement for intravenous fluid therapy, mmol.

Fig. 20-5 Bradycardia and atrial standstill in a severely hyperkalemic diarrheic calf. Heart rate is 84 beats/min. There is bigeminy, and the T waves are abnormally large. There is only one P wave, and it is not conducted. Serum potassium was 8.9 mmol/L, and sodium 116 mmol/L.



Although saline-based fluids are suitable for rehydration (Table 20-8), most severely depressed calves are acidotic, and more consistent recovery is obtained if an alkalizing agent is also used. A wide variety of alkalizing agents is available (lactate, acetate, gluconate), but clinical trials show that only bicarbonate is consistently effective in severely acidotic calves (Fig. 20-6).[93,461] Many diarrheic calves require large amounts of bicarbonate to correct their acidosis.[91] An isotonic solution (156 mmol/L) of bicarbonate can be readily made by dissolving 13 g of sodium bicarbonate (baking soda) in 1 L of water.[462] Sodium bicarbonate solutions can be mixed with saline; there is a possibility that precipitates may form if bicarbonate is mixed with calcium-containing solutions such as Ringer's.

Some clinicians may prefer to rehydrate the neonate first and then reconsider the need for bicarbonate if it is not up and sucking within 12 hours of therapy. However, this is time-consuming. It is not always necessary to completely correct acidosis; blood pH from 7.25 to 7.45 has little adverse affect (normal calves have a venous blood pH of 7.34, bicarbonate of 30 mmol/L, and a base excess of 5 mmol/L).

Ideally, dehydration and acidosis should be corrected over a 24-hour period. However, it is unusual to see problems when the fluid and acid-base deficits are corrected over 4 hours, although the calf may continue to improve after this period. Rapid resuscitation techniques include the administration of either hypertonic saline dextran or hypertonic sodium bicarbonate. Hypertonic saline dextran (7.2% saline containing 6% dextran 70) administered at 4 mL/kg of body weight during a 4-minute period concurrently with an isotonic alkalizing oral

electrolyte solution is effective in resuscitating dehydrated calves with diarrhea.[463,464] Hyperosmotic sodium bicarbonate solutions may also be used to rapidly resuscitate acidotic dehydrated calves.[465] The base deficit can be corrected by administering 8.4% sodium bicarbonate IV at a rate of 1 mL/min/kg over 15 minutes.[466,467] Hypertonic fluids should always be given concurrently with an isotonic oral electrolyte solution. After 24 hours of appropriate therapy, one would expect the calf to be standing and show a good suck reflex. Persistent depression is usually a sign of uncorrected acidosis or toxemia.

Table 20-7 Calculation of Bicarbonate Requirement from Calf Body Weight and Severity of Acidosis

Calf Weight (kg [lb])	Base Deficit (mmol/L)	Bicarbonate Requirements (mmol)	Volume in Liters 1.3% $NaHCO^{-}_{3}$ (L)*

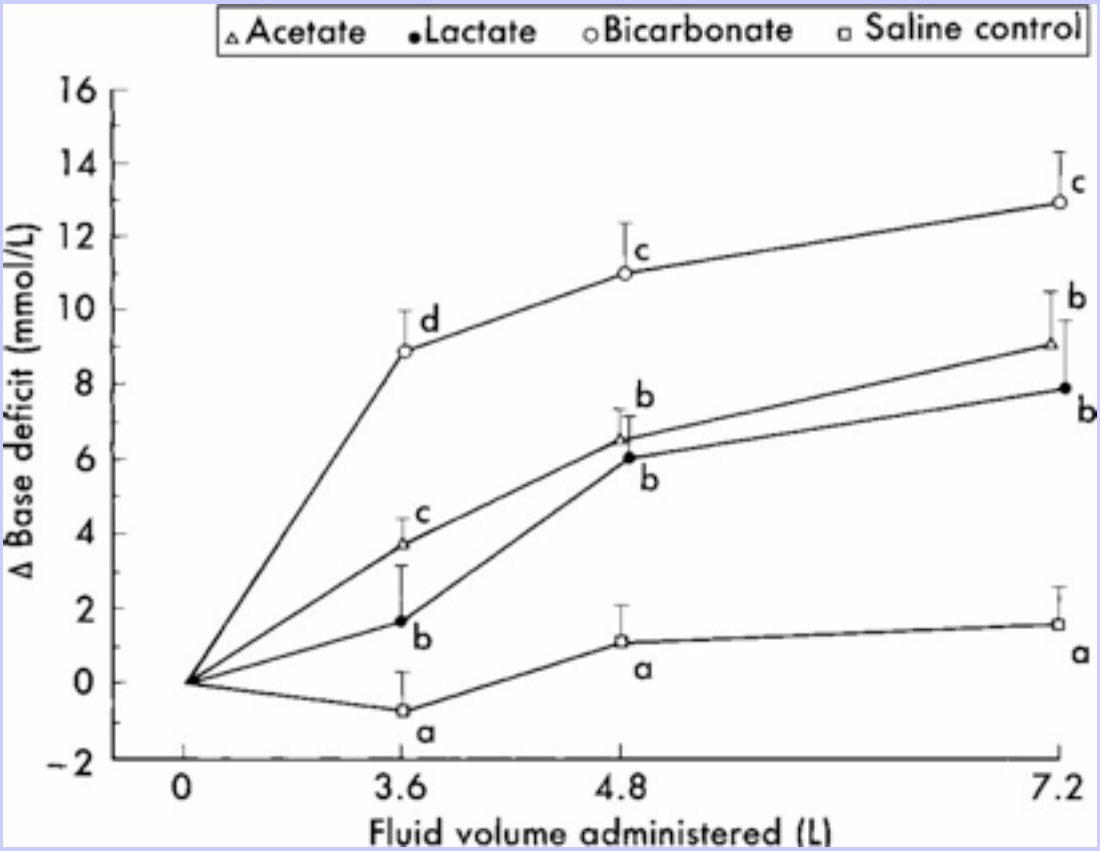
5% dextrose (D_5W)‡										278

* Do not mix sodium bicarbonate with calcium-containing solutions; precipitates may form. Mixtures of 1.3% sodium bicarbonate and saline are usually used for treating recumbent diarrheic calves.

† Multiple electrolyte solutions are equivalent, with the exception that one should be careful of using Ionalyte in severely hyperkalemic neonates. All are suitable for rehydrating neonates that can stand.

‡ Intravenous fluids are often spiked with 50% dextrose to give a final concentration of 5% dextrose in the drip when hypoglycemia is suspected.

Fig. 20-6 Comparison of the alkalizing effect of various bases in diarrheic calves with severe dehydration and acidosis. At the start of the trial, all calves were at least 8% dehydrated and had a mean blood pH of 7.032 and a base deficit of 18 mmol/L. All calves received a total of 7.2 L of fluid containing 102 mmol/L of saline plus 50 mmol/L of the sodium salt of the respective alkalizing agent. Letters (a, b, c, d) are statistically different ($p < .5$) from one another at that point. From Kasari TR, Naylor JM: Clinical evaluation of sodium bicarbonate, sodium L-lactate, and sodium acetate for the treatment of acidosis in diarrheic calves, *J Am Vet Med Assoc* 187:392, 1985.



Most diarrheic calves are not markedly hypoglycemic, but glucose supplementation is needed to treat severe hypoglycemia (glucose concentrations <2 mmol/L or <36 mg/dL). Severe hypoglycemia is treated by adding glucose to the intravenous fluids to a final concentration of 2.5% to 5%. Severe hyperkalemia is seen in some dehydrated diarrheic calves, but this responds to rehydration (restores renal perfusion and dilutes out potassium) and correction of acidosis (redistributes potassium into the cells). Nutritional support is not needed

if the calf is in good body condition but should be given if the calf is emaciated or if the calf has been deprived of milk for more than 3 days.

There are increased losses of potassium in diarrhea; the significance of this is uncertain, although potassium depletion can result in weakness. Usually there is no need to add potassium to intravenous fluids; the majority of calves respond to infusion of saline and 1.3% sodium bicarbonate. After 12 to 24 hours of intravenous fluid therapy most calves start on oral electrolyte solutions. These usually contain 10 to 30 mmol of potassium per liter. Clinical trials comparing the efficacy of low and high potassium solutions have not been reported.

Once the calf is able to nurse or drink, therapy is usually switched to oral electrolytes. This is also the route of choice for treatment of mildly affected calves on the farm. Calves with weak suck reflexes and calves that are unused to hand-feeding can be administered electrolytes using an esophageal feeder. Oral electrolyte solutions need to supply sufficient sodium to facilitate normalization of extracellular fluid deficits, nutrients to facilitate absorption of sodium from the intestine, alkalizing agents to treat metabolic acidosis, and supplemental energy.[468] The first two requirements depend on the coupled active transport of glucose and sodium ions across the brush border membranes of enterocytes, which results in passive absorption of water and other electrolytes.[469] This function remains largely intact in calves with ETEC diarrhea, but when there is endothelial damage it may be impaired. Certain amino acids (glycine, L-alanine, L-glutamine) enhance the absorption of sodium and water,[469] as do acetate and propionate.[470] In order to effectively combat acidosis, oral electrolyte solutions need to contain 50 to 80 mmol of alkalizing agent per liter. Acetate, lactate, citrate, gluconate, and bicarbonate are all used as alkalizing agents. Bicarbonate combines with hydrogen ions directly, whereas the other agents remove hydrogen ions during their metabolism within cells.[458] Electrolyte solutions that contain >40 mmol of bicarbonate or citrate per liter have marked adverse effects on milk clotting.[471] Bicarbonate raises abomasal pH, whereas citrate binds calcium, and so the presence of either interferes with the normal clotting of milk in the abomasum. Breakdown of abomasal milk clots results in the gradual release of some nutrients into the small intestine. Bicarbonate also reduces milk digestibility. A reduced growth rate was recorded when electrolyte solutions with bicarbonate were fed to milk-fed calves.[472] Solutions containing bicarbonate may also alkalize the gastrointestinal tract of milk-fed calves and promote bacterial overgrowth in the small intestine as well as ETEC attachment and toxin production.[473] Acetate is the best alkalizing agent to include in electrolytes that are to be fed to calves that are still receiving milk; it has excellent alkalizing ability and does not interfere with milk clotting in the abomasum. Any of the commonly used alkalizing agents are likely acceptable for calves held off milk.[471]

A wide variety of oral electrolyte preparations are on the market, and different products are suited to different situations. Almost all the products contain water and electrolytes and are suitable to use for rehydration (Table 20-9). Beware of products that are designed for medicating hundreds of liters of water; the final solution is often very dilute (<10 g of electrolytes per liter) and will not rehydrate sick calves. These products are often marketed as “boosters” and “stress relievers.” Glucose and glycine are usually added to oral electrolyte solutions to facilitate sodium absorption. Research in people has shown that adding glycine to solutions containing 110 mmol/L of glucose aids rehydration. It is probable, however, that there is little additional benefit to supplementing solutions that contain more than 200 mmol/L of glucose with glycine. Solutions that contain large amounts of glucose are hyperosmolar and are absorbed more slowly than isotonic solutions, but the differences are too small to be clinically important.[474] The ionic composition also affects absorption; mixtures containing sodium chloride and citrate, bicarbonate, or acetate have improved absorption over chloride salts alone. Oral electrolyte solutions are almost completely absorbed in healthy calves, but absorption can be as low as 60% in severe *E. coli* diarrhea.[475]

The ability to counteract acidosis varies greatly among oral electrolytes. Some have a net acidifying effect, whereas others alkalize blood (Fig. 20-7). These differences are therapeutically important and are responsible for differences in survival rates among products. Highly alkalizing solutions give the best results. One study showed that it was more important that an electrolyte solution contain bicarbonate than chloride.[476] This is particularly important in older calves. Recently there has been interest in adding glutamine to oral electrolyte solutions because it is an important fuel for the gastrointestinal tract and can promote mucosal repair.[477–479] However, studies show that oral electrolytes containing glutamine as the sole amino acid are no more effective in diarrheic calves than other well-designed solutions that use glycine as the amino acid.[480] Psyllium has been added to some oral electrolyte solutions for a number of perceived benefits, but controlled studies show no clinical advantages, although there may be some moderation of bacterial fermentation within the gastrointestinal tract.[481,482]

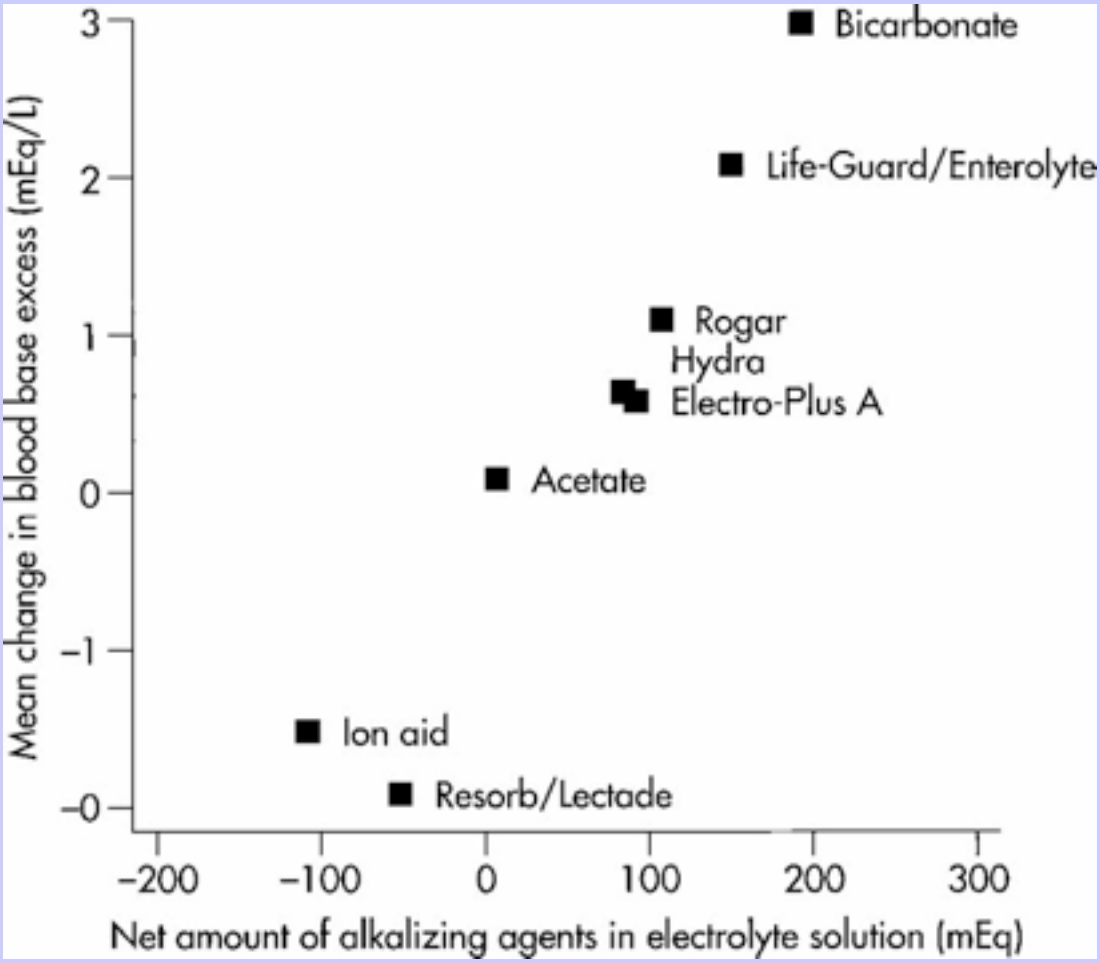
Updated table based on Naylor JM: Oral electrolyte therapy, *Vet Clin North Am Food Anim Pract* 15:487, 1999. Calculated from information listed in the Compendium of Veterinary Products, 2007 and product labels. Additional information obtained from Jones C, Kehoe S and Heinrichs J: Comparison of some available oral rehydration products. Pennsylvania State University, 2006, Department of Dairy and Animal Science, http://www.das.psu.edu/pdf/electrolytetable.pdf.

Note: Concentrations of calcium, magnesium, phosphate, and sulfate not included. Molarities assume that all compounds dissociate completely in solution. Where a maximum and minimum value for a compound was provided the mean value has been used.

?, Published information insufficient to provide reasonable estimate.

* Contain maltodextrins (glucose polymers). It has been assumed that these will be completely digested to provide glucose.

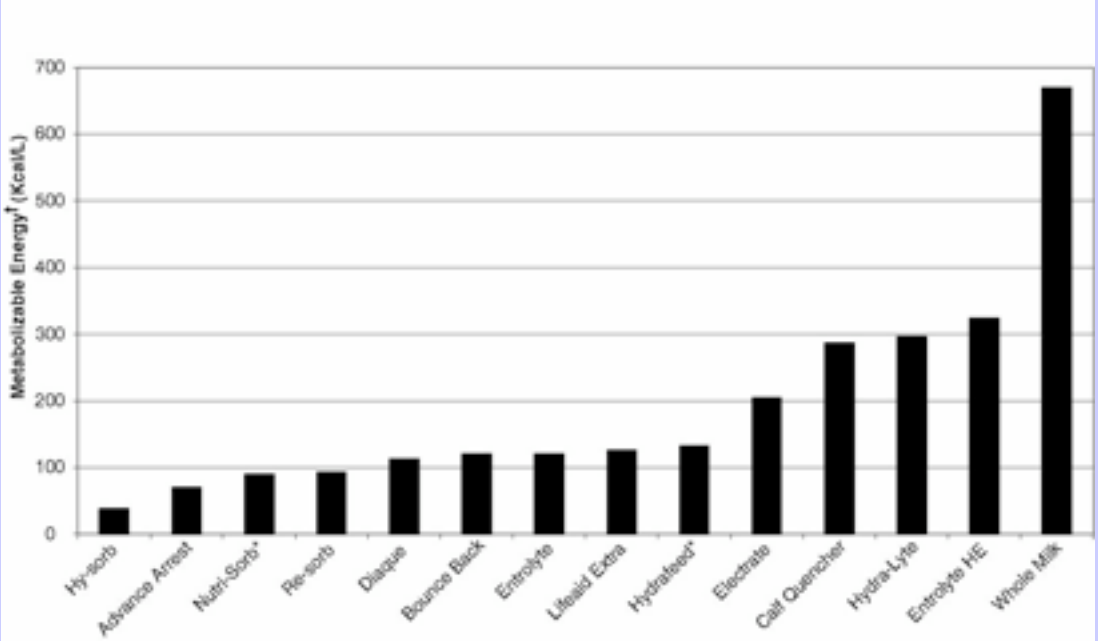
Fig. 20-7 Comparison of the alkalizing abilities of various oral electrolyte solutions. The Y axis shows the mean alkalizing effect after administration of one treatment (1.9 to 2.25 L) of the fluid to healthy calves, and the X axis shows the net amount of alkalizing agents in the solution. Bicarbonate and acetate are experimental solutions. (Life-Guard/Enterolyte is manufactured by SmithKline Beecham Labs, Rogar is Rogar STB's electrolyte powder, Hydra is manufactured by Vetrepharm, Electro-Plus A by Pitman-Moore, Ion Aid by Syntex, and Re-Sorb by Beecham.) *Modified from*Proc 14th World Congr Dis Cattle *1:362, 1986.*



The other problem to be considered in the chronically scouring calf is the need for nutritional support. Maintenance metabolizable energy requirements for a 50-kg calf are about 2000 kcal, and 3500 kcal are required to support a weight gain of 0.5 kg/day. These requirements can be met by 3.3 and 5.7 L of whole

cow's milk, respectively. Comparative studies indicate that weight loss in calves fed oral electrolytes are inversely proportional to the energy content of the solutions.[483] Assuming a 4-L daily intake and 100% digestibility of oral electrolyte nutrients, regular electrolyte solutions supply between approximately 15% and 25% of energy needs. As a result, diarrheic calves that are held off milk for prolonged periods lose weight[484] and can become emaciated. When maintaining body condition is a concern and little milk or solid food is being ingested, then a high-energy oral electrolyte should be fed. Products such as Enterolyte HE provide about 50% of energy requirements if fed twice a day (total intake 4 L) and about 75% if fed three times a day (total intake approximately 6 L). The energy content of various oral electrolyte solutions is presented in Figure 20-8.

Fig. 20-8 Comparison of the energy contents of various oral electrolyte solutions. Milk is also shown for comparative purposes. *ME estimated from water-soluble carbohydrate composition. †ME estimated from glucose and other water soluble carbohydrate composition of as-fed electrolyte solution assuming 1g (cry matter) of carbohydrate = 4kcal. This figure assumes electrolyte solutions are fed to neonatal calves prior to rumen development. (See text for manufacturers.)



20.16.5.2.1

MILK WITHDRAWAL

Milk withdrawal can reduce the severity of diarrhea and depression in severe scours. This is because malabsorption exacerbates diarrhea through the osmotic effect of unabsorbed milk nutrients and also promotes bacterial overgrowth and possibly malfermentation with production of organic acids. Milk also

has a trophic effect on epithelial cells and maintains higher gastrointestinal tract enzyme activities as well as providing protein for repair of damaged intestinal epithelium.[470] In experimental trials, continued feeding of milk maintained weight gain; however, when calves were fed enough milk to fully meet their requirements and the undrunk milk was tube-fed, calves initially had greater inappetence.[472,485] Withdrawal of milk without a high-energy alternative can rapidly result in cachexia and malnourishment.[472] In many calves, particularly the less severely affected, there is often a considerable degree of residual absorptive capacity; enough to support body weight gain if limited amounts of milk are fed. Milk withdrawal is recommended if the calf is depressed and not interested in sucking. In most cases electrolyte therapy will restore a calf's vigor and sucking drive within 1 to 2 days. Milk can then be reintroduced in small amounts (e.g., 1 L given two to four times daily). However, forced feeding (by tubing or drenching), dysfunction of the reticular groove reflex, or reflux of abomasal contents may result in ongoing acidosis because of production of D-lactate from fermentation of carbohydrates entering the reticulorumen.[98] If the calf is not interested in drinking or gets depressed when reintroduced to milk, a high-energy oral electrolyte preparation can be tried instead. Studies indicate that diarrheic calves have a generalized malabsorption rather than specific lactose intolerance.[88] Thus it may be more important to manage calves with milk intolerance by giving smaller amounts of milk in each feed instead of changing carbohydrate source. There is little point in withdrawing milk from calves that remain alert and interested in nursing; it is unlikely to result in clinical improvement. This is particularly likely to be the case when the calf receives whole cow's milk in frequent small quantities, that is, by natural sucking of the dam.

360

361

20.16.5.3 Role of Antimicrobials

There is some controversy regarding the use of antimicrobials for the treatment of calf scours. Reports questioning the use of antimicrobial therapy cite lack of efficacy, potential for adverse effects, potential for violative residues, and selection for antimicrobial resistance. Conversely, there are reports describing attenuation of clinical disease, reduced pathogen shedding, and lower mortality after the use of antimicrobials to treat scouring calves.

20.16.5.3.1 THERAPEUTIC TARGETING

Bacterial pathogens associated with neonatal calf diarrhea include *Salmonella* and *E. coli*. During disease outbreaks caused by these pathogens antimicrobial use may be targeted at the specific pathogen. Beneficial responses to antimicrobial therapy have also been reported in field trials involving undifferentiated pathogens.[486,487] Calves with diarrhea often have increased coliform bacterial numbers in the small intestine, regardless of cause,[488–490] and this colonization is associated with altered small intestinal function, morphologic damage, and increased susceptibility to bacteremia.[490] Calves with diarrhea are more likely to have FPT or partial FPT, and this group of calves, in turn, is more likely to be bacteremic.[491,492] Blood cultures indicate that gram-negative bacteria account for approximately 80% of bacterial isolates. *E. coli* is the species most commonly isolated.[491,493,494] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to be bacteremic; *E. coli* accounted for 51% of the isolates; other gram-negatives, 25%; gram-negative anaerobes, 5.9%; gram-positive cocci, 11.8%; and gram-positive rods, 5.9%.[491]

Antimicrobial therapy may therefore be targeted at a specific bacterial enteric pathogen isolated from sick calves or in severely ill calves (as manifested by reduced suckle reflex, >6% dehydration, weakness,

inability to stand, or clinical depression) may be used prophylactically to manage the risk of bacteremia. For this application, emphasis should be directed toward gram-negative organisms, particularly *E. coli*.

20.16.5.3.2

ANTIMICROBIAL SUSCEPTIBILITY

Antimicrobial susceptibility testing of fecal isolates is not a good predictor of clinical outcome. Three studies have reported no correlation between in vitro antimicrobial susceptibility of fecal *E. coli* and *Salmonella* species isolates and clinical response to antimicrobial treatment.[495–497] Antimicrobial efficacy is best evaluated by the clinical response of a number of calves to treatment, with calves randomly assigned to treatment groups, rather than by the results of in vitro antimicrobial susceptibility testing performed on fecal *E. coli* isolates.[498]

Antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to bacteria isolated from blood or tissues of bacteremic calves because the MIC break points are based on achievable antimicrobial concentrations in human plasma and MIC_{90} values for human *E. coli* isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC_{90} values for bovine *E. coli* isolates.[498] Even within a given herd there will be a diversity of bacteria isolated from bacteremic calves, so the collection of blood cultures and assessment of antimicrobial susceptibility does not necessarily provide information applicable to the next case.

20.16.5.3.3

ANTIMICROBIAL SAFETY

A number of antimicrobials have been demonstrated to produce deleterious effects when administered orally to healthy milk-fed dairy calves. The addition to milk replacer powder of procaine penicillin (2 to 60 mg/kg of milk replacer) increased the incidence and duration of diarrhea and decreased growth rate compared with untreated controls in a total of 36 milk-fed calves.[499] Penicillin is not labeled for treatment of calf scours and has an inappropriate antimicrobial spectrum to prevent or treat calf scours. Administration of neomycin sulfate (300 mg PO q24h for the first 4 days of life) tended ($p = .060$) to increase the proportion of calves developing diarrhea (99/233 = 43%) compared with the proportion in an untreated control group (58/174 = 33%).[500] Administration of neomycin sulfate (25 mg/kg PO q6h, n = 10), ampicillin trihydrate (12 mg/kg PO q8h, n = 6), or tetracycline hydrochloride (11 mg/kg PO q12h, n = 6) for 5 days increased the occurrence of diarrhea and decreased glucose absorption through unknown mechanisms compared with untreated controls (n = 6).[501] Two other studies did not observe adverse side effects in calves administered tetracycline hydrochloride (40 mg PO q12h; 11 mg/kg PO q12h).[502,503]

20.16.5.3.4

EFFICACY OF ORAL ANTIMICROBIAL THERAPY

The response to oral antimicrobial therapy is variable, with many formulations failing to demonstrate a beneficial effect.[498] Apramycin administered PO at either 20 or 40 mg/kg significantly decreased mortality.[487] Trials with orally administered neomycin reduced the duration of diarrhea but did not reduce mortality.[504,505] Similarly, trials with orally administered ampicillin failed to demonstrate a significant reducccction in mortality.[506] The results of trials with orally administered trimethoprim have been variable, with no significant improvement in outcome observed in a large field trial[507] and a significant reduction in mortality observed in an experimental *Salmonella* challenge study in which calves were administered 5 mg or

trimethoprim per kilogram and 25 mg of sulfadiazine per kilogram PO daily for 5 days.[508] Orally administered amoxicillin trihydrate has been demonstrated to reduce mortality and the duration of diarrhea when administered at a dose of 10 mg/kg PO q12h.[77,509]

In an epidemiologic study of *Salmonella* in dairy calves conducted in the United States, feeding medicated milk replacer and hay to calves from 24 hours of age to weaning was associated with a reduced risk of *Salmonella* shedding.[510] This observation contradicts an experimental study in which feeding chlortetracycline in milk replacer increased the severity of disease and the rate and duration of *Salmonella* shedding.[511] Similarly in another experimental trial, daily drenching of calves with 50 mg or 100 mg of chlortetracycline failed to alter the excretion pattern or the number of organisms excreted by calves infected orally with 10^6 *S. typhimurium*.[512]

20.16.5.3.5

EFFICACY OF PARENTERAL ANTIMICROBIAL THERAPY

Antimicrobial drugs with an appropriate gram-negative spectrum of activity include third-generation cephalosporins (ceftiofur), potentiated penicillins (amoxicillin), trimethoprim-sulfonamide (TMS) combinations, aminoglycosides, sulfonamides, florphenicol, and tetracyclines. There is a paucity of efficacy data to support the use of aminoglycosides, tetracycline, nonpotentiated sulfonamides, and florphenicol.

Ceftiofur has an appropriate antimicrobial spectrum, and therapeutic drug concentrations can be maintained with once-daily dosing. In an *S. typhimurium* challenge experiment, intramuscular administration of ceftiofur hydrochloride (5 mg/kg q24h for 5 days) reduced the severity of clinical signs and reduced fecal shedding of *Salmonella*. The MIC of the challenge strain in this experiment was 1 μg/mL, and the therapeutic protocol maintained plasma concentrations above this concentration for the duration of therapy.[264]

361

362

Potentiated sulfonamides have been evaluated in ETEC and *Salmonella* challenge experiments. Mortality in 2- to 3-week-old calves medicated with trimethoprim-sulfadiazine (in a 1:5 ratio) for 5 days 24 hours after *Salmonella* Dublin oral challenge was reduced.[508] Administration of either sulfadiazine or trimethoprim alone did not reduce mortality.[508] Trimethoprim may be used to treat sepsis in neonatal calves, but its half-life rapidly declines as ruminal function develops. In ruminating (6- to 8-week-old) calves, subcutaneous or oral administration of trimethoprim-sulfadiazine leads to high serum levels of sulfadiazine but little or no serum trimethoprim.[513]

Intramuscular administration of amoxicillin reduced mortality in *Salmonella* Dublin—challenged calves.[514] In a comparative trial of amoxicillin and trimethoprim-sulfadiazine, both drugs were found to have equal efficacy in reducing adverse clinical signs of disease when dosage regimens were based on the MIC of the pathogen.[515]

The frequency of bacteremia is sufficiently high that treatment of calves with diarrhea that are severely ill (as manifested by reduced suckle reflex, >8% dehydration, weakness, inability to stand, or clinical depression) should include routine treatment against bacteremia, with emphasis on treating potential *E. coli* bacteremia.[498] Parenteral administration of a broad-spectrum β-lactam antimicrobial—ceftiofur (5 mg/kg intramuscularly [IM] q24h), amoxicillin (10 mg/kg IM q12h), or trimethoprim-sulfadiazine (20 mg of sulfadiazine per kilogram with 5 mg of trimethoprim per kilogram IV or IM, q24h for 5 days)—is recommended for treating calves with diarrhea and systemic illness. (Note that these are off-label doses and

require an extended meat withholding period.) Antimicrobial therapy is not recommended for calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever).[498]

20.16.5.4 Antiprotozoal Drugs

Drugs reported to have some efficacy against *Cryptosporidium* in calves include, halofuginone,[516–522] paromomycin,[523,524] decoquinate,[525,526] and β-cyclodextrin.[527] Halofuginone is licensed for treatment of calves in Europe and appears to be the most efficacious. The efficacy of decoquinate is questionable, with the only controlled clinical study failing to demonstrate a beneficial therapeutic effect with daily treatment at 2 mg/kg/day.[526] A trial of lasalocid for treatment of *Cryptosporidium* infection has been conducted. Using a toxic dose of 8 mg/kg was found to reduce the shedding of cryptosporidia; however, the calves suffered adverse side effects. At a dose of 0.8 mg/kg, lasalocid was not effective.[528] The registered dose for preventing coccidiosis in calves is 1 mg/kg per head per day.

Coccidiosis is uncommon in calves less than 6 weeks of age. In hand-reared calves coccidiostats (lasalocid, amprolium, or decoquinate) may be added to milk replacer. Prophylactic options for beef calves are restricted to coccidiostat medicated pellets (monensin, lasalocid, amprolium, or decoquinate) or water (amprolium or sulfonamides). Therapeutic options include amprolium or sulfonamides such as sulfadimidine.

Both fenbendazole (5 mg/kg PO once daily for 3 days) or albendazole (20 mg/kg PO once daily for 3 days) have been shown to be effective treatments for *Giardia*.[222,298,529] Because of the high level of subclinically affected animals, all cows and their dams need to be treated, and reinfection is likely to occur unless calves are removed from environmental sources of infection.

20.16.5.5 Antiinflammatory Drugs

A nonstatistical trend toward decreased morbidity has been reported in a study evaluating the benefits of a single or double injection of flunixin meglumine in scouring calves.[530]

20.16.5.6 Probiotics

Probiotics are foods or drugs containing live microbes that are expected to confer beneficial physiologic effects to the host animal through microbial actions. Bacterial and fungal species included in these products include *Enterococcus faecium*, *Lactobacillus acidophilus, Lactobacillus delbrueckii* subsp. *bulgaricus, Lactobacillus plantarum*, *Lactobacillus rhamnosus*, *Bifidobacterium bifidum*, *Streptococcus salivarius* subsp. *thermophilus, Aspergillus oryzae*, and *Candida pintolopesii*. General mechanisms of action that have been ascribed to probiotics include competition for receptor sites on the intestinal surface, immune system stimulation, excretion of antimicrobial substances, and competition with pathogens for intraluminal nutrients.[531]

The number of controlled clinical trials evaluating probiotic formulations in calves is limited. In one report, feeding antimicrobial resistant *Streptococcus faecalis* to calves reared on an antibiotic-containing diet reduced *Salmonella* intestinal colonization of calves.[532] An improvement in weight gain and a reduction in diarrhea have been reported when calves were fed either 3×10^9 *Bifidobacterium pseudolongum* or *L. acidophilus* daily

from 1 to 56 days of age or a cell mixture containing 10^{10} colony forming units (cfu) of *Bacillus thermophilum*, 10^{10} cfu of *Enterococcus faecium*, and 10^{9} cfu of *Lactobacillus acidophilus* for 28 days.[533]

20.16.5.7 Intestinal Protectants

Several products that include intestinal protectants are marketed for treatment of calves with scours. Intestinal protectants include bismuth subsalicylate, kaolin or pectin, and activated charcoal. There are no efficacy data available regarding the use of kaolin in scouring calves. Suggested advantages of bismuth subsalicylate are its neutralization of bacterial toxins and antisecretory effect through its local antiprostaglandin activity.[534,535]

20.16.5.8 Prognosis

The prognosis for recovery decreases with the severity of depression. Severe hypothermia and the presence of intercurrent disease are grounds for a guarded prognosis.[536–538] An initial examination should be performed. Calves with a primary problem of septicemia are not usually worth treating because of the poor prognosis. The severity of dehydration, hypothermia, and acidosis should be estimated. Recumbent calves are usually treated IV with a saline-based rehydrating fluid (0.9% saline, Ringer's, lactated Ringer's, and so on) and isotonic sodium bicarbonate (especially for older and comatose calves). Calves that can suck are treated with oral electrolytes that contain 50 to 80 mmol/L of alkalizing agent. Products that use mainly acetate as the alkalizing agent are best for calves that are still drinking cow's milk (small quantities, frequently). Any alkalizing agent is likely effective in calves held off milk.

20.16.6 SUMMARY

Calf scours is caused by a variety of infectious agents. At the present time, the need to make a definitive diagnosis of ETEC and *Salmonella* infections has been established; these diseases can be controlled with antibiotics and prevented by vaccination.[539] There are public health implications to the diagnosis of cryptosporidiosis and salmonellosis. New vaccines may help control rotavirus and coronavirus infections. Treatment of diarrhea in neonates is primarily based on correcting dehydration and acidosis through the use of oral and intravenous electrolytes. Only in the case of bacterial infections can direct action be taken against the invading organism, but antibiotics may still be useful in preventing secondary bacteremias. Colostrum feeding will help reduce diarrhea in the first days of life. Management is very important in the control of diarrhea, and because infectious agents are almost always present at some exposure level, the underlying theme is to minimize the level of pathogen exposure and stress on the calf. In approaching a problem of neonatal death losses, the areas to be examined should include calf immunoglobulin status, calf feeding, calf housing, cleanliness of environment, calving area, cow vaccinations, diagnosis of specific infectious agents, and treatment protocols.

20.17 LAMENESS AND RELUCTANCE TO WALK

John K. House

20.17.1 SEPTIC ARTHRITIS

Septic arthritis may result from direct trauma or contamination of the joint, extension from periarticular infection, or hematogenous spread from another site. Systemic sites of infection include enteritis, pneumonia,

and inflamed umbilical structures. FPT increases the risk of sepsis. Destruction of the epiphysis and extension of infection into the joint are common and may be primary in some cases, rather than resulting from a primary synovial membrane infection that spreads to the epiphysis or physis. The most common pathogens isolated from septic joints of neonatal calves are enteric organisms including *E. coli* and *Salmonella* species. *Streptococcus* species, *Staphylococcus* species, and *A. pyogenes* are less common isolates. *A. pyogenes* is the most frequently isolated organism from joints of older calves.[540–542]

Bacteria commonly isolated from septic joints in lambs include *Streptococcus* species, coliforms, *A. pyogenes, Erysipelothrix rhusiopathiae,* and *F. necrophorum*.[455] Predisposing factors include poor docking hygiene and contaminated sheep dip. Sporadic outbreaks of polyarthritis in lambs, kids,[30,543,544] and calves[545] are associated with *Chlamydia* and *Mycoplasma* species infections. Chlamydia infections may occur in utero or postnatally; *Mycoplasma* infections often result from ingestion of *Mycoplasma*-contaminated milk.

Diagnosis of septic arthritis is based on the combination of clinical signs, radiographic examination, bacterial culture, and cytologic analysis of synovial fluid. A bacterium is isolated in only 60% of cases of septic arthritis in bovine medicine.[546] Synovial fluid cytologic analysis is useful for the differentiation between infectious and noninfectious arthritis. Trauma is the chief differential diagnosis. Lambs and kids with septic arthritis often fail to nurse and may have significant weight loss. Typically, polyarthritis caused by *Mycoplasma* species and *Chlamydia* is associated with high fevers and respiratory and occasionally neurologic disease. High morbidity and mortality are common. Conjunctivitis is commonly observed with chlamydial infections.[543] Cytologic findings consistent with septic arthritis include a synovial fluid total protein concentration greater than 4.5 g/dL, a nucleated cell count greater than 25,000 cells/mL, a polymorphonuclear cell count greater than 20,000 cells/mL, and a percentage of polymorphonuclear cells of greater than 80%.[547] Chlamydial inclusions may be found in Giemsa-stained smears of synovial cells and the organism isolated from joint fluid or plasma in early cases.[543] Isolation of *Mycoplasma* species requires specific media (Hayflick's media) and microaerophilic conditions. Normal synovial fluid does not rule out septic physitis or osteomyelitis, because the infection may be in the physis or small tarsal bones.

Careful examination of high-quality radiographs is important for the detection of bone lysis indicating infection. Initial radiographs may be normal because the degree of damage is often not detectable for 10 to 14 days after initial infection occurs. Radiographic features of septic arthritis include soft-tissue swelling, widening or collapse of the joint space, osteoporosis, and osteosclerosis. Ultrasound may be used to confirm involvement of the joint and rule out periarticular or tenosynovial infection to avoid iatrogenic contamination of the joint during arthrocentesis. Joint distention and hyperechogenic fragments in the synovial fluid are suggestive of septic arthritis. Normal synovial fluid is anechoic.

Acute septic arthritis in neonatal ruminants may be treated effectively via joint lavage combined with systemic and local antimicrobial treatment. Typically, however, neonatal ruminants are presented with a chronic disease process. Treatment options include joint lavage or arthrotomy to remove destructive inflammatory products and long-term antimicrobial therapy. Joint lavage is rarely efficacious in the treatment of chronic septic arthritis in calves, as accumulation of fibrin and pocketing of purulent material often make adequate joint drainage impossible.[548] Joint lavage may be facilitated via use of a rigid arthroscope or, in the case of simple joints (elbow and stifle), arthrotomy.[549] Empirical antimicrobial therapy should include a gram-negative and gram-positive spectrum. Culture of synovial fluid facilitates antimicrobial selection.

Therapeutic synovial concentrations of penicillin, oxytetracycline, ampicillin, and cephapirin can be attained in inflamed and normal joints of calves after systemic administration.[550–553] The distribution of trimethoprim-

sulfadiazine, penicillin, oxytetracycline, and cephapirin in joints is not enhanced or reduced by inflammation.[550–552] Penicillin, trimethoprim, and sulfadiazine equilibrate in 0.5 to 1 hour, and oxytetracycline in 4.5 to 6 hours.[551] The subsequent decline in antibacterial drug concentration in synovial fluid parallels that in serum.[550] Synovial inflammation accelerates distribution of antimicrobial drugs into joints[551] but has little effect on the peak drug concentration achieved in synovial fluid.[550,551] The peak concentration of ampicillin in synovial fluid after a single intramuscular injection of ampicillin trihydrate at a dose of 10 mg/kg is higher in normal and inflamed synovial fluid than in sera.[553] There are few bovine-derived data regarding the distribution of the newer generation antimicrobials into synovial fluid after systemic administration. Studies in other species suggest that most classes of antibacterial drugs are capable of crossing the synovial membrane. Synovial tissue is very vascular and does not have a basement membrane. In humans, synovial fluid concentrations of most antibacterials generally average at least 60% to 70% of serum drug concentrations at the time of peak serum concentrations and frequently exceed those in serum immediately before the subsequent systemic dose in patients with septic arthritis.[554] Antimicrobial dosing is targeted to achieve a peak antibacterial concentration that exceeds the MIC of the infecting organism by fivefold to tenfold.[554] The duration of therapy is dependent on the antimicrobial sensitivity of the pathogen and the immune status of the patient; prolonged (4 to 8 weeks) antimicrobial therapy is commonly required.

363

364

In a review of 81 cases of septic arthritis in cattle, a 72% recovery was achieved with a combination of surgical treatment (opening of the joint capsule; debridement; and excision of the synovium, infected cartilage, and bone), joint immobilization, and systemic antibiotic therapy. Of cattle treated conservatively with systemic and intraarticular antimicrobials, 43% recovered.[555]

20.17.2 NONINFECTIOUS LAMENESS

Neonatal ruminants that have nutritional myodegeneration often have a stiff, stilted gait. Lambs and kids may have difficulty nursing if they are unable to lift the head and may cry with pain when assisted to stand (see Chapter 42). Contracture of joints or tendons of the limbs produces difficulty in movement and predisposes to FPT by impeding the ability to adequately nurse. Degree of contracture varies from mild to severe and may be associated with scoliosis and/or torticollis. Conservative therapy consisting of splinting the front limbs to induce tendon laxity may be helpful. Calves with severe digital flexor tendon contractures often require surgical resection of one or both digital flexor tendons, followed by bandaging or casting and stall rest for 3 to 4 weeks.

20.18 UMBILICAL ENLARGEMENT

The umbilicus consists of three types of structures and undergoes functional and anatomic changes at birth. Two umbilical arteries connect internal iliac arteries to the placenta. These later regress and become the round ligaments of the bladder. One umbilical vein connecting the placenta to the liver and porta cava regresses to become the round ligament of the liver within the falciform ligament. The urachus connects the fetal bladder to the allantoic cavity.

20.18.1 PATENT URACHUS

Patent urachus is a persistence after birth of the tubular connection between the bladder and umbilicus. The urachus drains the bladder into the allantoic sac during gestation. Urine flow should gradually change, with some urine entering the amniotic sac through the urethra in later gestation. At birth, with umbilical cord rupture the

urachus should be closed, and urine should be voided through the urethra. Neonates with a patent urachus may dribble urine from the urachus during or after urination or may simply have a constantly wet umbilical stump.

Differential diagnoses include concurrent infection of the navel (omphalophlebitis). Ultrasound may assist in making the diagnosis and determining the involvement of umbilical arteries or vein. Moist hairs around the umbilicus and the presence of fluid coming from the navel are diagnostic. A complete physical examination should be performed. If abnormalities are noted, serum IgG, complete blood count, and urinalysis are helpful for detecting susceptibility to infection and presence of systemic or urinary tract infection. Surgical resection of the urachus to the tip of the bladder is the treatment of choice. Associated arteries and veins should be ligated and removed if they are infected or necrotic. Merely ligating the exterior stump can trap organisms and cause infection.

20.18.2 OMPHALITIS

Omphalitis is inflammation of umbilical structures that may include the umbilical arteries (omphaloarteritis), umbilical vein (omphalophlebitis), urachus, or tissues immediately surrounding the umbilicus. Umbilical abscess or infection of any of the three components of the umbilicus may produce local infection or be a source of septicemia. The source of infection is most commonly the external environment, coupled with FPT. Bacteria isolated from calf umbilical cord remnant infection include *A. pyogenes, E. coli,* and *Proteus* and *Enterococcus* species. The urachus is the most commonly affected structure in calves, and the umbilical arteries the least.[556] Omphalophlebitis may extend the length of the umbilical vein into the liver and result in liver abscessation.

When the umbilicus is enlarged and draining purulent material, infection is easily noted. When the urachus is fixed to the abdominal wall, calves are prone to cystitis and may show signs of pollakiuria and dysuria. In other cases the umbilicus may be dry and larger in diameter than expected. Some neonates may have a completely normal-appearing, dry external navel and be severely ill from infection of the urachus, umbilical arteries, or vein. In a neonate with sepsis without external signs of infection, involvement of the umbilicus can be difficult to determine. Abdominal palpation of the umbilical vein and arteries is a useful, simple, and effective means of assessing their size and of detecting pain associated with these structures. Inflamed structures may be identified by standing behind the neonate and pressing the hands together above the umbilicus. Ultrasound is also a useful ancillary diagnostic aid.[557] Persistent dilation of the umbilical vein or arteries with a hypoechoic-to-echogenic fluid, intraluminal gas, and wall thickening are findings consistent with infection. In calves the urachus normally retracts up into the abdomen at birth, and ultrasonographic identification of a urachal remnant is abnormal.[558]

Overt signs of infection are heat, swelling, purulent discharge, and pain. Concurrent signs of systemic infection such as joint infection, pneumonia, diarrhea, meningitis, or uveitis may be noted. Calves with urachal abscesses may show signs of dysuria or pollakiuria.[559,560] Infection in more than one umbilical vessel is common in the neonate, and urachal involvement is frequent. Umbilical abscessation that is walled off and does not involve deeper structures is a less severe problem and may be treated with drainage without surgical removal of the entire umbilicus.

Early treatment with antibiotics and supportive care may allow resolution before development of abscessation and distention of the urachus or the umbilical arteries and vein. Established infection usually necessitates surgical removal of involved structures in addition to medical therapy.[556] When omphalophlebitis extends into the liver, the umbilical vein may be marsupialized to facilitate drainage and flushing.[561] Prognosis is improved when adequate passive transfer of colostral immunoglobulins has occurred and when joints or other structures

are not involved. Sequelae such as renal abscessation, joint or bone infection, peritonitis, and other complications described for septicemia may develop if therapy is started too late or is discontinued prematurely.

20.19 ANEMIA

Anemia in the neonate should be interpreted in the context of the realization that normal hematologic values of the neonate may vary from those of the adult. In calves the incidence of anemia (hemoglobin <10 g/dL) is quite high, ranging from 15% to 30% in many herds.[562,563] The characteristics of the anemia include normocytosis, normochromia, and poikilocytosis. Anemia is reported to be secondary to iron deficiency.[562,563] Potential causes are reduced amounts of iron in milk, poor placental transfer of iron, and decreased intestinal absorption. Anemic calves with poikilocytosis have similar levels of serum iron, total iron binding capacity, and marrow iron and plasma copper levels compared with normal calves.[564] Anemic calves do not appear to have an increased incidence of disease or decreased growth rates.[565] An overall higher plane of nutrition versus iron supplementation alone produces higher PCVs and hemoglobin levels.[564] Calves less than 6 weeks of age have three types of hemoglobin in various amounts (adult 28%, fetal 40%, and neonatal 25%). The poikilocytosis may be a function of erythrocyte membrane defects or maturation transitions.[564]

364
365

In addition to frank blood loss from an injury, diseases causing anemia in the neonate include blood loss caused by gastric ulcer, anemia secondary to bone marrow necrosis, and anemia of chronic disease associated with localized infections. Hemolytic anemia may be due to neonatal isoerythrolysis (NI) or non-NI immune-mediated hemolytic anemia.[566] NI is caused by ingestion of maternal colostrum containing antibodies to one of the neonate?s blood group antigens. The dam may produce these antibodies after exposure to specific foreign blood group antigens during previous pregnancies or unmatched transfusions. It is uncommon in calves but has occurred after vaccination of pregnant cows against anaplasmosis or babesiosis. The presence of red cell antigens in the vaccine causes the production of antierythrocyte antibody, primarily against the A and F systems.[567] Cows mated to bulls carrying these red cell antigens may have hemolytic disease develop in their A- and F-positive calves after ingestion of colostrum-containing alloantibodies.

Hemolytic disease processes produce signs of weakness, pale or jaundiced mucous membranes, fever, and depression. Blood loss produces weakness and pale mucous membranes. Intestinal parasitism does not normally lead to anemia during the neonatal period. Intravascular hemolysis may produce hemoglobinuria and hemoglobinemia. Icterus develops when the ability of the liver to conjugate bilirubin is exceeded. Mainly, indirect bilirubin is elevated. Anisocytosis is observed in responsive anemias. Nonspecific stimulation of bone marrow may produce a leukocytosis.

Anemia has also been reported in calves infected with BVD virus, secondary to bone marrow necrosis.[568]

Determination of the nature of the anemia may allow specific treatment. Blood transfusion may be indicated when anemia develops rapidly or PCV drops below 14%. Associated conditions such as metabolic acidosis and hypoglycemia should be corrected. Anemia of chronic disease requires correction of the primary disease condition.

20.20 FEVER

Differential diagnoses for fever in neonates include bacterial or viral infections, excitement, seizures with subsequent generation of heat by muscular overactivity, and environmentally induced hyperthermia. Fever is an unreliable indicator of sepsis in neonatal calves.[569] Neonates with sepsis often have a normal or subnormal

temperature. Older ruminants with localized infection such as in joints or bone are more likely to have fever. Fever may be beneficial. The need to administer antipyretics to the febrile neonate is controversial. Body temperatures lower than 40.8° C (105.4° F) are not considered detrimental unless they are associated with heat stroke or seizures, [570] in which case cooling and antipyretics are indicated. Because many antipyretics are antiprostaglandins that can cause deleterious gastrointestinal and renal effects, these agents should be used judiciously. Correction of the initiating cause and maintenance of fluid balance are also important.

20.21 CYANOSIS

Cyanosis is the purple-blue coloration observed on mucous membranes or skin caused by reduced or poorly oxygenated hemoglobin in blood.[571] Cyanosis may be caused by congenital heart disease, respiratory impairment, or any circulatory condition producing a right-to-left shunt (Box 20-4). The degree of cyanosis depends on the arterial oxygen saturation, hemoglobin concentration, pH, peripheral circulation, and temperature of the neonate.[571] Shock and hypothermia are important causes of peripheral cyanosis. The affinity of hemoglobin for oxygen is reflected in the standard oxyhemoglobin dissociation curve. This curve is similar for neonates but is affected by the amount of 2,3-diphosphoglycerate (DPG) in the erythrocyte. Calves' erythrocytes have higher levels of 2,3-DPG, but the higher levels do not affect the affinity of hemoglobin for oxygen. A separate fetal hemoglobin exists in calves to increase affinity for oxygen.[572] Severe hypothermia and acidosis cause the oxygen dissociation curve to shift to the right and therefore contribute to tissue hypoxia. Cyanosis can be either central or peripheral.[571] Peripheral cyanosis results from increased peripheral extraction of oxygen from normally saturated blood or a significant decrease in the perfusion to an extremity.[571] In the neonate, causes include septic shock and severe hypothermia. Central cyanosis is more common in neonates and is related to congenital heart disease that causes right-to-left shunting or severe respiratory conditions that result in hypoxia. Examination and clinical pathologic evaluation for metabolic causes of cyanosis, hypothermia, and cardiac abnormalities should be conducted. History, medication use, auscultation, thoracic radiographs, and arterial blood gases are useful in determining the degree of respiratory component to cyanosis. Echocardiography may be required for identification of cardiac anomalies.

20.21.1 Box 20-4 Causes of Cyanosis

20.21.1.1 Cardiovascular Origin

Tetralogy of Fallot

Tricuspid atresia

Truncus arteriosus

Pentalogy of Fallot

Double outlet right ventricle

Single ventricle

Eisenmenger complex

Ventricular septal defect

Patent ductus arteriosus

20.21.1.2 Respiratory Causes

Alveolar hypoventilation

Drug-induced central nervous system (CNS) depression

CNS trauma or hemorrhage

Hypoglycemia or hypocalcemia

Altered neurologic function of spinal nerves (of respiratory muscles)

Thoracic cage abnormalities: pneumothorax, fractured ribs

Diaphragmatic hernia

Upper airway obstruction

Restrictive pleural space disorders: hemothorax, pleuritis

Hypoplastic lung

20.21.1.3 Impaired Diffusion

Pulmonary: pneumonia, edema, atelectasis

Shunting

Anatomic (congenital heart defects)

Pathologic: pulmonary hypertension

Ventilation-perfusion mismatch

365

366

20.22 HEART MURMUR

Heart murmurs in the neonate may be heard normally before physiologic closing of the ductus arteriosus during the first 1 to 5 days of life. Other causes of murmurs include congenital anomalies, severe anemia, and infectious valvular disease. Physical examination for other signs of heart disease helps determine the severity of the murmur. Jugular pulse, weak or irregular arterial pulse, and palpable thrill indicate a serious condition. Dyspnea, cyanosis, tachypnea, and failure to gain weight are common signs of congenital heart disease in calves. Timing and location of the heart murmur should be determined. Thoracic radiography may aid in determining heart size and in detecting pulmonary edema or distended pulmonary vessels. Echocardiography may reveal atrial or ventricular enlargement, thickened ventricular walls, anomalous orientations of outflow tracts, or ventricular septal defects (VSDs).

Patent ductus arteriosus (PDA) produces a continuous murmur localized over the left heart base. The diastolic component may not be heard with auscultation over other parts of the heart. As pulmonary hypertension develops, the murmur is shortened to a holosystolic type with normal arterial pulse. Large shunting of blood produces a bounding arterial pulse caused by wide fluctuations of systolic and diastolic pressures. Radiographs may reveal an enlarged heart with increased vascularity as a result of left-to-right shunting of blood. Echocardiography may reveal increased left atrial and left ventricular diastolic dimension/volume and hyperdynamic septal and left ventricular wall systolic motion (depending on the degree of right-to-left shunt).

VSD produces a large, harsh, holosystolic murmur that is loudest on the right cranial region of the thorax and is softer over the left heart base. Radiography may reveal heart size increase, left atrial enlargement, and dilated pulmonary vasculature. Two-dimensional echocardiography may show aortic and septal discontinuity. Injection of saline bubbles into the left ventricle and observation of bubbles in the right atrium or ventricle document a left-to-right shunting of blood. Tetralogy of Fallot or other types of complex malformations often produce loud murmurs and are associated with cyanosis, weakness, fatigue, and stunted growth. Tetralogy of Fallot produces a systolic ejection murmur heard at the left heart base. Echocardiography may reveal a thickened right ventricular wall, septal echo dropout in the area of the VSD, rightward displacement of the aortic root, and an abnormal pulmonary outflow region. Saline injection into the jugular vein demonstrates right-to-left flow from the right ventricle to the left ventricle or the aorta.

20.23 ICTERUS

Icterus is a relatively uncommon finding in neonates that may be observed with sepsis, anorexia, liver disease, and hemolytic anemia. Liver disease in the neonate may be caused by exposure to hepatotoxins or sepsis-producing bacterial hepatitis, or it may be secondary to hypoxia. *C. perfringens* type A has been implicated in an enterotoxemic condition in nursing lambs, kids, and calves that is characterized by icterus, hemoglobinuria, anemia, and intravascular hemolysis.[45]

20.24 FAILURE TO THRIVE: CACHEXIA AND WEAK CALF SYNDROME

John Maas

Neonates that are born weak or fail to grow as anticipated pose important problems. In the foal, twins, prematurity, hypothyroidism, and congenital heart or other organ defects may produce failure to thrive. Infections acquired

shortly after birth that produce chronic pneumonia, nephritis, endocarditis, arthritis, or gastric ulcers are a cause of morbidity in the neonatal period.

In calves the weak calf syndrome has been reproduced by feeding low-protein diets to prepartum cows that subsequently calved in environments in which the temperature was well below the thermoneutral zone for calves.[573] The dietary recommendation for crude protein intake for third-trimester pregnant cows and heifers is 0.9 kg (2 lb) of total crude protein per day. This is particularly important for heifers and cows calving early in the spring calving season, when temperatures well below freezing can occur. Cold rains also can produce the hypothermic conditions that aid in precipitating this syndrome.

Cows weighing 450 kg (1000 lb) therefore need to consume 9.9 kg (20 lb) dry matter of good- to excellent-quality hay that is 10% crude protein or more. A quadratic equation has been developed to predict crude protein (CP) intake of the dams if their serum total proteins, urea nitrogen, and creatinine are known.[574] This equation predicts the daily crude protein intake on a continuing basis.

$$\begin{aligned}\text{Daily CP consumption (kg)} &= 0.1806 + 0.04327(\text{BUN}) \\ &\quad -0.33497(\text{creat}) + 0.06963(\text{TP}) \\ &\quad -0.00025(\text{BUN})^2 + 0.06049(\text{creat})^2 \\ &\quad -0.00666(\text{BUN} \times \text{creat})\end{aligned}$$

where *BUN* is serum urea nitrogen (mg/dL), *creat* is serum creatinine (mg/dL), and *TP* is serum total protein (g/dL).

Also, the use of this formula could predict CP intake for pregnant heifers and pregnant cows. This relationship may prove to have important clinical applications when weak calf syndrome or protein-calorie malnutrition is suspected and the gestation diet of the dams is not available for analysis (as under some range conditions). Supplements such as molasses licks that contain urea may tend to overestimate CP intake.[575]

21 Chapter 21 Colostrum Substitutes and Milk Replacers

Arlyn Jud Heinrichs

Coleen M. Jones

In recent years research in the area of colostrum substitutes and milk replacers has focused on improving the quality of these products so that calf performance can be enhanced and rearing costs can be minimized. The goals of the dairy calf feeding program are to achieve optimum growth rates, develop a strong immune system, minimize health disorders, stimulate and optimize ruminal development, and control the cost of feeding the preweaning calf.

21.1 CALVES

21.1.1 Digestive Physiology of the Preruminant Calf

The gastrointestinal physiology of the newborn calf is poorly developed, and the calf is unable to digest a variety of feedstuffs normally fed to ruminant animals. The gastrointestinal tract of newborn calves undergoes maturation during the first 3 weeks of life and continues to grow and mature for an extended period of time. Because the young calf is technically a monogastric, the diet must be easily digestible and consist of predominately high-quality, human-grade feedstuffs.

The size and proportion of the calf stomach compartments change dramatically during the first few weeks of life and are affected by diet.[1] At birth the reticulorumen makes up approximately 30% of the stomach capacity, although it is nonfunctional. The omasum at birth makes up 10%, and the true stomach or abomasum makes up 60%. The abomasum is the only truly functional part of the four stomach compartments in the newborn. By 4 weeks of age, the reticulorumen makes up slightly more than half the total, the omasum remains about the same at 12%, and the true stomach makes up approximately 36%. By 16 weeks of age the reticulorumen makes up more than two thirds of the total stomach tissue weight. The omasum still makes up about the same proportion (18%). At this point the abomasum makes up only 15%. It has actually grown in size, but relative to the other compartments, it has become less important. The reticulorumen is now the predominant stomach system, having grown in size and in functionality.

In the ruminant animal the enzymes produced by ruminal microorganisms are largely responsible for the breakdown of simple and complex carbohydrates as well as fiber. However, at birth the rumen is nonfunctional, with little tissue development and no microbial population. In the absence of a rumen microbial population, the calf depends on digestive enzymes released primarily from the abomasum, pancreas, and small intestine for the digestion of fats, carbohydrates, and protein. Consequently, preruminant calves cannot efficiently digest complex carbohydrates and fiber.

In the young calf, liquids can bypass the rumen and flow directly to the abomasum through the esophageal groove. The esophageal groove forms when muscular folds from the reticulorumen come together, stimulated by sights and sounds calves associate with feeding and a reflexive response to swallowing. Any liquid (milk or water) consumed while the calf is excited by the anticipation of feeding bypasses the rumen and enters the abomasum. On the other hand, when the calf drinks in response to thirst, liquid enters the rumen instead of the abomasum. The esophageal groove forms whether calves are fed from a nipple bottle or from an open pail.[2] Closure of the esophageal groove also may be stimulated by drenching calves with sodium bicarbonate, which

may be useful in administering pharmaceuticals to the abomasum directly. Riek[3] demonstrated that a dose of 60 mL of a 10% sodium bicarbonate solution stimulated closure of the esophageal groove in 93% of calves tested.

During the first feeding of colostrum, the esophageal groove closes, and colostrum passes directly into the abomasum.[4] The liquid forms a clot as a result of the action of chymosin, pepsin, and hydrochloric acid. Chymosin, also known as *rennin,* is the enzyme that specifically binds with the casein protein of colostrum or milk. This clotting action causes the casein and fat in colostrum to form a curd or hard lump. This lump of fat and protein will be digested slowly and emptied into the small intestine over the next 12 to 18 hours. The stomach and small intestine produce limited amounts of enzymes in the first 48 hours of life. Curd formation allows the digestive tract, which has limited digestive capacity, to slowly yet efficiently digest the nutrients fed and to totally assimilate them, thus preventing digestive scours caused by delivery of undigested nutrients to the large intestine. The second feeding of colostrum or transition milk adds to the already formed curd in the stomach. This system allows the calf to receive a steady supply of nutrients over the first 24 to 48 hours of life as long as it is fed casein-containing liquids.[5]

The fraction of the colostrum that does not form a curd is whey. Whey is passed to the small intestine for digestion and absorption. Whey is composed of water, minerals, lactose, and a variety of proteins. Immunoglobulins are one of the important protein groups in whey obtained from colostrum. Immunoglobulins 367
from ruminants generally have the same features as other mammalian immunoglobulins. Established 368
classes of immunoglobulins are immunoglobulins G1 (IgG1), G2 (IgG2), M (IgM), and A (IgA); all are secreted at high concentrations into colostrum. Immunoglobulins pass out of the abomasum to the small intestine within 10 minutes after feeding, allowing them to be quickly absorbed into the bloodstream of the calf. The rapid absorption of these essential immunoglobulins is critical because no placental transfer of immunoglobulins from the dam occurs.

Digestion of carbohydrates by the newborn calf is relatively poor; the exception is lactose, or milk sugar. Calves younger than one month of age are limited in their ability to use starch, maltose, sucrose, or dextrin because they lack sufficient quantities of the necessary digestive enzymes. By three weeks of age, there is a marked improvement in the ability of the calf to digest starch. After this period there is also an increased ability to digest vegetable proteins.

Within a few days of birth the rumen begins to develop a microbial population. The number and types of bacteria that develop are a function of the type of feeds the calf eats. When the calf eats dry feed, the esophageal groove does not function and the feed enters the rumen. Inoculation of the rumen with microorganisms is by way of the environment, hair coat, bedding, and feeds eaten. The types of ruminal microbes that proliferate are those that best digest and use the feedstuffs being consumed. In addition to feed, ruminal microbes require water in order to grow properly and to digest feedstuffs. If water is not provided to the calf in early life, ruminal microbial growth will be limited. The neural stimulus that forms the esophageal groove does not generally function when water is fed separately from milk or milk replacer feeding. Therefore, much of the water that a calf drinks enters the rumen and is available to support growth of ruminal microbes.

21.1.2 Colostrum Substitutes

The first few weeks of life are critical to the growth and long-term performance of a dairy calf; however, during this period active antibody production does not occur to any extent in the bovine neonate. After birth the calf normally receives colostrum for a first feeding—and in many farm situations, for several feedings up to 3 days of age. From the perspective of the newborn calf, colostrum quality is determined primarily by IgG content and by cleanliness, or the absence of pathogenic bacteria. Cows produce colostrum with a wide range of IgG, and

studies of bacteria in colostrum show that keeping colostrum clean between harvest and feeding the calf can be difficult on many farms.[6,7] In addition to consistency and convenience, colostrum substitutes offer a method of breaking disease transmission cycles for Johne's disease and other infections that may be transmitted through colostrum and milk.

In the United States, colostrum products that contain immunoglobulins are regulated by the U.S. Department of Agriculture (USDA) Center for Veterinary Biologics. Two classes of colostrum substitute are recognized: supplement products that are unable to raise the blood concentration of IgG above 10 mg/mL and typically contain less than 100 g of IgG per dose, and colostrum replacer products that are able to raise serum IgG concentration above 10 mg/mL and contain at least 100 g of IgG per dose plus fat, protein, vitamins, and minerals needed by the newborn calf. When choosing colostrum substitutes consider both the IgG concentration of the product and the absorption efficiency of ingredients.

The primary sources of IgG in colostrum substitutes are dried colostrum, whey, or blood serum. The ingredients of the product and methods using in processing these ingredients can affect the ability of the product to provide absorbable IgG to calves. Apparent efficiency of IgG absorption (AEA) is used to compare the proportion of IgG absorbed to the amount fed. Supplement and replacer products based on bovine serum have an AEA similar to maternal colostrum (20% to 35%). Products based on colostrum or whey have a variable AEA, ranging from 5% to 25%, with an average of approximately 15%.

Colostrum supplements can be used to increase the amount of IgG fed to calves when only low- or medium-quality colostrum is available.[8] However, supplements cannot replace high-quality colostrum.[9] When a supplement is added to low-quality colostrum, the IgG is often absorbed poorly, and antibody absorption is reduced compared with high-quality maternal colostrum. Colostrum replacer contains more immunoglobulin than supplement products and provides more antibodies than poor- or moderate-quality colostrum. In research trials, calves fed colostrum replacer have performed as well as calves fed maternal colostrum with no differences in IgG levels, efficiency of IgG absorption, incidence of scours, or growth rates.[10,11]

Also note that feeding large quantities in a single feeding can reduce absorption efficiency. Therefore it is more beneficial to feed colostrum or a substitute with a higher IgG concentration than to try to feed more of a low IgG solution (by increasing the amount of powder or volume fed). Adding a second or third feeding of low IgG colostrum also is preferred to increasing the volume fed in a single feeding.

Some colostrum supplements include *Escherichia coli* antibody. This can be misleading, causing producers to believe that if they feed this product, it will protect their calves from *E. coli* as well as provide successful passive transfer. These products are designed to provide antibodies specific for *E. coli*, but because of the many different strains of *E. coli* present in different areas of the country and on different farms, these antibodies likely offer little protection.

Colostrum substitutes should be fed according to the manufacturer's instructions; some products are mixed with water and fed in an extra feeding, others are added to colostrum, and the number of feedings recommended may vary.

High-quality maternal colostrum is still the “gold standard” for feeding newborn calves. However, colostrum supplement and replacer products can be valuable tools to increase calf immunity when colostrum supplies are limited or disease eradication is desired. Colostrum supplements can be used to increase the amount of IgG fed to calves when no source of high-quality colostrum is available; however, supplements cannot replace high-quality colostrum. On the other hand, colostrum replacer contains greater levels of IgG and other nutrients and

provides an effective, convenient method of providing passive immunity to calves when maternal colostrum is not available.

21.1.3 Milk Replacer Quality and Formulation for the Dairy Calf

The period of time between colostrum feeding and the beginning of solid food consumption is highly dependent on the management of the individual dairy farm. Often the calf consumes a liquid-only diet for the first 2 weeks of life. Despite dry feeds (grains) being offered, very little, if any, are consumed for the first 7 to 10 days. Therefore the liquid feeding portion of the rearing program is very important to the health and initial growth of the calf.

More than 60% of the dairy calves in the United States are fed milk replacers for most or all of their liquid feeding period.[12] The dairy calf is typically fed a milk replacer for 6 to 8 weeks, at which point it is weaned. Calves can be weaned at any age from 3 weeks on, depending on the health and management of the animal. It is recommended that calves be weaned by 6 weeks of age, with a goal for most of the calves, most of the year, being 4 to 5 weeks of age at weaning. The United States national average in 2002 was 8.4 weeks[13]; however, many progressive farms regularly and successfully wean all calves at 4 to 5 weeks.

368

369

Convenience and economics are the two major factors that have driven the increase in use of milk replacers. Feeding milk replacer is often more convenient than feeding whole milk or pasteurized waste milk because calves are generally housed in different areas on the farm than the milking cows, and the transport of saleable or waste milk is difficult. This issue becomes more pronounced with larger farms. Often, supplying transition milk from the dam to the calf up to the time the milk is saleable is all that is possible from a labor and management standpoint. Milk replacer powder is easily stored and can be mixed in exact quantities to provide milk for each feeding. Another benefit of milk replacers is the ability to limit the spread of diseases, such as Johne's, that can be transmitted through milk.

Milk replacers can be manufactured with a variety of ingredients and levels of nutrients to match the management requirements of a wide variety of farms. Various additives that cannot be easily used in whole milk or waste milk feeding systems can be supplied in milk replacers to improve the nutrition and health of the calf.

One major reason for the use of milk replacers is the cost savings over the alternative of using whole milk. Savings are realized because milk replacers are composed primarily of byproducts of the cheese industry. Casein removed for dried skim milk production, and casein and fat removed for cheese production, carry much of the original value of the whole milk. The whey that remains is less valuable, and although demand for it in the world market is growing, it still commands a much lower price than skim milk. The trend for increased use of milk replacers will likely remain as long as the price differential between milk and milk replacers exists.

21.1.3.1 PROTEIN

The composition and quality of a milk replacer influence the growth, health, and overall performance of the calf. Composition and nutrient levels vary greatly among products. Protein sources are the most expensive ingredients in milk replacer. As a result, manufacturers continually seek less expensive ingredients. The source of milk replacer protein changes in response to ingredient cost and may include a variety of milk and nonmilk proteins. Milk replacers used in the United States are typically composed of whey and whey protein concentrate compounds. Dried whey contains 12% crude protein, mainly lactalbumin, and 74% lactose. Delactosed whey has higher protein content (20% to 26%) because some of the lactose in whey is removed. Whey protein concentrate is produced by ultrafiltration of liquid whey to remove lactose and other soluble

components and contains approximately 34% crude protein. Skim milk is rarely used in appreciable amounts in the United States because of the high cost. This is often not the case in other countries, depending on the agricultural economics situation. However, as new technologies continue to increase the value of whey proteins for use in human foods, skim milk is occasionally substituted for whey in the United States. Dried skim milk contains approximately 34% protein. Casein (85% protein) may also be used in milk replacer (sometimes listed on the label as dried milk protein or sodium caseinate).

The amino acids provided by various sources of protein differ in composition and in bioavailability. Availability depends on the method and conditions of processing and can vary greatly between feeds and processors. Milk proteins are typically more digestible (92% to 98%) and contain a more favorable profile of amino acids than nonmilk proteins. Compared with milk proteins, vegetable proteins (85% to 94% digestible) often contain more crude protein, but their amino acid content is not as desirable. Some soy-based milk replacer contains added lysine and methionine to improve the amino acid profile. Most soy isolates or concentrates used today are highly digestible to the young calf. Egg protein contains a favorable profile of amino acid acids, and most products are highly digestible. Manufacturers use available data to best fortify the product in an economical manner. Some evidence suggests that the amino acid composition of whey is actually more correct for meeting the calf's requirements for optimum growth than the amino acid composition of skim milk. In either case, research trials using skim milk or whey protein have proven both to be completely satisfactory in meeting the needs of the newborn calf for growth.[14]

Vegetable proteins in milk replacer are primarily of soy origin, but wheat and potato proteins also may be used. The soy proteins include soy protein isolates, soy protein concentrates, and chemically treated soy flours. Soy flour (50% protein) is obtained by grinding defatted soy flakes that have been heated to remove trypsin inhibitor or washed in aqueous ethanol to remove glycinin and β-conglycinin. These modifications improve digestibility and reduce allergic reactions. Soy protein concentrate (67% protein) is produced by washing defatted soy flakes with aqueous alcohol to remove the soluble carbohydrates. Isolated soy protein (85% protein) is produced by washing defatted soy flakes in alkali followed by acid precipitation and alkali resolubilization of the extracted protein. Wheat gluten (modified wheat protein) is derived from wheat flour by wet processing or milling and contains 80% protein. Milk replacers with 33% of total protein or without wheat gluten have resulted in comparable calf gains.[15] Modified potato protein is not common in the United States but is used in other countries. This protein is separated from water used to isolate potato starch and dried (80% protein).

Animal proteins, including plasma and eggs, also are used to replace some of the whey protein concentrate in milk replacers. Many of the amino acids in these ingredients are at very high levels compared with milk proteins. Animal plasma is a concentrated protein source obtained by removing red and white blood cells from fresh, whole blood. The resulting plasma is dried and contains 78% protein. Egg protein may be provided from spray-dried whole egg or a combination of whole egg and egg albumin. Whole egg contains high fat levels and 54% protein.

Bovine or porcine plasma products can be used successfully as partial replacements for milk proteins.[10] In addition to supplying a highly digestible source of protein, plasma proteins also supply a source of immunoglobulins that may have a beneficial effect in the calf's intestinal lumen. Morbidity and mortality were reduced in calves fed whey-based milk replacer containing bovine or porcine plasma compared with calves fed milk replacer based solely on whey.[16,17] There is limited dairy calf research on egg proteins, and it appears that the processing of the egg protein can have a dramatic impact on the outcome. Average daily gain and feed efficiency are generally somewhat lower for calves fed egg protein, particularly in the preweaning period.[18]

The performance and cost of these plasma and egg products has been intermediate to all-milk replacers and soy-based replacers.

Historically the rennet coagulation test and crude fiber content were used to evaluate milk replacer quality. These are no longer valid methods to evaluate quality, as the rennet coagulation test merely identifies the presence of casein in the milk replacer. A soft clot indicates that more than 15% of the protein is casein, a firm clot means that more than 50% of the protein is casein. However, most modern milk replacers are based on whey protein, which does not clot when mixed with rennet. Whey protein has been fully researched and is an excellent source of protein for calves; at least one study showed that whey protein was better than skim milk protein. Therefore failure to form a clot does not indicate poor protein quality in milk replacer; it does show that casein is not present. Milk replacers containing plant proteins are often higher in protein content to counteract their lower digestibility relative to milk proteins. Most soy protein isolates or concentrates used today are highly digestible to the young calf. Unmodified wheat or soy flours, potato protein, meat solubles, and fish proteins are among the least desirable ingredients in a dairy calf milk replacer. Milk protein contains no fiber, and in the past, crude fiber levels above 0.2% were considered evidence of a plant protein source. However, highly processed soy protein can contain little to no fiber and other nonmilk sources such as plasma and egg contain no fiber. Also, it is very difficult to accurately detect crude fiber at the low levels found in milk replacer.

369

370

The ingredients listed on the milk replacer tag should be listed in descending order of predominance as specified by the U.S. Food and Drug Administration (FDA) regulation 21CFR501.4. However, many states use a Uniform State Feed Bill that does not specify the need to list ingredients in order of predominance. In these states most companies do list ingredients in order of predominance to facilitate comparison of products. It is important to read and understand the ingredients in a milk replacer in order to compare and evaluate products. Some soy protein compounds and other highly processed ingredients are patented, and labels may bear the registered name and not the generic protein name (such as *soy isolate* or *concentrate*).

21.1.3.2

ENERGY

Energy in milk replacers is derived primarily from lactose and fat. The effects of milk replacer energy content are not always clear in practical applications because of interactions with environmental temperature, energy derived from dry calf starter, stage of ruminal development, and differences in metabolic efficiency of fat- and carbohydrate-derived energy. The thermal neutral zone for a young calf ranges from 10° C to 25° C. During periods of extreme stress, which include cold temperatures for calves housed outside, the energy intake of the calf should be increased to account for increased maintenance energy needs. This can be accomplished by increasing the amount of replacer fed daily by 30% to 50%, increasing grain consumption, or increasing the fat content of the replacer. Fats added to calf milk replacers are mainly edible animal fats, with some use of vegetable fats such as palm oil or refined coconut oil (digestibility 92% to 96%). The animal fats used can be lard or white grease (digestibility 88% to 96%).[19] It is important to note that when dry matter intake from milk is increased, it will substitute potential dry matter intake from grain. The long-term effects of this will be decreased grain intake and delayed ruminal development.

21.1.3.3

ADDITIVES

One obvious reason to use milk replacers is that nutrient fortification and additives for the promotion of growth and health can be incorporated without extra steps. This includes extra vitamins and minerals along

with various other additives. All macrominerals and microminerals are supplemented in milk replacer, as are vitamins A, D, and E and the B vitamins needed by preruminant calves.

The most common additives found in milk replacers today are lasalocid and decoquinate, for the prevention of coccidiosis, and oxytetracycline and neomycin, which aid in the prevention of bacterial scours. Milk-fed dairy calves often respond favorably to oral antibiotics with increased weight gains and improved feed efficiency, but often the level of antibiotics fed is less than what is required to effectively decrease scours. Antibiotics must not be used as a substitute for good management. In addition, continued public concern about the use of antibiotics in animal feed makes it likely that this option may be discontinued in the future. Feeding antibiotics in milk replacer requires a withdrawal period before slaughter, and bull calves intended for sale must not be fed medicated milk replacer.

A number of alternatives to antibiotics, such as probiotics (also called *direct-fed microbials*), yeast, oligosaccharides, and functional proteins, are now available in milk replacer. Many of these products have not been thoroughly researched, and results of research so far have been variable. Probiotics are live cultures of naturally occurring microorganisms. The most common probiotic ingredients are lactic acid-producing bacteria. In theory, probiotics can improve dry matter intake, weight gain, feed efficiency, and disease resistance. Research so far suggests a modest improvement in average daily gain and feed efficiency when probiotics are fed to young calves. It seems that probiotics would be most beneficial when calves are stressed and normal bacteria populations are disrupted. Keep in mind that probiotics are living organisms; follow the instructions for storage, and use products before their expiration dates. In addition, probiotic additives should not be used with medicated milk replacer because the antibiotics may kill the probiotic organisms.

Another category of additives is the prebiotics, which are structural carbohydrates that cannot be digested by ruminants but are excellent nutrient sources for beneficial bacteria in the calf's digestive tract. Examples include resistant starches, polysaccharides, pectins, and gums. The mode of action varies for different types of prebiotics. Prebiotics that are becoming more common in calf feeds are fructooligosaccharides (FOS) and mannanoligosaccharides (MOS), which are complex sugars isolated from the cell wall of yeast. Some pathogens, including *E. coli* and *Salmonella,* will readily and preferentially bind to these indigestible compounds rather than the intestinal wall. Once they bind, the bacteria cannot detach themselves, so they are passed out of the body with other undigested feedstuffs. In addition, beneficial bacteria in the intestine may use these oligosaccharides. Research has shown that these compounds are beneficial in reducing the severity of scours.[20] One study showed that calves fed a product containing the FOS allicin (an extract of garlic) and probiotic cultures and calves fed antibiotic had similar fecal scores.[21] However, no calves in this study were fed control milk replacer (with no additive), so it is impossible to determine if fecal scores were improved compared with calves that were not treated. Another group of researchers compared calves fed galactosyl-lactose (an oligosaccharide derived from whey), antibiotic, or no additive. In this study calves fed galactosyl-lactose or antibiotics were similar and tended to have more normal fecal scores and fewer days scouring than control calves.[22] In addition, calves fed galactosyl-lactose gained more weight than control calves. Although results so far are promising, peer-reviewed research into oligosaccharides is scarce at this time, and additional research is needed to support growth promotion claims.

Yeast is another common direct-fed microbial. *Saccharomyces cerevisiae* is the most frequently used yeast species and may be fed live or dead. Yeast cells are rich sources of protein, nucleotides, and B vitamins. They also stimulate beneficial bacteria and ruminal fermentation and assist in fiber digestion. A review of microbial additives concluded that adding yeast cultures to calf diets could result in no change or a modest improvement in feed intake, weight gain, and feed efficiency.[23] Performance depends on the specific conditions of each situation. However, yeast cultures do tend to increase microbial growth in the rumen, which may have benefits

370
371

in promoting ruminal development. One study reported that adding live yeast to milk replacer fed to calves with failure of passive transfer resulted in fewer days with scours than in control calves.[24]

A final type of antibiotic alternative is a group of proteins known as *functional proteins,* which can cause a physiologic response in the body. Some are able to survive the ruminal environment intact; others are released during digestion. The most well known of the functional proteins are the immunoglobulins. Research has shown that immunoglobulins from the blood are recycled into the intestine.[25] This means that providing immunoglobulins in colostrum or injecting immunoglobulins into the blood can help to boost immunity in calves. Both of these methods have been researched and found effective. In addition, plasma protein fed in milk replacer may provide antibodies that enhance the immune system locally in the intestine. Research with plasma protein seems to indicate that calves under stress benefit from these additional antibodies, whereas healthy, nonstressed calves usually do not benefit.

21.1.4 Enhanced Milk Replacer Feeding Systems

Many companies now offer high-protein, low-fat milk replacers (protein greater than 24% and fat less than 20%) that provide additional protein for increased growth. It is important to pay close attention to the feeding instructions for these milk replacers. Young growing ruminants will respond favorably to increasing amounts of dietary protein if additional energy and other nutrients are also provided. However, the efficiency of using this additional protein is reduced as levels increase. Calves must be fed more than in conventional programs, and the amount fed to each calf may need to be adjusted as the calf grows. To make these feeding programs cost-effective, the increased cost of high-protein milk replacer and the extra cost to feed more dry matter must be offset by long-term improvements in growth or decreased overall heifer production costs, possibly including reduced age at first calving. Thus far, research does not support long-term improvements in health or performance resulting from enhanced feeding during the preweaning period.[26] Typically, changes to the calf feeding program alone cannot achieve these long-term cost-reduction goals. Changes in the feeding and management of older calves and heifers must occur as well and will far outweigh any small changes in the preweaned calf feeding program. Calves also must be managed more carefully when feeding for higher rates of gain, as they may be more susceptible to nutritional scours, especially when milk replacer is fed at greater than 12.5% solids and water availability is limited. Grain intake often is reduced in early life with higher rates of milk replacer feeding, thereby limiting ruminal development. Often this feeding strategy results in restricted growth after weaning and produces calves that are similar in size to conventionally fed calves by 4 to 6 months of age, thereby eliminating any advantage in early growth.

21.1.5 Summary

It is noteworthy that much of the current research related to milk replacers is done by individual manufacturers, with less done in the public domain. This means that much of the peer-reviewed journal research is dated and often may not account for modern feed manufacturing technology. Recommended ranges of nutrients as shown in Table 21-1 are broad in many cases to account for some of these differences and to account for variety of protein sources and energy content in milk replacer products. Many farms want high rates of growth in their young calves and need milk replacers with marginally increased nutrient density, whereas others want only economy. The milk replacer industry has a variety of products to meet the needs of these various customers. As with most purchased items, quality is related to price.

Table 21-1 Nutrient Recommendations for Dairy Calf Milk Replacers from the National Research Council[29]*

Nutrient	Recommended Concentration
Crude protein	18-24
Fat	10-22
Calcium	1
Phosphorus	0.7
Potassium	0.65
Magnesium	0.07
Sodium	0.40
Chloride	0.25
Sulfur	0.29
Iron (ppm)	100
Cobalt (ppm)	0.11
Copper (ppm)	10
Manganese (ppm)	40
Zinc (ppm)	40
Iodine (ppm)	0.50
Selenium (ppm)	0.30
Vitamin A (IU/lb)	25,000-35,000
Vitamin D (IU/lb)	5000-7500
Vitamin E (IU/lb)	50-125

* Percentage of dry matter unless otherwise indicated.

Although milk replacers are important in the dairy feed industry today, keep in mind that many studies show that only 24% of growth before weaning can be accounted for by the energy provided in milk replacer. Calf starter makes up the remaining 76% of the energy for body weight gain in the first 2 months of life. It is important to note that overfeeding milk replacer, either in amount or concentration, will primarily replace dry matter intake that would normally come from grain. This will slow ruminal development and be less economical for the producer. In addition, scours, which cause the greatest amount of calf mortality and morbidity preweaning,[27] are greatly diminished postweaning. This occurs regardless of age at weaning and is more closely related to ruminal development and diet than age.

21.2 FOALS

The use of a milk replacer for foals becomes necessary when the mare has an inadequate milk supply or when the foal is orphaned at an early age. Milk replacers for foals should contain 18% to 22% crude protein, 12% to 16% crude fat, and 10% to 11% total solids. They should be highly digestible, easily reconstituted, and palatable.

Orphan foals should be fed milk replacer from 1 day of age (after receiving colostrum within 24 hours of birth) to a minimum of 1 month of age.[28] General guidelines for feeding foal milk replacers can be found in Table 21-2. Feeding less often than recommended may reduce growth rate as a consequence of inadequate milk replacer intake. It is important that foals receive the recommended amount of milk replacer powder daily so that starvation from underfeeding or diarrhea from overfeeding is avoided.

371
372

Table 21-2 Typical Feeding Recommendations for Foal Milk Replacers[28]

Age (days)	Number of Feedings per Day	Approximate Amount (mL/meal)	Amount of Water (mL/day)	Total Amount of Powder (g/day)
0-3	12	300	3000	480
4-5	8	500	3500	560
6-7	8	770	5300	860
8-10	8	1000	7000	1100
11-14	6	1660	8625	1335
15-21	4	3225	11,130	1750
>21	3-4	?	>15%-20% BW	>2.5% BW

BW, Body weight.

21.3 LAMBS AND KIDS

Milk replacers for lambs and kids are generally used to raise multiples or orphans but are used by dairy operations as well. Most principles discussed in the section on calves apply to lambs and kids. Milk replacers for lambs usually contain 21% to 24% crude protein and 24% to 30% crude fat. The lactose level in lamb milk replacers should not exceed 25%, as higher levels may result in abomasal bloat and diarrhea. Milk replacers for lambs are generally fed cold ad libitum from automatic nipple feeders. Lambs fed warm milk replacer a limited number of times during the day drink too much at each feeding and may develop abomasal bloat.

Creep feed can be offered to lambs after 1 week of age. It should contain 17% to 20% crude protein, be highly digestible, and be fed fresh daily. The introduction of creep feed at an early age helps the lamb develop a fully functional rumen by 35 to 40 days of age.

22 Chapter 22 Clinical Chemistry Tests

Gary P. Carlson

Laboratory data are discussed here in relation to case management. The focus is on interpretation of an abnormal finding in the typical clinical situation. An in-depth pathophysiologic explanation of these alterations is beyond the scope of this section. Should additional information be required, a textbook on veterinary clinical pathology should be consulted.[1,2]

All samples should be submitted with specific objectives in mind. In general, these objectives fall into one of the following categories:

- Evaluating organ system involvement or functional impairment
- Confirming a diagnosis or ruling out a disease condition
- Assessing response to therapy
- Formulating a more accurate prognosis

22.1 SUBMISSION OF LABORATORY SAMPLES

22.1.1 Veterinary Diagnostic Services

The clinician must be aware of inherent limitations of laboratory evaluation in certain clinical settings. In general, veterinary diagnostic laboratories are preferred to general medical laboratories, because human medical laboratories may be less familiar with animal diseases and the responses of animals to disease. There may also be differences in test methodology and interpretation. These species differences can cause confusion when results are evaluated on the basis of human criteria that may not apply to animals.

Various desktop or portable hand-held point-of-care devices are available to veterinarians for determination of serum chemistry, electrolytes, and acid-base balance. Many of these devices use self-contained strips, cartridges, or rotors and thus reduce errors associated with the maintaining, measuring, and mixing of reagents. In addition, some of these devices can use whole blood rather than serum or plasma. Some devices require refrigerated storage of reagent cartridges, which must then be warmed to room temperature for use. There are relatively few independently published data comparing the results obtained with these point-of-care devices and those obtained with standard laboratory procedures. A widely used hand-held device (iSTAT) has been shown to yield comparable results for blood electrolyte concentrations and acid-base balance in dogs and horses.[3] However, it was noted that the correlation' between results from this device and from standard laboratory techniques was poor for sodium in the dog and for hematocrit in the horse. Portable point-of-care devices can provide rapid, accurate, and relatively inexpensive results. As technology continues to improve, it can be anticipated that there will be wider and more general application of these devices in many large animal practice settings. Important requirements are the establishment of normal values with these devices for our large animal species of important age or production groupings as well as clear definition of the limitations and possible idiosyncratic reactions in certain species or clinical settings.

22.1.2 Selection of Procedures

Selection of specific laboratory tests fosters logically integrated thinking and concentrates on evaluation of the primary medical problems. However, the sophisticated autoanalyzers used by large commercial laboratories can perform a wide battery of tests quickly and efficiently with little additional cost. These panels may be broadly defined (e.g., a general large animal health panel) or may offer a more focused evaluation of a specific organ system (e.g., liver, kidney, or muscle). The clinician must ensure that the panel selected contains all the appropriate tests for a thorough evaluation of the individual patient's medical problems.

375

376

The following recommendations for diagnostic panels are intended to provide a clear indication of organ damage and/or dysfunction. The most directly applicable diagnostic procedures are listed under “Recommended,” and additional procedures that may be of benefit in certain circumstances are listed under “Optional.”

22.1.2.1 GENERAL PANEL

The broadly based general chemistry panel should provide a balanced evaluation of the most likely medical problems.

22.1.2.1.1 Recommended

Glucose

Blood urea nitrogen (BUN)

Creatinine

Creatine kinase (CK)

Aspartate aminotransferase (AST)

Sorbitol dehydrogenase (SDH)

γ-Glutamyltransferase (GGT)

Alkaline phosphatase (ALP)

Bilirubin (direct, indirect, and total)

Total protein

Albumin

Globulin

Albumin/globulin ratio (A/G ratio)

Bicarbonate or total carbon dioxide (total CO_2)

Sodium

Potassium

Chloride

Calcium

Phosphate

22.1.2.1.2 Optional

Venous or arterial blood gases

Ionized calcium

22.1.2.2 MUSCLE PANEL

The muscle panel should detect active skeletal and cardiac muscle destruction (rhabdomyolysis) and the degree of secondary renal damage. The possible causative factors are evaluated as optional procedures, depending on the history, clinical findings, or special circumstances. Muscle biopsy with special staining may be critical to the diagnosis of specific muscle diseases such as polysaccharide storage myopathy, immune mediated myopathy, and mitochondria myopathy. Special tests for muscle function and the genetic basis for some myopathies are discussed in the section on muscles (Chapter 42).

22.1.2.2.1 Recommended

CK

AST

Muscle biopsy

Urinalysis

BUN or creatinine

22.1.2.2.2 Optional

Blood selenium

Venous blood gases

DNA analysis (hyperkalemic periodic paralysis, glycogen branching enzyme deficiency)

Calcium (ionized and total)

Magnesium

Fractional excretion of:

Sodium

Potassium

Chloride

22.1.2.3 LIVER DISEASE PANEL

The liver panel should detect active damage to the hepatic parenchyma, involvement of the biliary system, and alteration in hepatic function.

22.1.2.3.1 Recommended

SDH

AST

GGT

ALP

BUN

Blood glucose

Fibrinogen

Total protein

Albumin

Globulin

Bilirubin (direct, indirect, and total)

Complete urinalysis

22.1.2.3.2 Optional

Liver ultrasound

Liver biopsy

Bile acids

Blood ammonia

Clotting panel

22.1.2.4 RENAL DISEASE PANEL

The kidney panel should provide a rough quantitative estimation of compromised renal function and should indicate the location and nature of the damage to the urinary tract.

22.1.2.4.1 Recommended

BUN

Creatinine

Calcium

Phosphate

Protein or albumin

Complete urinalysis

22.1.2.4.2 Optional

Renal ultrasound

Renal biopsy

Urine culture

Urine/plasma osmolality ratio

Urinary CK/creatinine ratio

Fractional excretion of:

Sodium

Potassium

Chloride

Endogenous creatinine clearance

Sulfanilate clearance

22.1.2.5 GASTROINTESTINAL DISEASE PANEL

The gastrointestinal disease panel should include evaluation of acid-base status, fluid and electrolyte balance, and renal function, which are common complicating features of gastrointestinal diseases. Additional optional or special diagnostic procedures may be necessary in calves or foals with neonatal diarrhea, in horses with colic, and in ruminants with gastrointestinal stasis or displacement.

22.1.2.5.1 Recommended

Packed cell volume (PCV)

Total plasma protein (TPP)

Sodium

Potassium

Chloride

Calcium (ionized and total)

Venous blood gases, pH, bicarbonate

Anion gap

BUN

Creatinine

Glucose

Peritoneal fluid cytology

Fecal occult blood

Fecal parasites

Ruminal fluid pH

22.1.2.5.2 Optional

Peritoneal fluid (glucose and pH)

Serum immunoglobulin

Plasma lactate (D and L forms)

Fecal protozoa

Fecal culture

Fecal *Clostridium difficile* toxin

Fecal cytology

Rectal biopsy

376

377

Absorption test:

Glucose

Xylose

22.1.3 Metabolic Profiling

The health status and productivity of dairy cattle, swine, and other food animals maintained in large confined groups involve a fragile balance between metabolic events, nutrition, agents of disease, management, and environmental factors. In these production units the health status of the herd as a whole is of paramount importance. Subclinical disease or nutritional imbalance may contribute to suboptimal productivity. Most productivity problems in these settings are multifactorial. Defining and finding solutions to these problems can be a difficult and complicated task. Sequential assessment of weight gains, body conditions scores, milk quality, and milk production are useful measures of the presence of subclinical production disorders but do not identify the cause. Metabolic profiling is a tool that has been employed in some situations. Blood samples are drawn from a number of individuals as representative of the group as a whole. Some have recommended the submission of pooled serum samples from representative individuals, much like the use of bulk tank tests as a reflection of the general level of mastitis in a herd. Sampling may be done routinely and sequentially. In dairy cattle this may be

done during gestation or lactation but frequently focuses on the periparturient period when a combination of nutritional and metabolic events often contributes to costly production disorders.

Metabolic profiles might include most of the parameters listed under the recommended general panel (p. 376), with the addition of magnesium, total cholesterol, nonesterified fatty acids (NEFA) and β-hydroxybutyrate (BOHB). BOHB, NEFA, and cholesterol may provide an indication of energy balance, whereas BUN, creatinine, total protein, albumen, and CK may be helpful in assessing protein status. In certain settings, trace minerals or fat-soluble vitamins may be important indicators of underlying nutritional problems. Metabolic profiling is not a substitute for careful clinical examination, analysis of husbandry practices, and ration analysis, but it may play a useful role in some modern large- scale operations in which a variety of subclinical problems can quickly translate into financial disaster.

22.2 SOURCES OF VARIATION IN NORMAL VALUES

22.2.1 Laboratory

One of the most commonly overlooked sources of variation in clinicopathologic data is the difference in results obtained by different laboratories. This can result in fivefold to tenfold differences in the normal range of certain enzyme activities between laboratories using similar but not identical methodologies. In the past there was marked variation in the units of measure used to express the activities of different serum enzymes. The standard method of representing serum enzyme activity is in international units per liter (IU/L), which is used in this text. Correction factors for converting the commonly used but older units of measure to international units are given in Table 22-1. The normal values given in Tables 22-2 and 22-3 are those used at the University of California Veterinary Medical Teaching Hospital or are from the literature.[2,3] It is always best to use normal values and reference intervals established for the species, age, and production type by the diagnostic laboratory to which samples are submitted.

Table 22-1 Conversion of Conventional Units to International Units

Component	Conventional Unit	Multiply By	International Unit (IU)
CHEMISTRY			
Ammonia	µg/dL	0.5872	µmol/L
Bilirubin	mg/dL	17.1	µmol/L
Cholesterol	mg/dL	0.02586	mmol/L
Creatinine	mg/dL	88.4	µmol/L
Glucose	mg/dL	0.05551	mmol/L
Lactate	mg/dL	0.111	mmol/L
Urea nitrogen	mg/dL	0.357	mmol/L
ELECTROLYTE			
Sodium	mEq/L	1	mmol/L
Potassium	mEq/L	1	mmol/L
Chloride	mEq/L	1	mmol/L
Calcium	mg/dL	0.2495	mmol/L
Magnesium	mg/dL	0.4114	mmol/L
Phosphorus	mg/dL	0.3229	mmol/L
BLOOD GAS			
Po_2	mm Hg	0.1333	kPa
Pco_2	mm Hg	0.1333	kPa
Bicarbonate	mEq/L	1	mmol/L
Tco_2	mEq/L	1	mmol/L
PROTEIN AND HEMATOLOGY			
Protein	g/dL	10	g/L
Albumin	g/dL	10	g/L
Fibrinogen	mg/dL	0.01	g/L
Hemoglobin	g/dL	10	g/L
Iron	µg/dL	0.1791	µmol/L
Transferrin	mg/dL	0.01	g/L
Haptoglobin	mg/dL	0.01	g/L
HORMONE			
Cortisol	µ/dL	27.59	nmol/L

Triiodothyronine (T_3)	ng/dL	0.01536	nmol/L
Thyroxine (T_4)	µg/dL	12.87	nmol/L

From Kaneko JJ, Harvey JW, Bruss ML, eds: *Clinical biochemistry of domestic animals,* ed 5, New York, 1997, Academic.

kPa, Kilopascal; Po_2, partial pressure of oxygen; Pco_2, partial pressure of carbon dioxide; Tco_2, total carbon dioxide.

22.2.2 Species

There is relatively modest variation among species for most clinicopathologic parameters. Notable exceptions are plasma electrolyte concentration, erythrocyte potassium concentration in some breeds of sheep, and serum bilirubin concentration, which is higher in horses than in other species. BUN is a less reliable indicator of renal function in ruminants and horses than creatinine because urea nitrogen can be metabolized by the intestinal microflora. Donkeys and burros have a much higher GGT level than horses and cattle.

22.2.3 Breed

Significant differences in hematologic parameters exist between hot-blooded and cold-blooded horses. Hot-blooded horses include most of the athletic breeds of horses (the thoroughbred, quarter horse, standardbred, and Arabian breeds). Cold-blooded horses include the pony and draft breeds. Cold-blooded horses have lower red cell values both at rest and after exercise and maintain a slightly lower leukocyte count; they also have lower resting and fasting indirect bilirubin concentrations.

Table 22-2 Clinical Chemistry: Normal Range for Large Animals

Component	Unit	Equine	Bovine	Ovine	Caprine
CHEMISTRY					
Total bilirubin	mg/dL	0.5-2.3	0-0.1	0.1-0.2	0-0.1
Direct	mg/dL	0-0.6	0	0	0

N/A, Not applicable.

22.2.4 Age

There are several important differences in hematologic and clinical chemistry between neonatal and adult animals. The effects of age have been studied most carefully in horses and cattle. Suckling neonatal animals tend to have lower BUN, slightly lower total protein and globulin, moderately higher GGT and phosphate, and markedly greater alkaline phosphatase than do adult animals.

22.2.5 Sex

With the obvious exception of sex hormone concentrations, there are few recognized differences in clinical chemistry values between sexes. In most domestic animals the intact male tends to have a slightly higher erythrocyte count, hemoglobin concentration, and PCV than the female or neutered male. This sex-related difference has been demonstrated most clearly in the horse.

22.2.6 Factors Influencing Results or Their Interpretation

Many factors influence the reliability and interpretation of results obtained by laboratory analysis. Sample collection and handling are very important factors. The sample collection site (e.g., jugular vein, mammary vein, tail vein, or carotid artery) can have an important effect on the results of tests such as blood gas evaluation, glucose, or ketones. The choice of anticoagulants depends on whether the samples are to be submitted for serum, plasma, or whole blood determinations. The specific sample requirements for the most commonly ordered clinical chemistry determinations are listed in Table 22-4. Serum is required for most chemistry determinations, and serum separator tubes work very well in most settings. There have been some indications that results of some serum hormone assays may be influenced by collection of blood in serum separator tubes. Heparin is the anticoagulant of choice for most chemical determinations requiring plasma. In former times fluoride-oxalate was the anticoagulant of choice for blood glucose determination, because it halts glycolysis by the red cells. However, fluoride may interfere with certain chemical procedures (specifically the glucose oxidase method for blood glucose determination) and should be used only for blood lactate determination or in selected circumstances in which glucose determinations are required and samples must be held for some period of time without refrigeration. Citrate is the anticoagulant of choice for clotting tests and blood typing. Ethylenediaminetetraacetic acid (EDTA) is the anticoagulant most often used for hematologic evaluation. Both citrate and EDTA are chelating agents, which may interfere with a wide variety of chemical determinations.

Table 22-4 Recommended Anticoagulants for Hematologic or Clinical Chemistry Evaluation

Anticoagulant	Specimen	Test or Procedure
Ethylenediamine tetraacetic acid (EDTA)	Whole blood Whole blood Plasma	Complete blood count, cross-match, platelet count Blood selenium Refractometric protein and fibrinogen
	Peritoneal fluid	Fluid analysis
	Bone marrow	Hematologic evaluation
	Synovial fluid	Fluid analysis
Heparin	Whole blood	Blood pH, blood gases
	Plasma	Electrolytes, osmolality
	Synovial fluid	Mucin clot test
Fluoride and oxalate	Plasma	Lactate
Citrate	Whole blood	Blood typing
	Plasma	Coagulation tests (PT, PTT, factor analysis)
None, serum separator tubes	Serum	Most chemistries, electrolytes, osmolality Protein electrophoresis
		Hormones (cortisol, T_3, T_4)
		Immunoglobulins (IgG, IgM, IgA)

Modified from Brobst DF, Parry BW: Normal clinical pathology data. In Robinson NE, ed: *Current therapy in equine medicine,* ed 2, Philadelphia, 1987, Saunders.

PT, Prothrombin time; *PTT,* partial thromboplastin time; T_3, triiodothyronine; T_4, thyroxine.

379

380

Samples should be submitted as soon after collection as possible, but circumstances may require storage of some samples for 12 to 24 hours. For collection of serum, whole blood should be allowed to clot before refrigeration. Serum should be separated from the red cells immediately after clot formation and then kept refrigerated. Samples should be stored in clean containers free from exposure to sunlight, medications, or chemicals. If whole blood is left at room temperature for longer than 60 minutes, blood glucose will be falsely low as a result of red cell glycolysis. Storage of whole blood may result in in vitro hemolysis, with the potential for misleading increases in the serum or plasma enzymes AST and lactate dehydrogenase (LDH) due to hemolysis. Failure to separate serum or plasma from the red cells within an hour of collection may lead to leakage of erythrocyte potassium and a falsely elevated serum or plasma potassium concentration.

Stress, transportation, excitement, and handling produce physiologic responses in animals that affect a variety of hematologic and biochemical parameters. This is most evident in the horse, which shows marked increases in red cell mass and to a lesser extent plasma protein concentration in response to excitement, exercise, or catecholamine administration. The red cell count and hemoglobin concentration can increase by as much as 50%,

whereas plasma protein concentration may increase by 1 to 2 g/dL. Leukocytosis is induced as the marginating leukocyte pool is mobilized into the general circulation. Prolonged stress results in the release of endogenous corticosteroids, which produce the typical “stress response” in the leukogram. A similar leukogram is found in race horses some 4 to 6 hours after racing. The combination of catecholamine and glucocorticoid release associated with stress, transport, and excitement, as well as with many gastrointestinal catastrophes, may result in markedly elevated blood glucose concentrations (up to 400 mg/dL). Modest elevations (twofold to fourfold increase) in muscle-derived enzymes occur in association with prolonged transport or endurance exercise.

Large losses or compartmentalization of sodium-containing fluid accompanies many systemic disorders, particularly digestive problems such as diarrhea, colic, displacement of viscera, excessive sweat losses, and some urinary tract diseases. These forms of dehydration lead to decreases in plasma volume, which are indicated by moderate-to-marked increases in the PCV and TPP concentration. The concentration of other compounds dissolved in the plasma may also increase as a result of decreases in the plasma volume. The concentrations of compounds that are largely protein-bound, such as calcium, are generally closely related to protein concentration. More than 50% of serum calcium is bound to albumin. Increases or decreases in plasma protein concentration normally result in proportional changes in total serum calcium concentration, whereas the physiologically active ionized calcium may remain unchanged.

Diseases that cause a reduction in effective circulating fluid volume often also cause alterations in renal function. This so-called “prerenal azotemia” results in moderate to marked elevation in BUN and creatinine. Although this is generally considered primarily a prerenal azotemia, real pathologic changes in the kidneys often are associated with the systemic processes initiated by these disorders. Reevaluation of renal function (urinalysis BUN, creatinine) in these patients during the course of disease is important because it affects prognosis, response to fluid administration, and the potential for nephrotoxicity and systemic toxicity of a variety of chemotherapeutic agents.

Fasting laboratory data are important for evaluation of many disease conditions in human and small animal patients. Truly fasting conditions are rather difficult given the large and complex gastrointestinal tract of most herbivores and are thus seldom used. The feeding of animals in relation to sample collection can, however, have an impact on the data obtained. Hay feeding in horses is reported to affect sodium, potassium, and protein concentrations within the first few hours after feeding. Animals feeding on lush green pasture or large amounts of silage may have slightly different parameters from those fed high-concentrate rations. The anion-cation balance of the ration has an impact on relative serum electrolyte concentration, acid-base balance, and urine pH and urinary electrolyte excretion. Lactescent (cloudy) plasma may be observed in samples from nursing foals or calves. The fluid intake of the normal nursing neonate may range from 100 mL/kg/day to more than 250 mL/kg/day. This high fluid intake is reflected by a commensurately high output of urine with a low specific gravity and low osmolar content.

The administration of certain medications may have an impact on some laboratory parameters. Tranquilization may be necessary for restraint and safe sample collection. The practitioner should be aware that tranquilizers often decrease red cell mass and plasma protein concentration. This is particularly true of the phenothiazine-derivative tranquilizers when used in the horse. Xylazine administered to large animals produces a modest catecholamine release, which may be evidenced by the slight sweating response seen in many horses sedated with this drug. Glucose concentration will increase modestly in response to the xylazine-induced catecholamine release. Repeated intramuscular injections with certain antibiotics (especially erythromycin and tetracycline) or other preparations that are locally irritating may produce slight-to-moderate elevations in muscle-derived serum enzyme activities. Intravenous administration of certain drugs and compounds such as dimethyl sulfoxide

(DMSO) can produce intravascular hemolysis and hematuria. The amount of hemolysis in these circumstances is relatively small and of little consequence, except that it can cause confusion as to why hemoglobinuria occurred.

22.3 FLUID AND ELECTROLYTE BALANCE

22.3.1 Packed Cell Volume and Total Plasma Protein

Changes in the plasma volume generally are reflected by changes in the PCV and the TPP concentration. In dehydrated humans, changes in the PCV are believed to be the more reliable guide to changes in plasma volume because substantial protein fluxes into and out of the circulation have been shown to occur. However, in most animal species the range of normal for the PCV is much wider than for the TPP concentration. This is particularly true of horses, in which excitement, pain, or catecholamine release can produce variable mobilization of splenic erythrocytes, making it difficult to obtain a truly resting PCV. For these reasons, precise quantitative estimation of a change in plasma volume using these parameters is more complex and less reliable in large animal species. As plasma volume increases or decreases, the change in the PCV is always less than the change in the TPP concentration. However, a large disparity in the changes in the PCV and the TPP concentration in a patient with a history of loss of sodium-containing fluid and clinical evidence of reduced effective circulating fluid volume suggests blood or protein loss. Marked increases in the PCV with a normal-to-low TPP concentration frequently are encountered in animals with acute protein-losing enteropathies such as salmonellosis or equine toxic enteritis. In horses undergoing treatment for diarrhea, the excessive administration and retention of sodium-containing fluids is a key factor in the development of edema and hypoproteinemia. Blood loss generally results in a decrease in both PCV and TPP concentration.

380

381

22.3.2 Serum Sodium

The serum sodium concentration is a function of the exchangeable cation content (i.e., the exchangeable sodium [Na] in the extracellular fluid [ECF] volume plus the exchangeable potassium [K] in the intracellular fluid [ICF] volume relative to total body water), as indicated in the following formula:

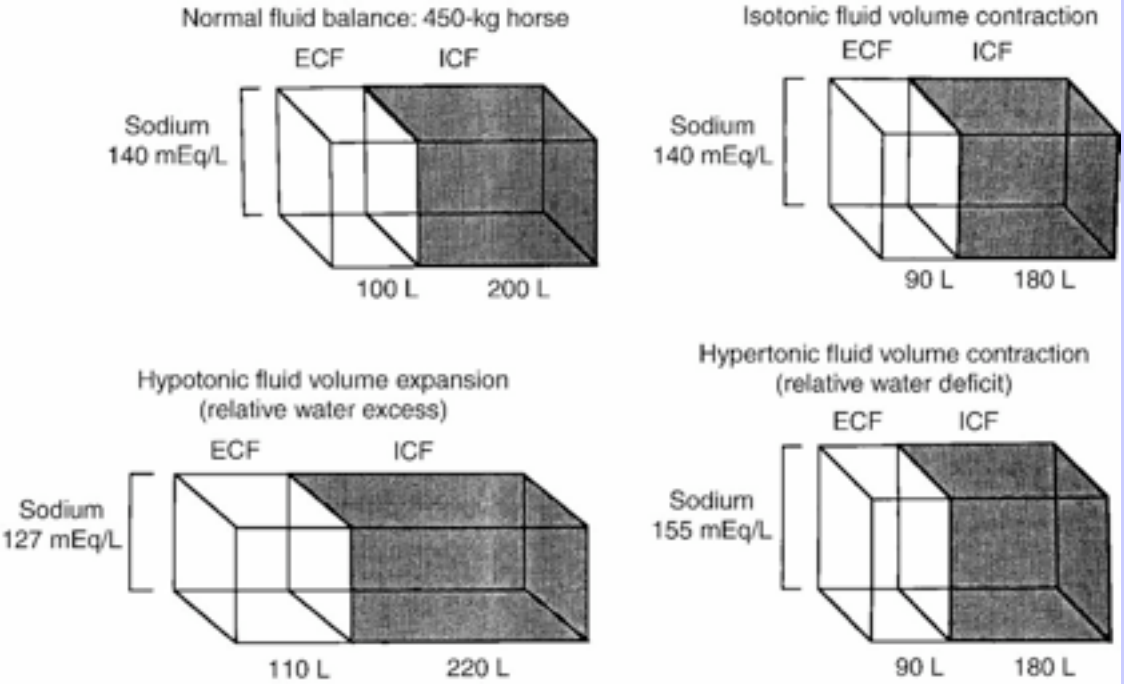
$$\text{Serum Na}\,(\text{mEq}\,/\,\text{L}) \simeq \frac{\text{Exchangeable}\,(\text{Na} + \text{K})}{\text{Total body water}}$$

Changes in the sodium concentration reflect the net changes in this relationship and often do not represent accurately the changes in sodium balance. Changes in water balance are thus primarily responsible for changes in the serum sodium concentration. Hyponatremia is an indication of a relative water excess, whereas hypernatremia is an indication of a relative water deficit.

Dehydration is defined as a loss of body water (fluid volume contraction). It occurs in a variety of clinical circumstances. The serum sodium concentration provides a means of categorizing dehydration in a physiologically meaningful way. Hypertonic dehydration, which occurs when water losses exceed the losses of sodium and potassium, is indicated by hypernatremia. The response of horses to feed and water deprivation is an example of this form of dehydration. Isotonic dehydration occurs with a balanced loss of water and electrolytes —that is, approximately 140 to 150 mEq of sodium plus potassium (Na + K) for each liter of water lost. Because the relative water balance has not changed, the serum sodium concentration remains unchanged despite the accumulation of what may have been a substantial sodium deficit. The early stages of acute diarrhea and the dehydration of heavily sweating endurance horses are examples of isotonic dehydration. Hypotonic dehydration occurs when the losses of exchangeable cations (Na + K) exceed the net change in water balance; this condition

is indicated by hyponatremia. Hypotonic dehydration often is seen in animals with subacute or chronic diarrhea that develop substantial water and electrolyte deficits but then replace part of the water deficit through water consumption. Fig. 22-1 shows the compartmental distribution of fluid between the ECF volume and the intracellular fluid (ICF) volume in four situations.

Fig. 22-1 Compartmental distribution of fluid between the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume in a 450-kg horse with normal fluid balance; with isotonic fluid volume contraction; with hypotonic fluid volume expansion; and with hypertonic fluid volume contraction. Modified from Kaneko JJ, Harvey JW, Bruss ML, eds: *Clinical biochemistry of domestic animals,* ed 5, New York, 1977, Academic.



22.3.2.1

HYPONATREMIA

Hyponatremia is often but not invariably associated with conditions that cause sodium depletion such as vomiting, diarrhea, excessive sweat losses, and adrenal insufficiency. The fluid losses in these conditions are most often hypotonic or isotonic, and initial fluid and electrolyte deficits do not result in hyponatremia until water intake, renal water retention, or both disturb the balance between the remaining exchangeable cations and the total body water.

The accumulation of sodium-containing fluid in body cavities or the gut lumen caused by ascites, peritonitis, or rupture of the bladder or by displacement, torsion, or volvulus of the gut is referred to as a *third-space problem*. When such accumulations develop rapidly, the plasma volume is reduced, and the serum sodium

concentration subsequently may decrease as compensating renal responses cause water retention. Rupture of the bladder in neonatal foals is associated with marked hyponatremia and hypochloremia. As fluid intake continues and dilute urine accumulates in the abdomen, sodium, chloride, and other ions are drawn from the rest of the ECF into this accumulating fluid. No sodium or chloride has been lost from the body, and the observed decreases in the electrolyte concentration are caused by changes in the relative water balance. The neurologic signs seen in these foals are largely caused by the effects on the central nervous system of the rapidly developing and marked hypotonic hyponatremia. Progressively severe neurologic disturbances may be seen as the serum sodium concentration falls below 115 mEq/L and then below 100 mEq/L. The severity of the neurologic abnormalities is a function of both the rate at which hyponatremia develops and the absolute degree of hyponatremia. Neurologic disturbances can occur iatrogenically if excessive amounts of free water (usually given as 5% dextrose) are administered to patients with altered renal function.

Mastitis results in an increased loss of sodium in the milk, and a low-grade mastitis problem in a dairy herd on a marginal dietary salt intake may result in sodium depletion and medullary washout. Decreased milk production, polyuria, hyposthenuria, and a low urine sodium level may be noted, although the serum sodium concentration may remain within the lower range of normal.

The most common causes of hyponatremia are listed in Box 22-1. Marked hyperlipidemia or hyperproteinemia produces a falsely low sodium concentration value because lipid or protein occupies a significant volume in the serum or plasma sample and because sodium is present only in the aqueous phase. This potential cause of hyponatremia is indicated by an increase in the osmolar gap between measured and calculated osmolality. The use of direct ion-specific electrodes for electrolyte determinations avoids this potential cause of a falsely low sodium concentration value.

381

382

22.3.2.1.1

Box 22-1 Causes of Hyponatremia

22.3.2.1.1.1

COMMON CAUSES

Relative water excess

Loss of sodium-containing fluid (decreased effective circulating volume)

Diarrhea

Excessive sweating

Blood loss

Fluid drainage

High-volume gastric reflux

High-volume pleural drainage

Adrenal insufficiency

Sequestration of fluid (third-space problems)

Peritonitis

Ascites

Ruptured bladder

Torsion or volvulus of the gut

Excessive administration of 5% dextrose to patient with renal disease

False hyponatremia

Hyperlipidemia

Hyperproteinemia

Hyperglycemia

22.3.2.1.1.2

UNCOMMON CAUSES

Water retention with normal effective circulating volume

Psychogenic polydipsia

Renal disease

Inappropriate antidiuretic hormone secretion

Marked hyperglycemia causes a reduction in the measured serum sodium concentration of approximately 1.6 mEq/L for every 100 mg/dL increase in the glucose concentration. Increases in the plasma glucose concentration generate osmotic forces that result in the movement of cellular water into the ECF, diluting the plasma sodium concentration.

22.3.2.2

HYPERNATREMIA

Hypernatremia can occur in the initial stages of diarrhea, vomiting, or renal disease if water loss exceeds electrolyte loss (Box 22-2). When water losses are replaced by increased water consumption, enhanced renal water retention, or both, the serum sodium concentration decreases. Food and water deprivation in normal horses and cattle is associated with substantial reduction of renal and fecal output, but continued cutaneous and respiratory insensible water loss may result in hypernatremia. In this case the hypernatremia is the result of a primary water loss. Hypernatremia may occur transiently as a result of sodium excess after administration of hypertonic saline or sodium bicarbonate if water intake is restricted or impaired. Hypernatremia has been reported in calves fed an inappropriately mixed oral electrolyte replacement solution as their only fluid intake.[4] The hypernatremia observed with salt poisoning in cattle and swine is the result of water restriction in animals that have been maintained on a high-salt intake.

22.3.3

Serum Potassium

The serum potassium concentration is influenced by factors that alter internal balance (the distribution of potassium between the ECF and the ICF) and those that change external balance (potassium intake and output). Changes in the serum potassium concentration occur in a wide variety of clinical circumstances and have profound neuromuscular effects that are largely the result of changes in cell membrane potential. The responses to dehydration and acid-base imbalance often complicate the evaluation of the potassium concentration. For example, calves with acute diarrhea often develop potassium depletion because of excessive losses and inadequate intake, but the serum potassium concentration of these animals usually is normal to increased as the result of renal shutdown and the metabolic acidosis induced by dehydration, sodium depletion, and hypovolemia. Hypokalemia may become evident only as other fluid and electrolyte losses are replaced.

22.3.3.1

Box 22-2 Causes of Hypernatremia

22.3.3.1.1

COMMON CAUSES

Pure water losses

- Panting
- Water deprivation

Sodium excess (water restriction)

- Salt poisoning
- Feeding only electrolytes, no free water

22.3.3.1.2

UNCOMMON CAUSES

Water loss exceeds electrolyte loss

- Vomiting
- Diarrhea
- Burns
- Intrinsic renal disease
- Diuretics
- Diabetes insipidus
- Central
- Nephrogenic
- Hypertonic saline or sodium bicarbonate administration
- Mineralocorticoid excess

Measuring the erythrocyte potassium concentration is relatively easy and has been suggested as an aid in assessing the need for potassium supplementation in racehorses with recurrent muscle disease. However, experimental studies in horses indicate that the erythrocyte potassium concentration does not always accurately reflect potassium deficits.

22.3.3.2

HYPOKALEMIA

Hypokalemia may result from depletion of the body's potassium stores or from a redistribution of potassium from the ECF into the ICF space (Box 22-3). Hypokalemia is most commonly seen with altered intake and absorption and with excessive potassium losses from the gastrointestinal tract caused by vagal indigestion, torsion of the abomasum, ileus, or diarrhea. Excessive renal loss may result from mineralocorticoid excess, certain diuretics, or altered renal function, as reported in horses with renal tubular acidosis. Marked hypokalemia develops when reduced dietary intake caused by anorexia is associated with excessive potassium losses.

Hypokalemia without potassium depletion results from the movement of extracellular potassium to the intracellular space. This form of hypokalemia occurs in response to an acute alkalosis and to the

administration of insulin or glucose. Overzealous and rapid administration of sodium bicarbonate can produce an alkalosis with a profound and rapidly developing hypokalemia. Animals with moderate potassium deficits that are vigorously treated with sodium bicarbonate to correct a coexisting mild metabolic acidosis may be particularly prone to this problem. The initial response to catecholamine administration is a modest, transient increase in potassium caused by α-adrenergic stimulation, which often is followed by hypokalemia caused by β-adrenergic receptor responses.

382

383

22.3.3.2.1

Box 22-3 Causes of Hypernatremia

Altered External Balance

Mineralocorticoid excess

Diuretics

Renal tubular acidosis

Postobstruction diuresis

22.3.3.2.1.2.2 Altered Internal Balance

Excessively rapid bicarbonate administration

Insulin and/or glucose administration

Catecholamine administration or endogenous release

* *External balance* refers to the relative changes in potassium intake and output; *internal balance* refers to the distribution of potassium between the extracellular and the intracellular fluid compartments.

22.3.3.3 HYPERKALEMIA

Hyperkalemia may develop in vitro as a result of hemolysis or leakage of erythrocyte potassium after storage of whole blood (Box 22-4). The release of potassium from leukocytes or platelets into the serum after clot formation is a potential cause of hyperkalemia if marked leukocytosis or thrombocytosis is present. Hyperkalemia also results from renal potassium retention in Addison's disease, acute renal failure, and renal shutdown. A number of factors contribute to the movement of intracellular potassium into the ECF, resulting in hyperkalemia. Hyperkalemia often is associated with metabolic acidosis, particularly when the acidosis results from volume depletion and is complicated by renal shutdown. Hyperkalemia has been reported in animals with massive muscle necrosis, but neither hyperkalemia nor metabolic acidosis is a common feature in horses with exertional rhabdomyolysis. Vigorous short-term exercise of horses at high intensity results in a marked but transient hyperkalemia (9 to 10 mEq/L) that may be associated with the profound lactic acidosis seen with anaerobic workloads.[5] Potassium returns to normal within minutes, and often a modest hypokalemia occurs later in the recovery period. Episodic hyperkalemia and muscular weakness are associated with the condition known as *hyperkalemic periodic paralysis* (HYPP).[6] HYPP is inherited as an autosomal-dominant trait in horses, with a specific quarter horse lineage[7] (see Chapter 42 for a more complete discussion of this disorder). The disease is the result of a single DNA base pair substitution that leads to the production of an abnormal voltage-regulated sodium channel at the cell membrane.[8] Sudden marked increases in the serum potassium concentration, up to 8 to 9 mEq/L, are the result of transcellular movement of potassium and are associated with profound electrocardiographic abnormalities and fluid shifts.

22.3.3.3.1 Box 22-4 Causes of Hyperkalemia

22.3.3.3.1.1 COMMON CAUSES

False hyperkalemia

In vitro hemolysis

Prolonged storage of blood (over 6 hours) without separation of serum or plasma

Altered external balance

Hypovolemia with renal shutdown

Altered internal balance

Metabolic acidosis

Vigorous exercise

22.3.3.3.1.2 UNCOMMON CAUSES

False hyperkalemia

Markedly elevated leukocyte or platelet count

Altered internal balance

Hyperkalemic periodic paralysis in quarter horses

Diabetes mellitus

Tissue necrosis

Renal disease

Addison's disease

22.3.4 Serum Chloride

Alterations in the chloride concentration usually are associated with nearly proportional changes in the sodium concentration as the result of changes in relative water balance. In addition, the chloride concentration tends to vary inversely with the bicarbonate concentration; therefore, when disproportionate changes in the chloride concentration relative to sodium occur, significant acid-base imbalances should be anticipated. Disproportionate

increases in chloride are associated with a normal-to-low anion gap hyperchloremic metabolic acidosis, but they also are seen as a result of the compensating responses for a primary respiratory alkalosis (Box 22-5). A striking hyperchloremic metabolic acidosis has been reported in horses with renal tubular acidosis.[9,10] Disproportionate decreases in chloride relative to sodium characteristically are seen in metabolic alkalosis but also may be seen as part of the compensating response for chronic primary respiratory acidosis (Box 22-6). Hypochloremic metabolic alkalosis is a common feature in many digestive disorders of ruminants and is caused by loss of chloride-rich fluids or sequestration of such fluids in the abomasum and forestomachs.

22.3.5 ## Osmolality

Measurement of the serum osmolality provides an indication of relative water balance in much the same way as the serum sodium concentration does. In most circumstances these parameters are closely correlated. Comparing the measured osmolality with the calculated osmolality, as determined from the measured concentrations of the major solutes in serum (sodium, glucose, and urea), provides a means of determining if the serum water content deviates widely from normal or if foreign, low—molecular-weight substances are present in the blood. The difference between the measured osmolality and the calculated osmolality is called the *osmolar gap*. Decreases or increases in the osmolar gap could indicate laboratory error, but increases of more than 10 mOsm/kg generally are the result either of a decrease in the serum water content (caused by hyperlipidemia or hyperproteinemia) or of the presence of abnormally high concentrations of low—molecular-weight substances in the serum. These substances can include a variety of exogenous and potentially toxic compounds such as mannitol, ethanol, methanol, propylene glycol, ethylene glycol, isopropanol, ethyl ether, acetone, trichloroethane, and paraldehyde.

22.3.6 Serum Calcium

Calcium plays a vital role in many of life's processes, including maintenance of neuromuscular excitability, permeability of cell membranes, conduction of nerve impulses, muscle contraction, and blood clotting. For these reasons the serum calcium concentration or, more correctly, the ionized calcium concentration normally is maintained within a relatively narrow range, despite wide variation in intake and output. Calcium metabolism is regulated by dietary factors, vitamin D and its active metabolites, and the hormones parathormone and calcitonin. The serum calcium concentration is maintained by adjusting intestinal absorption, renal excretion, and mobilization of available calcium from the large stores in bone. Calcium exists in the serum in three forms: ionized calcium, complexed calcium, and protein-bound calcium. Ionized calcium, which normally constitutes 40% to 60% of the total calcium, is the physiologically active form of calcium. Protein binding (protein-bound calcium normally constitutes 40% to 50% of the total calcium) can cause confusion. Hyperalbuminemia may result in a modest hypercalcemia, whereas hypoproteinemia, especially hypoalbuminemia, regularly results in a moderate hypocalcemia. The ionized calcium concentration generally remains within normal limits, despite increases or decreases in total calcium associated with the change in protein concentration. The acid-base balance has additional influence on the amount of ionized and protein-bound calcium. Alkalosis reduces ionized calcium and increases protein binding, whereas acidosis produces the opposite effect. Ion-specific electrodes are available for determining the ionized calcium level, which can be very useful if blood samples are handled appropriately. Most diagnostic laboratories provide the total serum calcium value, which is composed of ionized, complexed, and protein-bound calcium.

22.3.6.1

HYPOCALCEMIA

Large increases or decreases in the serum calcium concentration generally are the result of a failure in the normal mechanisms of calcium homeostasis rather than a reflection of absolute calcium deficits or calcium-phosphorus imbalances. Hypocalcemia occurs with some frequency in domestic animals, particularly in high-producing dairy cattle near the onset of lactation. In cattle the serum calcium concentration normally decreases to less than 8 mg/dL with the stress of parturition and the onset of lactation (Box 22-7). Failure to mobilize sufficient calcium to maintain serum calcium results in the clinical syndrome of parturient paresis (see Chapter 41 for a more detailed discussion of this syndrome). Most animals are recumbent with a calcium level of 6 mg/dL or less, and fatalities may occur if the level drops below 4 mg/dL. Parturient paresis is associated with a normal to increased serum magnesium level, hypophosphatemia, and hypocalcemia. Change in the cation-anion balance in the diet of dairy cattle during the periparturient period has modest effects on the acid-base balance and enhances calcium mobilization from storage sites, thus reducing the incidence of milk fever in cows at high risk. Grass tetany is associated with marked hypomagnesemia and modest hypocalcemia, whereas the inorganic phosphorus level remains within the normal range.

384

385

22.3.6.1.1

Box 22-7 Causes of Hypocalcemia

22.3.6.1.1.1

COMMON CAUSES

Parturient paresis (milk fever)

Grass tetany

Hypoalbuminemia (decreased total calcium; ionized calcium may remain unchanged)

Fat necrosis

Lactation tetany

Transport tetany

Synchronous diaphragmatic flutter

Blister beetle toxicosis (cantharidin)

Acute renal failure

Anorexia in lactating cows

22.3.6.1.1.2

UNCOMMON CAUSES

Acute toxemia and associated anorexia in lactating dairy cows

Hypoparathyroidism

Exertional rhabdomyolysis

Malignant hyperthermia

Pancreatic disease

Oxalate toxicity

Tetracycline administration

Furosemide administration

Alkalosis induced by excessive bicarbonate administration

Systemic diseases resulting in anorexia (e.g., traumatic reticuloperitonitis, ketosis, and displaced abomasum) or acute toxemic conditions (e.g., coliform mastitis, septicemia, or aspiration pneumonia) that produce anorexia in lactating cattle frequently result in hypocalcemia. Hypocalcemia also is seen in sheep on marginal rations if stressed by inclement weather or when being moved. Hypocalcemia is seen in cattle with fat necrosis, presumably as the result of incorporation of calcium with the fat as a form of soap. Horses with exhaustive disease syndrome or transit tetany often develop decreases in ionized calcium with resultant muscle cramps and synchronous diaphragmatic flutter, which generally respond to intravenous calcium administration. Horses, cattle, and sheep usually respond initially to acute renal tubular damage with mild hypocalcemia and hyperphosphatemia.

22.3.6.2

HYPERCALCEMIA

Marked hypercalcemia, with a serum calcium level ranging from 14 to 20 mg/dL, and modest hypophosphatemia frequently are observed in horses with chronic renal failure that are fed a high-calcium diet such as alfalfa hay (Box 22-8). In these horses, blood samples collected in standard EDTA tubes may actually clot. This occurs because the serum calcium concentration is so high that there is insufficient EDTA to bind all the calcium, and some free calcium is available to complete the clotting process. Vitamin D intoxication can develop as a result of excessive dietary supplementation or the ingestion of certain plants such as *Cestrum diurnum* (day blooming jasmine) and *Solanum malacoxylon,* which contain toxic quantities of vitamin D analogs. Primary hyperparathyroidism is exceedingly rare in large animals, but pseudohyperparathyroidism with hypercalcemia occasionally can develop in animals with tumors that produce protein substances with

parathormone-like biologic activity. This has been reported in a few animals with lymphosarcoma or gastric squamous cell carcinoma.

22.3.6.2.1 Box 22-8 Causes of Hypercalcemia

22.3.6.2.1.1 COMMON CAUSES

- Chronic renal failure in horses
- Hypervitaminosis D
  - Excessive dietary supplements
  - Plant intoxication
    - *Cestrum diurnum* (day blooming jasmine)
    - *Solanum malacoxylon*
- Excessive or too rapid intravenous administration of calcium

22.3.6.2.1.2 UNCOMMON CAUSES

- Neoplasia (pseudohyperparathyroidism)
  - Lymphosarcoma
  - Gastric squamous cell carcinoma
- Hyperparathyroidism

22.3.7 Serum Phosphorus

Phosphorus is found primarily in the skeleton and teeth in close association with calcium in the intricate and dynamic crystalline structure of bone. Intracellularly, phosphate plays an essential role in the degradation and synthesis of many compounds. Also, as adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP), it is the primary form of energy storage and transfer required for almost all of life's processes. Phosphorus in the ECF exists primarily as the buffer pair H_2PO^{-3} and HPO^{-4} and plays a role in acid-base balance. Like calcium, phosphorus is regulated by dietary factors, the active metabolites of vitamin D, and the hormones parathormone and calcitonin. Imbalances of calcium and phosphorus or the presence of

compounds that bind these substances in the gut can produce serious imbalances that are not always evident on analysis of serum samples. Measurement of urinary output or creatinine clearance ratios for calcium and phosphate are simple and helpful procedures. They provide an indication of an imbalance while more definitive procedures such as ration analysis are contemplated.

22.3.7.1

HYPOPHOSPHATEMIA

Serum phosphorus concentrations are not always an accurate guide to phosphate balance, but dietary deficiencies of phosphorus are frequently manifested by hypophosphatemia. Hypophosphatemia is a common feature in cattle with parturient paresis (see also Chapter 41) and horses with chronic renal failure (Box 22-9). It has been reported in animals with experimental oxalate toxicity, in chronic wasting states, or with starvation. Postparturient hemoglobinuria is a disorder of cattle, primarily lactating dairy cattle, that often is associated with diets low in phosphorus. Although marked hypophosphatemia is often reported, it is not an invariable feature of this disorder.

22.3.7.2

HYPERPHOSPHATEMIA

Age-related differences exist in the normal range of serum phosphorus concentration. Young animals have much higher values than adults, with values for neonates commonly up to 7 to 9 mg/dL. The serum phosphate concentration declines progressively with age. Hyperphosphatemia is seen in animals with vitamin D toxicity, transiently in horses after long-distance endurance rides, and initially in horses with acute renal failure (Box 22-10).

385

Higher normal range in neonates

22.3.7.2.2.2

UNCOMMON CAUSES

Acute rhabdomyolysis

Vitamin D toxicity

22.3.8

Serum Magnesium

Disturbances of magnesium metabolism occur principally in cattle and sheep. Complex nutritional and environmental interactions contribute to a variety of clinical syndromes attributed to magnesium deficiency and the onset of tetany in grazing animals.

22.3.8.1

HYPOMAGNESEMIA

Hypomagnesemia is reported in cattle with grass tetany and in sheep with grass staggers (Box 22-11) (see also Chapter 41). A serum magnesium level below 1.8 mg/dL is considered low; values below 1 mg/dL are considered severe and are likely to be associated with clinical signs. Hypomagnesemia caused by dietary magnesium deficiency has been reported in calves reared in confinement and fed a milk diet exclusively.

22.3.8.2

HYPERMAGNESEMIA

Hypermagnesemia occurs infrequently but may be seen with overzealous administration of Epsom salts ($MgSO_4$), either orally as a drench by means of nasogastric intubation or as an enema for the treatment of digestive disorders (Box 22-12). Intravenous administration of magnesium produces muscle relaxation but does not alter consciousness, and hypertonic $MgSO_4$ solutions are not considered a humane means of euthanasia.

22.3.8.2.1 **Box 22-11 Causes of Hypomagnesemia**

22.3.8.2.1.1 **COMMON CAUSES**

- Grass tetany
- Winter tetany
- Grass staggers
- Calves on a milk-only, magnesium-deficient diet
- Endurance exercise

22.3.8.2.1.2 **UNCOMMON CAUSE**

- Undernutrition

22.3.8.2.2 **Box 22-12 Causes of Hypermagnesemia***

- Epsom salt ($MgSO_4$) overdose given orally or as an enema
- Intravenous administration of magnesium in excessive amounts

* Hypermagnesemia is an uncommon condition in large animals.

22.4 ## ACID-BASE IMBALANCE

Using the traditional approach to acid-base balance, the four primary acid-base imbalances and their compensating responses are presented in Table 22-5. Acidosis is associated with an increase in the hydrogen ion concentration (decreasing pH), whereas alkalosis is caused by a decrease in the hydrogen ion concentration (increasing pH). When the primary imbalance is associated with a change in the bicarbonate concentration, the acid-base imbalance is called a *metabolic disorder*. The compensating response for a metabolic acid-base imbalance is mediated by the respiratory tract, which alters the partial pressure of carbon dioxide (P_{CO_2}) to counterbalance the primary imbalance and to partly restore the pH toward normal. Primary respiratory imbalances are related to changes in alveolar ventilation, which result in an increased P_{CO_2} in respiratory acidosis and a decreased P_{CO_2} in respiratory alkalosis. The compensating response for these primary respiratory acid-base imbalances is mediated by the kidneys through alterations in the excretion or retention of hydrogen ions and bicarbonate. Heparinized blood samples for acid-base evaluation must be drawn anaerobically and sealed immediately. Arterial blood samples

should be submitted for evaluation of primary respiratory disorders and for evaluation of ventilation in patients under general anesthesia. Venous blood samples are easier to obtain and provide reliable data for most primary metabolic acid-base abnormalities.

Blood gas analysis should be done as soon after collection as possible. However, appropriately collected blood samples yield reliable results for as long as 4 hours if held in ice water. The patient's rectal temperature should be provided to the laboratory so that corrections can be made for variation in body temperature. Changes in body temperature have a major impact on the partial pressure of oxygen (P_{O_2}) as well as the P_{CO_2} but relatively little effect on estimations of bicarbonate or base balance. During brief exercise at maximal intensity, the temperature of the central venous blood may exceed the rectal temperature by as much as 3° C. In these circumstances, the central blood temperature is more appropriate than the rectal temperature for correcting blood gas determinations. The blood sampling site (arterial, venous, or capillary blood) has a significant impact on the blood gas values obtained.[11] Arterial blood samples yield higher values for pH and lower values for P_{CO_2} than venous blood, but the bicarbonate is higher in venous blood. The use of blood gas data for evaluation of acid-base imbalances in animals has been reviewed.[12,13] In addition, an excellent review of the traditional and nontraditional approaches to evaluation of acid-base balance as related to fluid therapy in small animals has application to many large animal situations and is well worth reading.[14]

Table 22-5 Acid-Base Imbalances and Compensatory Responses

Disorder	ph	$[H^+]$	Primary Imbalance	Compensatory Response
Metabolic acidosis	↓	↑	↓ $[HCO_3^-]$	↓ P_{CO_2}
Metabolic alkalosis	↑	↓	↑ $[HCO_3^-]$	↑ P_{CO_2}
Respiratory acidosis	↓	↑	↑ P_{CO_2}	↑ $[HCO_3^-]$
Respiratory alkalosis	↑	↓	↓ P_{CO_2}	↓ $[HCO_3^-]$

$[HCO_3^-]$

, Bicarbonate concentration; P_{CO_2}, partial pressure of carbon dioxide.

22.4.1 Metabolic Acidosis

Metabolic acidosis is characterized by a decrease in pH and bicarbonate concentration. Metabolic acidosis is traditionally thought to be produced by the addition of hydrogen ions or the loss of bicarbonate ions. The most

common causes include the lactic acidosis of ruminal overload, hypovolemia associated with loss or compartmentalization of sodium-containing fluid, ketoacidosis in ketosis and pregnancy toxemia, loss of bicarbonate-rich saliva with oral diseases or esophagostomy in cattle, gastrointestinal loss of bicarbonate as a result of diarrhea, and renal failure, which may result in decreased ability to excrete hydrogen and thus to retain bicarbonate (Box 22-13). Other causes include ingestion of certain drugs or toxic compounds such as salicylate, methanol, ethylene glycol, or paraldehyde. Increased ventilation provides the compensating respiratory response for metabolic acidosis, and a decline in the P_{CO_2} generally begins within minutes. This temporarily minimizes the fall in blood pH, but long-term correction of metabolic acidosis requires renal bicarbonate retention and enhanced acid excretion. Complete correction of metabolic acidosis may be difficult in patients with intrinsic renal disease or those with diseases such as renal tubular acidosis that impair the ability of the kidneys to excrete acid or retain bicarbonate, or both.

22.4.2

Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in pH and bicarbonate. It occurs fairly commonly in domestic animals, particularly in association with digestive disturbances in ruminants. An initiating process capable of generating alkalosis is necessary and must be coupled with additional factors to maintain metabolic alkalosis. Generation of metabolic alkalosis is traditionally thought to be caused by excessive hydrogen loss, bicarbonate retention, or contraction alkalosis (Box 22-14). Contraction alkalosis occurs when the ECF volume is reduced because of loss or sequestration of fluids high in sodium and chloride but without proportionate loss of bicarbonate. This is a contributing mechanism for the generation of the metabolic alkalosis reported in heavily sweating endurance horses and in response to the diuretic furosemide in the horse. The most common causes of increased hydrogen ion loss are the gastrointestinal losses caused by salivary secretions in ponies after surgical esophagostomy[15]; massive gastric reflux associated with anterior enteritis, ileus, or small bowel obstruction in horses; and sequestration of fluid in the abomasum and forestomach associated with a variety of gastrointestinal displacements or functional disturbances (vagal indigestion) of ruminants. Continuous salivary losses in horses after surgical esophagostomy result in transient metabolic acidosis followed by progressive metabolic alkalosis. Most of these disorders cause significant dehydration and sodium, chloride, and potassium deficits.

22.4.2.1

Box 22-13 Causes of Metabolic Acidosis

22.4.2.1.1

COMMON CAUSES

Rumen overload (lactic acidosis)

Ketosis

Pregnancy toxemia

Hypovolemic shock

Acute diarrhea

Colic with strangulated bowel

Strangulating abomasal torsion

Peritonitis

Uroperitoneum (ruptured bladder)

Exercise above anaerobic threshold (normal response in horses)

22.4.2.1.2 UNCOMMON CAUSES

Renal failure

Renal tubular acidosis

Urea toxicity

Salicylate toxicity

Methanol toxicity

Paraldehyde toxicity

Ethylene glycol toxicity

The factors responsible for maintaining metabolic alkalosis involve impaired renal bicarbonate excretion. These factors are associated with the renal response to decreases in the effective circulating fluid volume, chloride depletion, or potassium depletion. Renal tubular sodium resorption is enhanced in response to hypovolemia. Maintenance of electroneutrality requires that sodium resorption in the proximal tubule be accompanied by a resorbable anion, whereas in the distal tubule, sodium resorption is associated with the secretion of another cation, usually hydrogen or, to a lesser extent, potassium. Chloride is the only resorbable anion normally present in appreciable quantities in the proximal tubular fluid. In metabolic alkalosis, plasma bicarbonate is increased and the chloride concentration is generally decreased as the result of disproportionate chloride losses. The relative lack of the resorbable anion chloride in the proximal tubule thus allows a larger amount of sodium to reach the distal tubule, where aldosterone and other factors enhance hydrogen or potassium loss into the tubular lumen in exchange for sodium. Potassium depletion reduces or eliminates potassium exchange as a means of sodium retention, thus placing greater emphasis on hydrogen ion exchange. Because renal hydrogen excretion is linked with bicarbonate resorption, the excess bicarbonate cannot be eliminated, and metabolic alkalosis is maintained. This is the reason for the *paradoxic aciduria* seen in some patients with metabolic alkalosis, and it is

the reason these patients respond when given intravenous fluids containing chloride and potassium. The compensating respiratory response to metabolic alkalosis is hypoventilation, resulting in an increase in the P_{CO_2}. Excessive bicarbonate administration is an additional potential cause of metabolic alkalosis. Most normal animals can tolerate large doses of bicarbonate, and excesses are rapidly eliminated by renal excretion.[16] However, patients with decreases in effective circulating fluid volume, particularly when coupled with potassium or chloride deficits, may not tolerate a bicarbonate load because renal clearance of excess bicarbonate is likely to be impaired. Attempts to alter the acid-base balance, and thereby affect the athletic performance of racing horses, by prerace administration of high doses of sodium bicarbonate—containing "milk shakes" has become a major concern around the world. This has stimulated substantial research on the acid-base balance of horses before and after racing. In many racing jurisdictions stringent prerace or postrace standards for blood pH or bicarbonate levels (or both) have been enacted to control this practice. The prerace administration of the diuretic furosemide is allowed in some racing jurisdictions. This drug results in a mild metabolic alkalosis with increased bicarbonate, and allowances for this may be included in some regulations. Racing supplements (which may contain sodium bicarbonate), bicarbonate precursors, and diets that supply a high cation-anion balance also have the potential to produce a significant metabolic alkalosis.

22.4.2.2

Box 22-14 Causes of Metabolic Alkalosis

22.4.2.2.1

COMMON CAUSES

- Sequestration of fluid in the abomasum and forestomach in ruminants
- Gastric reflux in horses with ileus
- Massive sweat loss in horses (endurance horses)
- Chloride depletion
- Potassium depletion
- Contraction alkalosis (extracellular fluid volume contraction without bicarbonate loss)
- Salivary loss of chloride in horses with esophagostomy
- Use of diuretics (especially furosemide)

22.4.2.2.2

UNCOMMON CAUSES

- Excessive bicarbonate supplementation or therapy
- Mineralocorticoid excess

Vomiting

22.4.3

Respiratory Acidosis

Respiratory acidosis is characterized by a decrease in pH and an increase in P_{CO_2}, which develop because of decreased effective alveolar ventilation. CO_2 diffuses through the lungs much more readily than oxygen; thus diseases that compromise ventilation normally result in decreases in P_{O_2} before significant increases in P_{CO_2} develop. The most common causes are acute upper respiratory obstruction and primary pulmonary diseases, including pneumonia, pneumothorax, and chronic obstructive lung disease (Box 22-15). Diseases or drugs that affect the respiratory center of the central nervous system also may produce respiratory acidosis, as can general anesthesia. The compensating response for respiratory acidosis is renal retention of bicarbonate. This response requires days to develop and is seen only in chronic respiratory acidosis. Exogenous bicarbonate does not correct respiratory acidosis and should not be administered to affected patients.

22.4.3.1

Box 22-15 Causes of Respiratory Acidosis

22.4.3.1.1

COMMON CAUSES

Primary pulmonary disease

Obstruction of the upper airway

Laryngeal edema

Aspiration pneumonia

Pneumonia

Pneumonia and pleuritis complex

Pneumothorax

Chronic obstructive pulmonary disease

Depression of the respiratory center of the central nervous system

General anesthesia with inappropriately assisted ventilation

Drugs

Opiates

Anesthetics

Tranquilizers

Central nervous system diseases

22.4.3.1.2 UNCOMMON CAUSES

Cardiac arrest

Muscle weakness or dysfunction

Tetanus

Botulism

Myasthenia

Severe hypokalemia

Neonatal respiratory distress syndrome

22.4.4 Respiratory Alkalosis

Respiratory alkalosis is caused by hyperventilation, which may be stimulated by hypoxemia associated with pulmonary disease, congestive heart failure, severe anemia, or neurologic disorders (Box 22-16). The initial compensating response to acute respiratory alkalosis is a modest decline in the ECF bicarbonate concentration, the result of cellular buffering. Subsequent renal responses result in a decrease in the ECF bicarbonate concentration through reduced renal bicarbonate resorption. The decline in bicarbonate may be offset by chloride retention; thus hyperchloremia and decreased P_{CO_2} may be associated with compensated respiratory alkalosis, as well as with compensated metabolic acidosis. Compensating responses for chronic respiratory alkalosis that lasts several weeks actually may be sufficient to return pH to normal.

22.4.5

Mixed Acid-Base Imbalances

Mixed acid-base disorders occur when several primary acid-base imbalances coexist.[17] Metabolic acidosis and alkalosis can coexist, and either or sometimes both may occur with either respiratory acidosis or respiratory alkalosis. The following factors should be considered when evaluating possible mixed acid-base disorders:

1. Compensating responses to primary acid-base disturbances do not result in overcompensation.
2. Compensating responses rarely correct pH to normal. A normal pH in a patient with an acid-base imbalance is an indicator of a mixed acid-base disturbance.
3. A change in pH in the opposite direction to that predicted for a known primary disorder indicates a mixed disturbance.
4. Bicarbonate and P_{CO_2} always deviate in the same direction with primary acid-base disturbances. If these parameters deviate in opposite directions, a mixed abnormality exists.
5. If the change in the anion gap does not approximate the change in bicarbonate, a mixed acid-base imbalance should be suspected.

388

389

Mixed acid-base abnormalities occur with some frequency in domestic animals and often are overlooked. The practitioner must be aware of the potential for mixed acid-base imbalances to correctly interpret blood gas data in complex clinical situations.

22.4.5.1

Box 22-16 Causes of Respiratory Alkalosis

22.4.5.1.1

COMMON CAUSES

- Hypoxemia
  - Pulmonary diseases
  - Congestive heart failure
  - Severe anemia
- Stimulation of the respiratory center of the central nervous system
  - Psychogenic hyperventilation
  - Excitement, fear, transport, pain
  - Gram-negative septicemia

Neurologic disorders

22.4.5.1.2 UNCOMMON CAUSES

After correction of metabolic acidosis

Inappropriate mechanical ventilation

Salicylate toxicity

22.4.6 Anion Gap

The anion gap can be an extremely helpful tool for categorizing causal factors in acid-base imbalances and may prove a useful prognostic guide in animals with serious digestive disorders. The anion gap can be calculated as the difference between the major cations (sodium plus potassium) and the measured anions (chloride plus bicarbonate). The anion gap normally is 12 to 16 and provides an approximation of the so-called “unmeasured anions.” These are anions that are not measured routinely in the clinical laboratory; they include the anionic equivalents of plasma proteins (particularly albumin), sulfate, phosphate, lactate, ketones, and a variety of inorganic anions. Significant differences exist in the normal range of the anion gap among species, and there also may be age-related differences. Foals are reported to have a larger anion gap than adult horses.

Hypoalbuminemia and hyperchloremic metabolic acidosis are the most common causes of a decrease in the anion gap resulting from decreases in unmeasured anions. The cause of normal to low anion gap hyperchloremic metabolic acidosis often can be differentiated on the basis of the serum potassium concentration. Animals with hyperchloremic metabolic acidosis associated with gastrointestinal fluid losses or renal tubular acidosis most often manifest hypokalemia, whereas hyperkalemia generally is seen in patients with decreased mineralocorticoid secretion (Addison's disease) or renal failure with renal shutdown. Decreases in the anion gap can be seen with increases in cationic proteins associated with polyclonal gammopathy or multiple myeloma. Decreases in the anion gap also result from overhydration caused by decreases in the protein concentration and changes in the relative concentration of plasma sodium and chloride.

Most commonly, high anion gap acidosis is associated with accumulation of a metabolizable acid such as lactic acid associated with anaerobic exercise, grain overload, or hypovolemic shock. The commonly employed laboratory procedures for the determination of lactate only measure the L form of lactate. Microbial fermentation in the gastrointestinal tract may result in the production of both the D and L forms of lactate. It has recently been shown in milk-fed calves and kids that accumulation of D-lactate is a major factor in the profound acidosis associated with certain digestive disorders. Unfortunately, at present, determination of D-lactate requires special procedures that may not be readily available. Ketoacidosis, uremic acidosis, and poisoning with a variety of anionic poisons result in increases in nonmetabolizable acids that are also causes of an increased anion gap. When a high anion gap metabolic acidosis is found, a thorough search for the potential causes of the accumulated unmeasured anions is indicated. The anion gap also is useful for identifying mixed acid-base imbalances. A mixed metabolic acid-base imbalance should be suspected when the change in the anion gap does not approximate the change in bicarbonate. Increases in the anion gap can be associated with dehydration and

contraction alkalosis caused by changes in the protein concentration and the relative concentration of plasma sodium and chloride.

22.4.7 Bicarbonate and Total Carbon Dioxide

Bicarbonate accounts for approximately 95% of the measured CO_2; thus the total CO_2 (TCO_2) or "CO_2 content" of serum or plasma provides a measure of metabolic changes in the acid-base balance. Most automated chemistry profiles now provide the bicarbonate level directly, whereas some may still provide the TCO_2. Bicarbonate or TCO_2 is decreased in metabolic acidosis and increased in metabolic alkalosis. However, the bicarbonate or TCO_2 values provide only a crude indication of acid-base status. When acid-base abnormalities are suspected, appropriate samples should be submitted for blood gas determination.

22.4.8 Buffer Base, Standard Bicarbonate, and Base Excess or Base Deficit

The terms *buffer base, standard bicarbonate,* and *base excess* (or *base deficit*) represent derived calculated estimates of the metabolic component of acid-base balance. The buffer base indicates the sum of all the buffer anions in blood under standardized conditions. The standard bicarbonate is the plasma bicarbonate concentration that would be found under specific conditions that eliminate respiratory influences on the values obtained. The base excess or base deficit often is supplied in routine assessment of acid-base balance; it indicates the deviation of bicarbonate from normal. The calculated base deficit provides a means of estimating the amount of bicarbonate required to correct metabolic acidosis. The bicarbonate estimate is calculated by multiplying the base deficit by the probable bicarbonate space (about 40% to 60% of body weight), as in the following equation:

$$\text{mEq } HCO_3 \text{ needed} = \text{mEq base deficit} \times \text{kg body weight} \times 0.5$$

22.4.8.1 NONTRADITIONAL OR STRONG ION APPROACH TO ACID-BASE BALANCE

Peter Stewart first described the quantitative physiochemical approach to acid-base balance over 25 years ago.[18,19] In this approach acid-base balance is determined by three independent variables: strong ion difference (SID), the partial pressure of CO_2, and the total concentration of nonvolatile weak acids (A_{tot}), the principal components of which are plasma proteins and inorganic phosphate. Bicarbonate and pH are dependent variables determined by these three independent variables. Several studies have attempted to adapt Stewart's approach for practical application in human and veterinary medicine.[14,20–27] Most of these studies used rather old human values for A_{tot} and Ka. Experimentally determined species-specific A_{tot} and Ka data are now available for horses, cattle, dogs, and humans.[28–30]

Peter Constable refined Stewart's model and developed an approach that he called the *simplified strong ion model* of acid-base equilibrium.[31] Constable assumed that plasma ions act either as strong ions, volatile buffer ions (HCO^{-3}), or nonvolatile buffer ions. Plasma pH is determined by five independent variables: PCO_2, SID, the concentration of individual nonvolatile plasma buffers (albumin, globulin, and phosphate), ionic strength, and temperature. The simplified strong ion model explains many of the anomalies when the Henderson-Hasselbalch equation is applied to plasma and is algebraically simpler than Stewart's model.

Strong electrolytes are assumed to be completely dissociated in aqueous solution and chemically nonreactive. The SID is simply the difference between the total concentration of strong cations (sodium, potassium, and

magnesium) and the total concentration of strong anions (chloride, sulphate, lactate, acetoacetate, and B-hydroxybutyrate). Sodium, potassium, and chloride are normally the principal determinants of SID. The SID is synonymous with buffer base and as such can be considered as roughly equivalent to the metabolic component of the traditional approach to acid-base balance. In fluids with little or no protein, such as cerebrospinal fluid (CSF), bicarbonate concentration is the same as the SID. Abnormalities in P_{CO_2} are viewed in essentially the same manner in both the traditional and nontraditional approaches to acid-base balance. Plasma albumen makes up the majority of A_{tot}. The A_{tot} exists in both dissociated A^- and undissociated HA forms. A decrease in A_{tot} resulting from hypoalbuminemia causes an alkalosis with an increase in bicarbonate, whereas hyperalbuminemia has the opposite effect. Increases in A^- can cause an increase in anion gap, whereas decreases in A^- result in a decrease in anion gap. Change in protein concentration may potentiate or ameliorate the effects of alterations in SID on acid-base balance.

389

390

When protein and inorganic phosphate remain within the normal range, acid-base balance is controlled by changes in P_{CO_2} mediated by the respiratory system, whereas changes in SID are largely under the control of the kidneys. Heavy sweat loss in an endurance horse, displaced abomasum in a cow, or the prerace administration of the diuretic furosemide in a race horse produces metabolic alkalosis. In each case the alkalosis is the result of a disproportionate loss of chloride relative to sodium, yielding hypochloremia and an increase in SID. Correction of the alkalosis is brought about by the provision of chloride, generally as sodium chloride or potassium chloride. This results in a decrease in SID and thus a return of the dependent variables (bicarbonate and pH) toward normal. Metabolic acidosis with a large base deficit is generally treated with sodium bicarbonate. In the strong ion approach to treatment the rationale for the administration of sodium bicarbonate is to provide the strong cation, sodium, without a strong anion. Other metabolizable anions could be substituted for bicarbonate and achieve similar effects.

Calculation of SID is simple and provides useful insight in patients with metabolic acid-base disturbances. Factors that influence SID range from changes in free water, to sodium-chloride imbalances that result from excessive losses or disproportionate retention of sodium or chloride, to the accumulation of strong organic anions. Organic acidosis can be produced by the accumulation of exogenous as well as endogenous anions. The anion gap does not always accurately predict the presence of unmeasured strong anions. Mathematic methods have been developed as a means for the detection of unmeasured anions[18,32] and more recently for the calculation of the simplified strong ion gap.[33]

Both the traditional and the nontraditional or strong ion approaches to acid-base balance have proven useful to address practical problems in both research and medical settings. The traditional approach to acid-base balance is more widely accepted and user-friendly. The strong ion approach may provide a better understanding as to why the bicarbonate concentration is changing as it integrates acid-base and electrolyte disorders. The strong ion approach has recently gained wider acceptance from members of the human critical care community, who have found it useful for the analysis of the complex fluid, electrolyte, and acid-base problems of patients in intensive care units. Several easy-to-use computer or calculator programs have been developed for the mathematically challenged that facilitate implementation of the strong ion approach to acid-base balance.

22.5 SERUM ENZYMES

Some of the common and less common causes of elevated serum enzyme activity are listed in Box 22-17.

22.5.1 Box 22-17 Causes of Elevated Serum Enzymes

22.5.1.1 ELEVATION OF SORBITOL DEHYDROGENASE (SDH)

22.5.1.1.1 Common Causes

- Severe anoxia
- Acute liver failure
- Liver abscess
- Secondary to damaged bowel
  - Strangulating intestinal lesion
  - Acute toxic enteritis
- Chronic liver failure

22.5.1.1.2 Less Common Causes

- Acute and severe anemia
- General anesthesia
- Anoxia

22.5.1.2 ELEVATION OF γ-GLUTAMYLTRANSFERASE (GGT)

22.5.1.2.1 Common Causes

- Acute liver failure
- Chronic liver failure
- Pyrrolizidine alkaloid toxicity

Aflatoxicosis

Cholangiohepatitis

Cholelithiasis

Liver flukes

22.5.1.2.2 Uncommon Causes

Higher normal range in young animals

Fatty liver

22.5.1.3 ELEVATION OF ALKALINE PHOSPHATASE (ALP)

22.5.1.3.1 Common Causes

Acute liver failure

Chronic liver failure

Pyrrolizidine alkaloid toxicity

Cholangiohepatitis

Cholelithiasis

Liver flukes

22.5.1.3.2 Uncommon Causes

Higher normal range in young animals

Fatty liver

22.5.1.4 ELEVATION OF CREATINE KINASE (CK)

22.5.1.4.1 Common Causes

Exertional rhabdomyolysis (azoturia, myositis, tying-up)

Polysaccharide storage myopathy

Streptococcus equi–associated myopathy

Nutritional myodegeneration (selenium, vitamin E deficiency)

Postendurance ride multisystemic disorder

Alert downer cow syndrome (muscle crush syndrome)

Malignant hyperthermia

Malignant edema

Prolonged recumbency with inability to rise

22.5.1.4.2 Uncommon Causes

Normal postexercise modest increase

Acute cardiomyopathy

Purpura hemorrhagica

Equine influenza

Sarcosporidiosis

Local irritation from intramuscular injections

22.5.1.5 ELEVATION OF LACTATE DEHYDROGENASE (LDH)

22.5.1.5.1 Common Causes

- Muscle disease
  - Exertional rhabdomyolysis (azoturia, myositis, tying-up)
  - Polysaccharide storage myopathy
- *Streptococcus equi*–associated myopathy
  - Nutritional myodegeneration (selenium, vitamin E deficiency)
  - Postendurance ride multisystemic disorder
  - Alert downer cow syndrome (muscle crush syndrome)
  - Malignant hyperthermia
  - Malignant edema
- Liver disease
  - Acute liver failure
  - Chronic liver failure
  - Cholangiohepatitis
  - Cholelithiasis
- In vitro hemolysis

22.5.1.5.2 Uncommon Causes

- Hemolytic anemia

Acute cardiomyopathy

Purpura hemorrhagica

Equine influenza

Sarcosporidiosis

Local irritation from intramuscular injections

Fatty liver

22.5.1.6 ELEVATION OF ASPARTATE AMINOTRANSFERASE (AST)

22.5.1.6.1 Common Causes

Muscle disease

Exertional rhabdomyolysis (azoturia, myositis, tying-up)

Polysaccharide storage myopathy

Streptococcus equi–associated myopathy

Nutritional myodegeneration (selenium, vitamin E deficiency)

Postendurance ride multisystemic disorder

Purpura hemorrhagica

Equine influenza

Sarcosporidiosis

Local irritation from intramuscular injections

Fatty liver

22.5.2 Sorbitol Dehydrogenase

SDH is a liver-specific enzyme in all large animal species, and increases in this enzyme indicate hepatocellular damage and leakage of enzymes. Increases in SDH also are seen with obstructive or strangulating gastrointestinal lesions and with acute toxic enteritis as a result of liver damage associated with absorption of bacteria or their toxins (or both) from the damaged bowel into the portal circulation. This enzyme is a sensitive indicator of liver damage, and modest increases may be seen with anoxia, acute anemia, or general anesthesia. The half-life of SDH in the circulation is short (a matter of hours), and elevations indicate active and ongoing liver damage. This enzyme is not stable when stored at room temperature, but refrigerated samples may yield useful results after several days of storage.

22.5.3 Creatine Kinase

CK is a highly sensitive and specific indicator of muscle damage in domestic animals. Although CK is found in both cardiac and skeletal muscle, elevations of this enzyme most commonly are associated with exertional myopathies (rhabdomyolysis) and also are seen as musculoskeletal manifestations of systemic disease. Intramuscular injections, vigorous exercise, or prolonged shipping may result in modest releases (up to a fourfold increase over resting values) of CK into the circulation without producing histologic evidence of muscle damage. Endurance exercise may lead to moderate elevation of CK (2000 to 15,000 IU/L) in some horses that show no recognizable sign of exertional myopathy. The half-life of this enzyme in the circulation is very short (2 hours in horses and 4 hours in cattle), and even marked elevations in CK may return to normal within 12 to 24 hours after a single muscle insult. Although marked elevation of CK can be a guide to the extent of muscle damage, the short half-life and the potential for continuing myonecrosis have a marked influence on the enzyme activity observed at any point in time. A persistent elevation of CK suggests a process resulting in active and continuing muscle damage and provides grounds for resting athletic horses. Elevated CK provides no information on the factors responsible for the rhabdomyolysis. Hemolysis may produce falsely high values for CK.

22.5.4 Aspartate Aminotransferase

AST is found in high concentration in a variety of tissues, including skeletal and cardiac muscles, the erythrocytes and kidneys, and the liver. This enzyme is a nonspecific indicator of tissue damage and tends to be less sensitive to mild insults than the tissue-specific enzymes SDH and CK. The half-life of AST in the circulation is relatively long, and elevations may persist for as long as 10 days after an episode of myonecrosis or liver damage. As a general rule, extensive muscle necrosis tends to produce much higher elevations of AST than severe liver necrosis. This enzyme is most useful when compared with the tissue-specific enzymes as determined sequentially over the time course of a disease process. Elevations of CK and AST indicate muscle damage, whereas elevations of SDH and AST indicate liver damage. Marked but transient elevations of CK and SDH are associated with a single insult to the muscles and liver, respectively, whereas AST increases gradually and remains elevated for a much longer time. Thus a moderate to marked increase in AST in an animal with progressively declining SDH or CK indicates that some tissue damage occurred within the past 7 to 10 days but also that the process may no longer be active. This often is a favorable prognostic indicator. Persistent elevation of or a progressive increase in CK or SDH and AST over time indicates an active, continuing process of tissue damage, and the prognosis is more guarded. AST is relatively stable at room temperature, but hemolysis or lipemia may interfere with the assay.

391

392

22.5.5 γ-Glutamyltransferase

GGT is an important marker of hepatobiliary disorders and cholestasis in large animals. GGT is quite stable, and reliable results can be obtained from samples submitted several days after blood samples have been drawn, provided the serum is refrigerated. The activity of this enzyme is highest in the cells of the periportal region of the liver, in the pancreas, and in the renal tubular cells. Pancreatic diseases resulting in inflammation and necrosis are relatively rare in large animal species. Damage to the renal tubular cells leads to a release of GGT into the tubular lumen and the urine. Because this enzyme is a relatively large molecule, it is not resorbed into the systemic circulation, and renal tubular damage does not result in elevated serum GGT activity. Increases in GGT relative to creatinine in the urine have been used as an index of acute renal tubular damage. However, the validity of the normal range for this ratio in horses has been questioned.

In large animal species an elevation in serum GGT is one of the more reliable indicators of damage to the liver and biliary obstruction. Disease processes such as pyrrolizidine alkaloid intoxication, chronic active hepatitis, cholangiohepatitis, and cholelithiasis produce liver damage, primarily in the periportal region, leading to marked and persistent elevation of GGT activity in the serum. In these instances, elevations in serum ALP activity generally are associated with the increase in GGT. Two syndromes, fatty liver syndrome in dairy cows and hyperlipemia syndrome of periparturient mares of pony and miniature horse breeds, are associated with liver damage, which is often reflected by elevation of GGT.

Most suckling neonatal large animals have high levels of GGT activity in their serum. This is the result of absorption of maternal GGT, which is present in relatively high levels in the colostrum. Elevation of GGT in neonates should be regarded as a normal finding unless it is associated with other evidence of liver disease. The normal range of serum GGT activity for burros, donkeys, and asses may be substantially higher (two to three times) than the normal range of serum GGT activity for horses. Caution should therefore be used when evaluating this enzyme in these species. Elevation in serum GGT activity has been reported in thoroughbred racehorses that are performing below expectations. The reasons for the increase in GGT are not known, but horses often respond to a period of rest or reduction in workload. These horses show little histologic evidence of liver damage, and other indices of liver damage and dysfunction usually are within normal limits. The stress of training may be associated with an elevated GGT. Certain trainers, often highly successful trainers, appear to have a disproportionately large number of horses with elevations of this enzyme. The normal range for GGT of thoroughbreds in race training may be slightly higher than that of normal sedentary horses.

22.5.6 Alkaline Phosphatase

ALP is used in most species as a marker for intrahepatic or extrahepatic obstruction of the biliary system. The enzyme is also released by osteoblasts from metabolically active bone. This may be the reason that young, rapidly growing animals normally have high levels of serum ALP. Elevations in ALP are also reported in cases of rickets and healing fractures. The intestinal isoenzyme of ALP is very similar to the ALP isoenzyme found in neutrophils. Elevations in the ALP activity of abdominal fluid in horses with intraabdominal disease may reflect the release of this enzyme from the neutrophils rather than being a specific marker of damage to the bowel.

ALP has been useful for evaluating liver disease in large animals, particularly in horses with pyrrolizidine alkaloid intoxication, chronic active hepatitis, and cholangiohepatitis, and in some patients with cholelithiasis. A profound elevation in ALP activity is thought to reflect periportal liver damage and biliary obstruction in these patients. A moderate to marked elevation in ALP may be observed in a wide range of disorders resulting in hepatic necrosis and intrahepatic cholestasis. Because this enzyme is not organ specific in large animals, elevations in ALP activity must be interpreted in relation to more organ-specific enzymes such as SDH and GGT.

22.5.7 Other Enzymes

Lactate dehydrogenase is found in relatively high concentrations in a variety of organs and tissues of the body from the heart, liver, muscle, and kidney to the erythrocytes and leukocytes. An elevation in serum LDH enzyme activity must be evaluated in relation to other, more organ-specific enzymes. LDH isoenzyme analysis can be helpful in differentiating organ system damage, but the analysis is time-consuming and not always available. An elevation in LDH activity is expected in hepatic necrosis and serves as an indicator of an active disease process. Extensive muscle damage and rhabdomyolysis tend to result in a more massive release of enzyme and much higher serum enzyme activity. A modest elevation in LDH may be seen in some hemolytic disorders and some

cases of leukemia. Blood samples must be handled with care, because hemolysis results in falsely elevated serum LDH activity.

Glutamic dehydrogenase and ornithine carbamoyltransferase are two enzymes that are reported to be sensitive indicators of hepatic necrosis in ruminants. Alanine aminotransferase (ALT) is an important liver-specific enzyme that has wide application in small animals and is often included in automated chemistry profiles. This enzyme has not been useful for evaluation of liver disease in large animal species, and occasionally horses with marked rhabdomyolysis and no other evidence of liver disease show an elevation in serum ALT activity.

22.6 BILIRUBIN

Bilirubin is a breakdown product of the heme component of the hemoglobin molecule. Bilirubin exists in the serum in two forms and is responsible for the yellow color known as *icterus,* or *jaundice,* of the mucous membranes. Unconjugated, prehepatic, albumin-bound bilirubin is also known as *"indirect-reacting" bilirubin,* as determined by the van den Bergh reaction. Indirect-reacting bilirubin must be taken up by the liver cells, where it is conjugated and then excreted in the bile. Conjugated bilirubin is known as *"direct-reacting" bilirubin,* as determined by the van den Bergh reaction. Horses normally have a much higher serum bilirubin level than ruminants, and hot-blooded horses have a higher bilirubin level than cold-blooded horses of the pony and draft breeds. The horse also differs from ruminants in that horses often develop moderate icterus in response to fasting or anorexia associated with 392
many systemic diseases. The increase in the bilirubin concentration in these horses is caused almost entirely by an 393
increase in unconjugated (indirect-reacting) bilirubin, and within a few days the bilirubin can increase from the normal range up to 6 to 8 mg/dL. Therefore the total serum bilirubin concentration is of little diagnostic value in the ill horse unless both the direct- and indirect-reacting bilirubin values are determined.

Total serum bilirubin is elevated in animals with hemolytic anemia, and this increase is caused largely by an increase in indirect-reacting bilirubin (Box 22-18). The degree to which bilirubin is elevated in hemolytic anemia is a function of the rate of red cell destruction and the capacity of the liver to excrete the newly formed bilirubin. The total bilirubin rarely exceeds 10 mg/dL in hemolytic anemia. An exception is the hemolytic anemia of neonatal isoerythrolysis in newborn foals, which often is associated with marked clinical icterus. In these foals the serum bilirubin may exceed 25 mg/dL, a variable but substantial proportion of which (40% to 60%) is likely to be direct-reacting bilirubin.

The second major cause of clinical icterus and increased serum bilirubin is liver failure. Liver failure results in impaired uptake and excretion of bilirubin. Acute liver failure caused by hepatic necrosis results in marked to moderate increases in both direct- and indirect-reacting bilirubin. In horses with acute liver failure, bilirubin often exceeds 10 mg/dL, and this increase is caused primarily by increases in indirect-reacting bilirubin. Direct-reacting bilirubin rarely exceeds 25% of the total bilirubin in the horse, and increases of this magnitude suggest an intrahepatic or extrahepatic biliary obstruction. With chronic liver failure, icterus is more variable, and total bilirubin rarely exceeds 10 mg/dL. Liver failure in ruminants, particularly chronic liver failure, is associated with a much less striking elevation in serum bilirubin than occurs in horses. In the absence of hemolytic anemia, a bilirubin value above 2 mg/dL indicates impaired hepatic function in ruminants.

22.7 GLUCOSE

The concentration of glucose in the blood normally is regulated by the hormones insulin and glucagon, but it is influenced by several other factors as well.

22.7.1 Hypoglycemia

Fasting usually does not result in hypoglycemia except in neonatal animals (Box 22-19). Newborns have limited energy reserves, and any disease, injury, congenital defect, maternal rejection, agalactia, or management error that limits energy intake can result in marked hypoglycemia associated with profound depression, even coma. Rapid, semiquantitive field tests for blood glucose (Dextrostix* and Chemstrip BG†) provide a practical means of early recognition of this problem. Hypoglycemia may be seen in animals with acute toxic enteritis, coliform mastitis, septicemia, and colic associated with strangulated bowel, as well as in the later stages of endotoxemia and in some horses with exhaustion after prolonged exercise. Hypoglycemia is a reasonably consistent feature with primary ketosis and fat cow syndrome in cattle, with pregnancy toxemia in sheep and goats, and in hyperlipemia syndrome, which is seen primarily in pregnant or lactating ponies.

* Ames Division, Miles Laboratories, Inc., Elkhart, Ind.

† Boehringer Mannheim Diagnostics, Inc., Indianapolis, Ind.

22.7.2 Hyperglycemia

Hyperglycemia may be seen with excitement, transportation, or stress and probably is mediated by increases in catecholamine and glucocorticoid hormones (Box 22-20). The stress and pain of acute severe colic in horses frequently results in hyperglycemia, and elevations of blood glucose above 250 mg/dL are associated with a poor prognosis in such cases. Endotoxemia initially results in a transient hyperglycemia that may be followed by marked hypoglycemia in the terminal stages of the toxemia. The later stages of Cushing's syndrome in horses generally are associated with a non—insulin-responsive hyperglycemia and glycosuria. Similar changes can be induced transiently when exogenous glucocorticoid hormones are administered at a high dose rate. Insulin-responsive diabetes mellitus rarely occurs in large animals but has been reported in association with destructive pancreatic lesions.

22.8 CREATININE

Creatinine is derived from the cyclic use of phosphocreatine, the muscle energy store, resulting in the production of inorganic phosphate and creatinine. In the resting animal this process occurs at a relatively constant rate. The absolute muscle mass and level of physical activity may influence the rate of creatinine production and thus the serum concentration. Starvation, with loss of muscle mass, may result in a slightly reduced serum creatinine level, whereas serum creatinine may be slightly higher in muscular, athletic individuals than in sedentary animals.

Creatinine is distributed throughout the body water and is not reused. Creatinine is normally excreted by the kidneys, primarily by glomerular filtration. In azotemic patients a substantial part of creatinine is metabolized and excreted by nonrenal routes. Serum or urine creatinine concentrations determined by the standard alkaline picrate reaction may be falsely elevated by the presence of noncreatinine chromogenic compounds in the serum. These chromogens include glucose, fructose, ascorbic acid, hippuric acid, urea, ketones, and several other compounds. The contribution of these compounds can be reduced or eliminated, and most automated chemical laboratories use such methodology. However, if inappropriately high creatinine is reported in patients without other evidence of renal failure, the method of creatinine measurement should be ascertained.

Alterations in renal blood flow caused by decreases in effective circulating fluid volume (hypovolemia) produce an elevation in serum creatinine and BUN; this can be considered a prerenal azotemia (Box 22-21). It occurs with some frequency in animals with acute enteritis, peritonitis, acute heart failure, massive blood loss, and some forms of colic and in horses with exhaustive disease syndrome. An important point is that many of these disorders initiate the release of inflammatory mediators, which may cause renal damage and impaired renal function above and beyond that associated with impaired renal blood flow and hypovolemia. Prerenal azotemia usually is seen in animals that are dehydrated and volume depleted and that have a history of loss or compartmentalization of sodium-containing fluid. Prerenal azotemia often can be marked (creatinine level above 6 mg/dL), but if uncomplicated, it generally responds rapidly to fluid replacement therapy. Urine production, the urine sodium concentration, and the fractional excretion of sodium usually are low, and the urine specific gravity usually is elevated. The ratio of urine to plasma urea or creatinine, as well as the urine-to-plasma ratio of osmolality, are reported to be higher in horses with prerenal azotemia compared with renal azotemia.[16]

The serum creatinine concentration provides a crude measure of the glomerular filtration rate. However, serum creatinine, like BUN, is not a very sensitive or early indicator of changes in renal function. In ruminants, creatinine is a more reliable indicator of renal failure than BUN. Urea nitrogen can be secreted in saliva and metabolized by the ruminal microflora; this frequently results in a disparity between BUN and creatinine levels in ruminants with renal failure. Although small increases in creatinine may be seen with progressively compromised renal function, nearly two thirds to three fourths of the nephrons must be nonfunctional before the serum creatinine level clearly exceeds the normal range. Both acute and chronic renal failure are usually associated with elevated creatinine. Acute renal failure, especially in animals with anuria or oliguria, is usually associated with progressive daily changes in blood parameters. In contrast, blood parameters of animals with chronic renal failure tend to remain relatively constant. A transient but markedly elevated serum creatinine has been observed in some newborn foals that have no other evidence of compromised renal function. Many of these foals are born to mares that had medical problems before parturition. Alterations in placental function may allow the accumulation of creatinine in the foal's circulation. In most of these otherwise normal foals this marked elevation in serum creatinine resolves within the first few days of life.

22.8.1

Box 22-21 Causes of Elevated Creatinine

22.8.1.1

COMMON CAUSES

Prerenal azotemia

Reduced renal perfusion

Hypovolemia

Congestive heart failure

Dehydration after endurance exercise

Renal azotemia

Acute renal failure

Chronic renal failure

Postrenal azotemia

Urolithiasis

Renal calculi

Ureteral calculi

Urethral calculi

Ruptured bladder

22.8.1.2 UNCOMMON CAUSES

False azotemia

Noncreatinine chromogens in serum or plasma

Perirenal abscess

Renal carcinoma

Renal dysgenesis

Carcinoma of the bladder

Postexhaustion multisystemic syndrome in horses

Severe exertional rhabdomyolysis with myoglobinuria

Severe intravascular hemolysis with hemoglobinuria

Intoxication or poisoning

Heavy metal poisoning

Nonsteroidal antiinflammatory drug intoxication

Aminoglycoside intoxication

22.9 BLOOD UREA NITROGEN

The term *blood urea nitrogen* is ingrained in the veterinary literature, despite the fact that urea nitrogen determinations usually are performed on serum or plasma samples. This is of little consequence, because the actual difference in urea concentrations of whole blood and serum or plasma is relatively small. Urea provides a nontoxic means of excreting ammonia generated by amino acid catabolism and the intestinal microflora. It is distributed throughout the body water. In the intestine, urea is broken down by urease, which is produced by the intestinal microflora, and the nitrogen, as ammonium ion, is recycled to the liver. Urea is excreted by the kidneys, primarily by glomerular filtration.

394

395

22.9.1 Box 22-22 Causes of Decreased Blood Urea Nitrogen

22.9.1.1 COMMON CAUSES

Liver failure

Neonatal animals (BUN is normally lower than in adults)

22.9.1.2 UNCOMMON CAUSES

Low-protein diet

Anabolic steroid administration

Urea production occurs almost exclusively in the liver, and liver failure is frequently associated with a decrease in BUN (Box 22-22). Urea nitrogen tends to be low in nursing animals because of their high fluid intake and urine output and their anabolic state of rapid growth. Urea nitrogen may be reduced slightly in animals given anabolic steroids or fed diets low in protein but of adequate calorie content.

Starvation or other processes that result in rapid tissue catabolism such as fever, burns, or corticosteroid administration may result in modest increases in BUN (Box 22-23). BUN, along with creatinine, provides a crude index of altered renal function in most animal species. BUN is influenced more directly by dietary factors than is creatinine, and creatinine is generally a better guide to renal failure. This is particularly true in ruminants, in which BUN may remain within normal limits in animals with marked impairment of renal function. With these considerations in mind, the discussion of prerenal, renal, and obstructive causes of azotemia in the section on creatinine apply to BUN.

22.10 SERUM PROTEIN

The serum or plasma proteins consist of albumin and globulin fractions. These are discussed in Chapter 26.

Nonsteroidal antiinflammatory drug intoxication

Aminoglycoside intoxication

22.11 URINALYSIS

Urinalysis can be an extremely useful diagnostic tool, providing information on many systemic disorders. It is essential in the evaluation of primary renal disease. Urine normally is collected as a voided sample or after catheterization. Voided urine samples are safe and easy to collect but are easily contaminated. Catheterization is preferred for bacteriologic evaluation, but the resultant mild trauma may result in a slight increase in urine red cells and protein. Because of the urethral diverticulum at the level of the pelvis, it is difficult to successfully catheterize male ruminants. Urethral obstruction is common in male small ruminants, and percutaneous aspiration may be the

only way to obtain a urine sample in affected animals. Urinalysis should be performed as soon after collection as possible (within 30 minutes) to avoid degeneration of cellular elements, changes in pH, or bacterial overgrowth. If this is not possible, samples should be refrigerated. Urine volume and composition are influenced by feed and water intake, salt supplementation, environmental factors, exercise, stress, systemic disease, and drug administration. Urine samples collected after administration of a diuretic are dilute and unsuitable for routine urinalysis. The tranquilizer xylazine, which is often used to assist in the catheterization of male horses, may alter the results of the urinalysis because it produces diuresis as a result of glycosuria.

22.11.1 Specific Gravity

Specific gravity is defined as the weight of urine relative to the weight of distilled water. The specific gravity of serum is approximately 1.008 to 1.012. The urine specific gravity is an indicator of renal function, because it reflects the action of the renal tubules and collecting ducts on the glomerular filtrate by providing an estimation of the number of particles dissolved in the urine. It is usually measured by refractometry. Urine dipsticks with reagent pads for estimating the urine specific gravity in humans should not be used for this purpose in domestic animals, because a poor correlation has been reported compared with refractometry in large animals.[26] Normal animals have the capacity to dilute their urine specific gravity to less than 1.010 and to concentrate to greater than 1.050. The normal range reported for most adult large animals is 1.020 to 1.050. Suckling neonatal animals normally produce a very dilute urine with a specific gravity below 1.010. Although this could represent immature renal function, it more likely reflects their high-volume fluid intake, because normal neonates can concentrate their urine if fluids are withheld.

Failure to produce a concentrated urine, as reflected by a specific gravity below 1.020, in the face of dehydration is an indication of altered renal function, which may be caused by primary renal disease, diabetes insipidus, medullary washout, or nephrogenic diabetes insipidus. With severe and chronic sodium depletion, tubular sodium may be insufficient to sustain normal countercurrent mechanisms for water resorption. This process is called *medullary washout* and has been reported as a cause of polyuria in lactating dairy cattle on a salt-deficient diet. At least 50% of renal function must remain for highly concentrated urine to be produced. Isosthenuria, a urine specific gravity that remains around 1.010 despite variation in hydration, occurs when renal disease progresses to the point at which renal function is reduced to less than a third of normal. Altered renal function in these animals is usually reflected by a moderate to marked elevation in BUN and creatinine levels and by other changes in the urinalysis. Hyposthenuria occurs when the specific gravity remains below 1.010; this indicates altered release of or response to antidiuretic hormone, as occurs with diabetes insipidus, medullary washout with chronic sodium depletion, nephrogenic diabetes insipidus, psychogenic polydipsia, and chronic liver failure in some horses.

395

396

22.11.2 pH

The normal range of urine pH for adult herbivores is alkaline, with values ranging from 7 to 9. Neonatal foals tend to have a slightly acid urine with a pH below 7. Aciduria in adults may be seen in postrace samples collected from racehorses, after prolonged fasting, with ketosis in ruminants, or in response to metabolic acidosis. A paradoxic aciduria frequently is seen in ruminants with hypochloremic, hypokalemic metabolic alkalosis, as was explained earlier. Urine pH is also influenced by the cation-anion balance of the diet.

22.11.3 Protein

Protein normally is not detected in urine, although a false-positive protein reaction may be noted on urine dipsticks if the sample is strongly alkaline. Urine with a positive reaction for protein on dipsticks should be checked for protein by a chemical method. Proteinuria should be evaluated in relation to the other findings in the urinalysis. Persistent and strongly positive reactions for protein in the absence of leukocytes, red cells, bacteria, or casts suggest glomerular protein loss, as in glomerulonephritis or amyloidosis. The presence of bacteria and leukocytes with proteinuria suggests sepsis in the urinary tract, whereas hemorrhage or inflammation in the urogenital tract often is associated with proteinuria.

22.11.4 Glucose

Glucose is not found in the urine of normal large domestic animals unless the blood glucose level increases above the renal threshold, which is thought to be approximately 100 to 140 mg/dL in ruminants and approximately 160 to 180 mg/dL in horses. The causes of hyperglycemia and glycosuria were described in a previous section; they include Cushing's syndrome, stress, and catecholamine or glucocorticoid hormone release. Hyperglycemia and glycosuria can be created iatrogenically when glucose-containing fluids are administered at an excessive rate. Glycosuria is a fairly consistent finding in sheep with enterotoxemia type D (pulpy kidney). The presence of glycosuria without hyperglycemia strongly suggests renal tubular damage resulting from a toxic or ischemic insult.

22.11.5 Occult Blood

Both myoglobin and hemoglobin give a positive reaction on urine occult blood dipsticks. In most instances proteinuria shows a positive result as well. A tentative clinical impression sometimes can be formed to differentiate myoglobin from hemoglobin in dark urine if the sample is shaken vigorously in a closed, transparent container. Myoglobin tends to produce a brown foam, whereas hemoglobin produces a reddish foam. Hemoglobinuria caused by intravascular hemolysis is generally associated with clinical and hematologic evidence of a hemolytic anemia. Hematuria may result in a positive occult blood reaction if lysis of some of the intact red blood cells has occurred. This is likely to happen if the urine is very dilute or if it is held at room temperature for an extended period before analysis. False-positive reactions can occur if microbial peroxidase or oxidizing contaminants are present.

22.11.6 Myoglobin

Myoglobinuria should be associated with clear clinical and clinicopathologic evidence of extensive muscle damage. The ammonium sulfate precipitation method of differentiating hemoglobin from myoglobin is imprecise and frequently fails to detect myoglobin in the dark, coffee-colored urine of horses with severe rhabdomyolysis. Accurate differentiation of these compounds in urine requires more sophisticated procedures.

22.11.7 Cells

The normal range for cells generally is considered to be up to five red cells or leukocytes per high-power field. An increased number of erythrocytes indicates hematuria, which may be caused by neoplasia, trauma, inflammation, or coagulopathy. Pyuria, an increase in urine leukocytes, indicates an inflammatory process, and

when associated with bacteriuria it indicates a septic process in the urinary tract. The presence of sheets or rafts of transitional cells suggests neoplasia.

22.11.8 Casts

Casts are accumulations of protein and cellular material that form in the renal tubules, and when present in the urine, they indicate renal damage or tubular disease. Casts can consist of erythrocytes, leukocytes, or renal tubular cells. As cellular degeneration proceeds, the cell type is more difficult to determine, and the casts become granular and then waxy. Hyaline casts are noncellular and are formed from mucoprotein. They may be seen with glomerulonephritis, fever with passive congestion, or severe dehydration with altered renal blood flow.

22.11.9 Crystals

The crystalline structures in the urine of large animals are those usually associated with an alkaline urine. Calcium carbonate crystals normally are found in abundance in horse urine, particularly if the horse has been fed alfalfa hay. Triple phosphate and calcium oxalate crystals are frequently observed in relatively small numbers. The major crystals involved in urolithiasis of feedlot cattle is struvite ($Mg\ NH_4PO_4 \cdot 6H_2$). In the western United States silicate stones are most common in livestock under range conditions. Carbonate and oxalate stones are common causes of urolithiasis in small flocks of backyard sheep and goats fed alfalfa hay.

22.11.10 Bacteria

Bacteria sometimes are seen in small numbers in voided urine samples and may represent surface contaminants. Bacterial infections of the urinary tract usually are associated with significant pyuria. When this is noted, a catheterized sample (horse) or clean midstream catch (ruminant) should be obtained for Gram stain, culture, and sensitivity testing. Results from ruminant samples must be carefully interpreted, because male ruminants routinely urinate within the prepuce, thus heavily contaminating samples. Fortunately, urinary tract infections in male ruminants and horses are rare.

22.11.11 Urine Creatinine Clearance Ratio

Urinary electrolyte excretion is affected by a variety of factors, including dietary intake, alterations in renal function, and specific hormones that regulate renal electrolyte excretion. Determination of electrolyte concentrations from randomly collected urine samples is easily done and can be clinically useful when these concentrations are compared with serum concentrations. The presence of substantial amounts of sodium in the urine of an animal with hyponatremia suggests excessive renal sodium loss caused by altered renal function or hormonal control. However, marked variation in the rate of urine production can lead to serious problems in the interpretation of urine electrolyte concentrations. The standard physiologic methods of determining renal electrolyte clearance are complicated by the need for quantitative urine collection and are not well suited to most practical clinical situations. One means of overcoming these difficulties is expression of the renal electrolyte clearance relative to the endogenous creatinine clearance. Expression of the renal clearance as a ratio eliminates the need for quantitative urine collection. This derived value is known as the *creatinine clearance ratio* or the *fractional excretion* (FE) and is calculated by the following formula:

396
397

$$FE = \frac{\text{Urine}(X)}{\text{Serum}(X)} \times \frac{\text{Serum}(C)}{\text{Urine}(C)} \times 100$$

where *X* represents the electrolyte concentration and *C* represents the creatinine concentration.

The FE fluctuates somewhat during the day in relation to physical activity and feed and water intake. However, under standardized conditions, there is close agreement between the FE determined from single random samples of blood and urine and that based on samples quantitatively collected during a 12- to 24-hour period.[16] The FE of electrolytes has a very wide range of normal values. The principal sources of this variation are differences in dietary intake and environmental or experimental conditions. The FE of electrolytes has been useful for detecting specific dietary deficiencies or imbalances. Dietary salt deficiency is associated with an extremely low FE of sodium and chloride, whereas the plasma concentration of these ions generally remains within normal limits. In a similar fashion, dietary calcium and phosphorus imbalances seldom are reflected by the serum concentrations of these ions. Calcium deficiency and phosphorus excess are relatively common dietary problems in large animals and result in a low FE for calcium and a high FE for phosphorus. There are technical problems with the determination of the urine calcium concentration in horses because of their normally alkaline urine and the resultant precipitation of calcium carbonate in the urine. Mixed urine samples from horses must be acidified (hydrochloric acid can be used) to solubilize the calcium.

Increases in the FE of sodium are noted with renal tubular damage and impaired sodium resorption. The sodium FE increase has been a useful indicator for the differential diagnosis of prerenal azotemia, which almost invariably results in a low sodium FE, from the azotemia caused by primary renal disease, in which the FE for sodium often is markedly increased.

23 Chapter 23 Collection and Submission of Samples for Cytologic and Hematologic Studies

Debra Deem Morris

23.1 BLOOD

Accurate assessment of hematologic data depends heavily on the proper collection, preparation, and transportation of blood samples. Factors that must be considered are the most appropriate venipuncture site, proper restraint, the correct technique, the type of anticoagulant, the necessary volume of blood, and the handling of the samples before laboratory analysis. Many of these factors are determined by the test or tests to be performed.

23.1.1 Venipuncture Site and Technique

Because they are large and easily accessible, the jugular veins most often are used in horses and small ruminants. In adult cattle the subcutaneous abdominal (milk) vein and coccygeal (tail) vein also are easily accessible. The disadvantages of using a milk vein are the danger to the operator and the relatively common occurrence of hematomas. In horses, alternate sites for collection are the cephalic, lateral thoracic, and saphenous veins.

Blood should be drawn from animals at rest under conditions of least excitement to minimize physiologic variations in cell counts. Evacuated tubes (Vacutainer*) that contain the appropriate anticoagulant and their needles are most convenient for collecting blood. These tubes must be filled to capacity to ensure the proper blood-to-anticoagulant ratio. The chosen vein is raised by digital occlusion proximally; an 18- to 20-gauge, 1½- to 2-inch needle is then plunged through the skin into the vein at approximately a 30-degree angle. A clean venipuncture is important to avoid contamination of the blood by tissue thromboplastin, which encourages clot formation and invalidates hemostatic function tests.

The coccygeal vein in cattle is punctured between the sixth and seventh coccygeal vertebrae, where the caudal folds end[1] with the tail directly over the animal's back. The needle is inserted at a right angle to the skin to bone and then is withdrawn gradually while vacuum is applied to the syringe until sufficient blood has been obtained. This technique should not be used to collect blood for hemostatic testing.

Blood for hemostatic tests should be carefully transferred to the anticoagulated vial to prevent hemolysis. Because goat erythrocytes are very sensitive to hemolysis, a Vacutainer is not recommended for blood collection in goats.[2]

* Becton Dickinson, Inc., Rutherford, NJ.

23.1.2 Anticoagulants

An anticoagulant must be added to all blood samples collected for hematologic examination, because cell counts and morphology cannot be evaluated in clotted blood. Commonly used anticoagulants include ethylenediamine tetraacetic acid (EDTA), heparin, and sodium citrate. The minimum amount of blood needed for most routine blood studies is 2 mL. Regardless of the volume withdrawn, the proper blood-to-anticoagulant ratio must always be maintained.

The preferred anticoagulant for the complete blood count (CBC) is EDTA at a concentration of 1 to 2 mg/mL. An excessive EDTA concentration causes erythrocyte shrinkage and may invalidate the packed cell volume, mean corpuscular volume, and mean corpuscular hemoglobin concentration.[2] Vacutainers contain the appropriate amount of EDTA for the full volume of blood; therefore these tubes should be allowed to fill until the vacuum stops. In addition to the CBC, EDTA-anticoagulated blood is suitable for platelet counts, total plasma protein levels, and plasma fibrinogen determinations.

Trisodium citrate (3.8% aqueous solution) is used to anticoagulate blood to be used for hemostatic function tests.[3] It should be used in a 1:9 proportion with blood.

23.1.3 Handling and Transportation of Samples

The vial containing blood and anticoagulant should be inverted several times to ensure adequate mixing. Blood samples for hematologic studies (CBC) are best processed as soon as possible after collection. If delay is expected, the samples should be refrigerated at 4° C (39.2° F). Air-dried blood smears for the differential count should be prepared immediately if samples must be held longer than 2 hours. If refrigerated, the remainder of the blood sample produces an acceptable CBC for 24 hours. Cold packs and an insulated container should be used to transport blood samples to a laboratory. Blood smears can be held for several days before staining with Wright stain or any modified Romanovsky stain.

Blood samples for laboratory examination of the hemostatic system must be collected and handled with special care to prevent platelet clumping and activation of coagulation. If blood is collected into a Vacutainer, discarding the first tube ensures that the sample does not contain tissue fluids.[3] Optimally the samples are placed on ice and delivered to the laboratory within 1 hour of collection. If the sample must be stored for several hours, plasma should be collected immediately by centrifugation (800 to 1000 g for 15 minutes), harvested with a plastic pipette, and frozen, preferably at −70° C (−94° F). Platelet counts must be performed immediately. The platelet count may be estimated by examining a peripheral blood smear and comparing the number of platelets per oil immersion field with the number of red or white cells.

398
399

23.2 BONE MARROW

Air-dried smears can be made directly from a bone marrow aspirate or after the sample has been anticoagulated with EDTA. Because the volume of most aspirates is less than 0.5 mL, it is better to collect the sample in a syringe containing 1 to 2 drops of EDTA solution than to place it in a tube containing proportionately too much anticoagulant. Anti coagulant may not be required if smears can be made immediately after collection. These aspirates and smears should be handled as outlined for blood samples to be used for hematologic studies.

A bone marrow core must be preserved by placing it in a 10% neutral buffered formalin solution. Impression smears may be made from these samples by gently rolling them on a clean glass slide before placing them in the formalin solution.

23.3 LYMPH NODE ASPIRATES

Air-dried smears of lymph node aspirates are handled in the same manner as blood smears for the differential count.

24 Chapter 24 Alterations in the Erythron

Debra Deem Morris

The erythron is composed of all data pertaining to erythrocytes in the peripheral blood. In most instances the routine complete blood count (CBC), which includes microscopic evaluation of a blood smear, provides the data discussed in this chapter. After evaluation of the CBC, additional data on the erythroid compartment may be necessary, such as can be obtained from staining for Heinz bodies, the Coombs' test, or the erythrocyte fragility test. All pertinent tests associated with erythroid diseases are discussed in this chapter except bone marrow analysis.

Any description of hematologic alterations in large animals would be incomplete without a brief discussion of the unique features of the equine erythron. To correctly interpret hematologic data, the practitioner must appreciate the characteristics that distinguish the horse from other domestic animals.

1 *Unstable packed cell volume (PCV)*. The horse has a highly innervated muscular spleen that normally contains up to one third of the potentially circulating red cell mass. On adrenergic stimulation (which normally accompanies exercise, excitement, or blood loss), the spleen contracts and releases its reservoir of erythrocytes into the peripheral circulation, causing the PCV to increase by as much as 50%. For this reason the resting PCV of horses is highly unstable and must be evaluated serially under different levels of excitement. Also, the response of the spleen to massive hemorrhage precludes using the PCV to estimate the magnitude of blood loss for at least 24 hours.

2 *Rouleau formation*. Equine erythrocytes show a tendency for marked rouleau formation (aligning like stacked coins), which causes cells to separate rapidly from plasma (high erythrocyte sedimentation rate). This characteristic necessitates thorough mixing of blood in the sample vial before analysis and must be differentiated from autoagglutination (see p. 402).

3 *Icteric plasma*. Although hyperbilirubinemia causes plasma to become more intensely yellow or orange, equine plasma is normally yellow (icteric).

4 *Lack of peripheral signs of regeneration*. Equine erythrocytes are retained in the bone marrow until hemoglobin synthesis is complete; thus polychromasia (reticulocytosis), macrocytosis, and other peripheral blood signs of bone marrow regeneration are extremely rare in horses. The erythron of anemic horses cannot be assessed by peripheral blood alone.

5 *Howell-Jolly bodies*. Small numbers of these eccentric erythrocytic inclusions normally are found in equine blood. Their presence does not indicate a responsive anemia, as in other species.

24.1 ANEMIA

Anemia is functionally defined as decreased oxygen-carrying capacity of the blood. The most accurate laboratory indication of anemia is a drop in the PCV or hematocrit below the normal range. The PCV must always be interpreted in light of the animal's hydration status and level of excitement, especially in horses. Because goats have very small erythrocytes (Table 24-1), the PCV in these animals must be determined by microhematocrit centrifugation (12,000 g for 5 minutes) to prevent plasma trapping in the erythrocyte column.[1] This is the most accurate method of PCV determination in all species.

The three pathophysiologic mechanisms for the development of anemia are blood loss, increased erythrocyte destruction (hemolysis), and inadequate erythrocyte production. In the first two instances the bone marrow is normal and responds by increased erythropoiesis (regenerative or responsive anemias). In ruminants, regenerative anemias are attended by the appearance of immature erythrocytes in the peripheral blood. Inadequate erythrocyte production is caused by a bone marrow abnormality, and by definition the anemia is nonregenerative. Often anemia in large animals is caused by a combination of pathophysiologic mechanisms (Boxes 24-1 and 24-2).

24.1.1 Alteration in Mean Corpuscular Volume

The mean corpuscular volume (MCV) is a reflection of mean erythrocyte size, as expressed in the following equation:

$$\text{MCV (fl)} = \frac{\text{Hematocrit} \times 10}{\text{Erythrocyte count (millions / } \mu\text{L)}}$$

An *increased* MCV (macrocytosis) indicates a regenerative anemia, because immature erythrocytes are larger than mature ones. Iron deficiency results in a *decreased* MCV (microcytosis), because cells undergo an extra division as a result of inadequate hemoglobin concentration. Inadequate spinning of blood causes a spurious elevation of the MCV by trapped plasma. This is most commonly a problem in goats.

Table 24-1 Normal Values for Erythron Data in Ruminants and Horses

	Cattle	Sheep	Goats	Horses
PCV (%)	24-46	27-45	22-38	32-53
Erythrocytes ($\times 10^6$/L)	5-10	9-15	8-18	6.7-12.9
Hemoglobin (g/dL)	8-15	9-15	8-12	11-19
MCV (fl)	40-60	28-40	16-25	37-58.5
MCH (pg)	11-17	8-12	5.2-8	12.3-19.7
MCHC (g/dL)	30-36	31-34	30-36	31-38.6
Reticulocytes	0	<0.5%	0	0
Erythrocyte diameter (m)	4-8	3.2-6	2.5-3.9	5-6
Erythrocyte fragility (percent NaCl)				
Minimum (beginning hemolysis)	0.52-0.66	0.58-0.76	0.74	0.54
Maximum (complete hemolysis)	0.44-0.52	0.40-0.55	0.44	0.34
Erythrocyte sedimentation rate (mm/1 hr)	0	1-2.5	0	50-60
Erythrocyte life span (days)	160	140-150	125	140-150

MCH, Mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *NaCl,* sodium chloride; *PCV,* packed cell volume.

24.1.1.1

Box 24-1 Causes of Anemia in Horses

24.1.1.1.1

COMMON CAUSES

24.1.1.1.1.1

Through Blood Loss

Intestinal parasitism (strongylosis)

Ectoparasites (lice, ticks)

Gastric ulcers

Immune-mediated thrombocytopenia

Gastric squamous cell carcinoma

Equine purpura hemorrhagica

24.1.1.1.1.2 Through Hemolysis

Neonatal isoerythrolysis

Equine infectious anemia

Red maple leaf toxicosis

Equine ehrlichiosis

24.1.1.1.1.3 Through Inadequate Erythrocyte Production

Abdominal abscess or other chronic abscess

Chronic pneumonia or pleuritis

Equine purpura hemorrhagica

Equine ehrlichiosis

Lymphosarcoma

24.1.1.1.2 LESS COMMON CAUSES

24.1.1.1.2.1 Through Blood Loss

Disseminated intravascular coagulation

Moldy sweet clover toxicosis

Warfarin toxicosis

Hemophilia A or other congenital factor deficiencies

Guttural pouch mycosis

24.1.1.1.2.2 Through Hemolysis

Onion toxicosis

Autoimmune hemolytic anemia

Babesiosis (piroplasmosis)

Clostridial infections

Incompatible blood transfusion

24.1.1.1.2.3 Through Inadequate Erythrocyte Production

Myelogenous leukemia

Equine viral arteritis

Chronic renal failure (glomerulonephritis)

Radiation toxicosis

Idiopathic aplastic anemia

24.1.2 Alteration in Mean Corpuscular Hemoglobin

The mean corpuscular hemoglobin (MCH) is an estimation of the amount of hemoglobin (Hb) in the blood per erythrocyte. It is calculated according to the following equation:

$$\text{MCH (pg)} = \frac{\text{Hb (g/dL)} \times 10}{\text{RBC count (millions/}\mu\text{L)}}$$

An *increased* MCH may indicate (1) the presence of reticulocytes (immature erythrocytes) in the peripheral blood or (2) hemolysis, either in vivo *or* in vitro. Iron deficiency results in a *decreased* MCH.

24.1.3

Alteration in Mean Corpuscular Hemoglobin Concentration

The MCH concentration (MCHC) is the most accurate of erythrocytic indices. It can be expressed as a percentage or in grams per deciliter:

$$\text{MCHC}(\%) = \frac{\text{Hb}(g/dL) \times 100}{\text{Hematocrit}(\%)}$$

Reticulocytosis (erythroid regeneration) or iron deficiency results in a *decreased* MCHC; hemolysis (in vivo or in vitro) causes an *increased* MCHC. Inadequate spinning of blood produces a spurious reduction in MCHC.

401

Bracken fern toxicosis (also hemorrhage in enzootic hematuria)

Radiation toxicosis

Myelofibrosis (pygmy goats)

B, Bovine; *O*, ovine.

24.1.4 Anisocytosis

Variation in the size of erythrocytes is caused by the presence of macrocytes or microcytes (or both) among normal cells. Slight to moderate anisocytosis is normal in cattle, but marked anisocytosis in ruminants is a sign of regenerative anemia. Macrocytic erythrocytes may be seen at the peak of erythrocyte release during equine regenerative anemia, but in most horses effective regeneration occurs without macrocytosis.[2]

24.1.5 Polychromasia

Variation in color among the cells (using Romanovsky stains) is caused by the presence of reticulocytes that stain bluish because of residual DNA. In ruminants, polychromasia is a sign of regenerative anemia. Reticulocytosis can be quantitated most accurately by using new methylene blue stain, which causes cytoplasmic DNA to appear as blue granules. Insufficient cellular hemoglobin caused by iron deficiency results in decreased staining intensity and increased central pallor of erythrocytes (hypochromia). Hypochromia is difficult to recognize in large animals because their erythrocytes are small.

24.1.6 Poikilocytosis

The presence of abnormally shaped erythrocytes indicates increased erythrocyte fragility or diseases characterized by erythrocyte fragmentation. In rare cases, poikilocytosis may accompany iron deficiency or disseminated coagulopathy in large animals.

24.1.7 Basophilic Stippling

Tiny blue granules occasionally are observed in Romanovsky-stained erythrocytes containing residual DNA. This is a normal feature of regenerative anemia in cattle and sheep. In cattle, basophilic stippling also may indicate chronic lead poisoning.

24.1.8 Howell-Jolly Bodies

Basophilic nuclear remnants commonly are seen in immature erythrocytes during responsive anemia in ruminants. In healthy horses a few Howell-Jolly bodies occur normally.

24.1.9 Nucleated Erythrocytes

Nucleated erythrocytes and metarubricytes occasionally appear in the peripheral blood during the responsive phase of severe anemia in ruminants.

24.1.10 Heinz Bodies

Oxidative stress to erythrocytes causes denaturation of hemoglobin, which precipitates as aggregates, called *Heinz bodies*. Heinz bodies appear as round structures projecting from one edge of the red cell and are most easily visible on new methylene blue preparations. Erythrocytes containing Heinz bodies are susceptible to

intravascular hemolysis and removal in the mononuclear phagocyte system (MPS). Heinz body hemolytic anemia is seen in cattle that have ingested toxic amounts of onions or plants of the *Brassica* genus. Horses develop Heinz body anemia in association with toxicoses caused by phenothiazine, red maple leaves, and, in rare cases, onions.

24.1.11 Autoagglutination

Aggregation of erythrocytes may be observed grossly or microscopically during immune-mediated anemia in horses or cattle. Marked rouleau formation, which occurs normally in horses, may be differentiated from agglutination by diluting the blood sample 1:4 with 0.9% saline. Both rouleau formation and autoagglutination, rarely induced by severe inflammation, are dispersed by saline dilution.

402

403

24.1.12 Increased Erythrocyte Fragility

The erythrocyte fragility test is a measure of the susceptibility of erythrocytes to hemolysis in a range of hypotonic saline concentrations (see Table 24-1). An increase in osmotic fragility is *indirectly* suggestive of immune-mediated anemia; the Coombs' test is more specific.

24.1.13 Positive Direct Antiglobulin (Coombs') Test Result

A positive Coombs' test result indicates the presence of antibodies on the surface of erythrocytes. A positive test result may be found in idiopathic autoimmune hemolytic anemia in any species and in horses with neonatal isoerythrolysis or equine infectious anemia. The Coombs' reagent is a mixture of antibodies directed against immunoglobulins and complement of a certain species. Because the endpoint of this test is agglutination, it cannot be performed on blood that is autoagglutinating. There are many false-negative results.

24.1.14 Erythrocytic Parasites

During the acute stages of bovine anaplasmosis and babesiosis in horses, cattle, sheep, and goats, intraerythrocytic parasites can be found. *Anaplasma marginale* is seen as a round, basophilic inclusion at the edge of cells, present in highest numbers before a hemolytic crisis. *Babesia* trophozoites occur in erythrocytes as round, bizarre, rod-shaped, or typical piriform (teardrop-shaped) structures. Absence of intraerythrocytic parasites does not rule out anaplasmosis or babesiosis.

24.1.15 Clinical Signs of Anemia

The major clinical signs of anemia (e.g., tachycardia, tachypnea, reduced exercise tolerance, and depression) reflect physiologic adjustments to inadequate oxygen transport to body tissues. The PCV level at which clinical signs occur depends on the rate of development, the severity of the anemia, and the physical demands placed on the animal. Other clinical signs depend on the cause and mechanism of anemia development. Anemia is accompanied by mucosal pallor except when it is caused by hemolysis, which results in icterus. Red urine (hemoglobinuria) indicates intravascular hemolysis, which may be accompanied by fever. Melena, hematuria, and petechial hemorrhages may indicate chronic blood loss.

Although diagnosing anemia is easy, determining the cause, which dictates proper treatment, may be complex. The practitioner first must determine the pathophysiologic classification of the anemia and then consider possible causes.

24.1.16 Approach to Diagnosis of Anemia in Horses

1 Take the history. Important factors are the diet, housing, pasture conditions, drug history, date of the most recent Coggins' test, travel history, time course of current signs, and any past illnesses. In considering neonatal isoerythrolysis, the number of the dam's previous foals and their sires must be ascertained.

2 Perform a physical examination. Take note of the mucous membranes. Icterus in horses may be associated with fasting or cholestatic liver disease, as well as hemolysis. Hemoglobinuria, which is uncommon in horses, indicates intravascular hemolysis (this is difficult to distinguish from myoglobinuria; therefore the plasma should be examined). Epistaxis or other signs of bleeding diathesis suggest a source of chronic blood loss. A thorough search should be made for evidence of chronic disease affecting the respiratory and gastrointestinal tracts. Take note of any weight loss and the character of feces. Any chronic inflammatory disease such as abdominal abscess, pneumonia, or lymphosarcoma causes a mild to moderate nonregenerative anemia. Immune-mediated hemolytic anemia often is associated with equine lymphosarcoma.

3 Perform a CBC. *403*

404

a PCV is reduced.

b $\frac{\text{PCV}(\%)}{\text{Hb}(g/dl)}$

The ratio of PCV/HB less than 3 suggests intravascular hemolysis (e.g., PCV=15; Hb=6; 15/6 is <3).

c Pink plasma suggests intravascular hemolysis.

d MCV above 60 fl (rare) suggests regenerative anemia.

e Heinz bodies (substantiate by new methylene blue staining) suggest toxicosis caused by phenothiazine, red maple leaves, or wild onions.

f Agglutination (substantiate by diluting blood 1:4 with 0.9% saline) suggests immune-mediated anemia. Perform Coggins' test in adult. In newborn foal, perform hemolytic cross-match with dam.

4 Evaluate leukogram and plasma proteins.

a Neutrophilia, hyperglobulinemia, and/or hyperfibrinogenemia suggests chronic infection.

b Hypoproteinemia may indicate blood loss anemia or an underlying disease causing protein loss (e.g., granulomatous bowel disease or intestinal lymphosarcoma). In horses, gastric squamous cell carcinoma causes chronic blood loss anemia associated with iron deficiency.

5 Perform bone marrow analysis. This is necessary to adequately characterize anemia in horses as regenerative or nonregenerative.

6 Analyze urine. A positive result for occult blood without microscopic hematuria indicates hemoglobinuria (intravascular hemolysis) or myoglobinuria (myopathy). Hemoglobinuria is associated with pink plasma.

Saturated ammonium sulfate usually precipitates and removes color caused by hemoglobin; however, spectrophotometric tests are best for differentiating from myoglobin.[3]

7 Test feces for occult blood. A positive result may indicate gastrointestinal blood loss as a cause of chronic anemia. Gastric ulcers (foals) and gastric squamous cell carcinoma should be considered.

8 Test serum iron and total iron-binding capacity (TIBC). Low serum iron and a high TIBC are consistent with iron deficiency (chronic blood loss). Low serum iron with normal TIBC suggests the anemia of chronic disease.

9 Perform a Coggins' test. A positive result indicates equine infectious anemia.

10 Perform a Coombs' test. A positive result indicates immune-mediated anemia.

24.1.17 Approach to Diagnosis of Anemia in Ruminants

1 Take the history. Note the type of diet, access to pasture, other herd or flock members with clinical signs of systemic disease, immunization status, and exposure to new animals.

2 Perform a physical examination. Icterus in ruminants is rare except in association with hemolysis. Pallor indicates blood loss or inadequate erythrocyte production. Fever may be a sign of hemolysis or of an underlying systemic disease. Most hemolytic anemias in ruminants, *except anaplasmosis,* cause hemoglobinuria. Check the breath for onion odor.

3 Perform a CBC.

- a PCV is reduced.
- b Pink plasma suggests intravascular hemolysis.
- c Regenerative changes indicate blood loss or hemolysis with normal marrow.
- d If no signs of regeneration are present, abnormal bone marrow, acute blood loss (less than 4 days), or acute hemolysis is indicated.
- e Increased Hb, MCH, and/or MCHC with a low PCV indicates intravascular hemolysis.
- f Basophilic stippling without other signs of regeneration may indicate chronic lead poisoning.
- g Heinz bodies suggest ingestion of onions or *Brassica* plants. May need to do new methylene blue stain to observe.
- h Autoagglutination suggests immune-mediated anemia. Perform dilution tests.

4 Evaluate plasma proteins.

- a Hypoproteinemia suggests blood loss.
- b Hyperproteinemia, hyperglobulinemia, and/or hyperfibrinogenemia suggests chronic inflammatory disease.

5 Analyze urine. See discussion under Approach to Diagnosis of Anemia in Horses. Myoglobinuria is associated with clear plasma.

6 Test feces for occult blood. Bleeding abomasal ulcers cause acute or chronic anemia in cattle.

7 Perform bone marrow analysis. This test is necessary in the absence of peripheral blood signs of regeneration.

24.2 ERYTHROCYTOSIS (POLYCYTHEMIA)

Erythrocytosis is defined as an increase in the PCV, erythrocyte count, and hemoglobin concentration above the normal range. Erythrocytosis may be absolute or relative (apparent), caused by hemoconcentration (dehydration, shock) or splenic contraction (Box 24-3). Absolute erythrocytosis (primary or secondary) is caused by increased erythropoiesis that creates a greater total circulating erythrocyte mass.

Primary absolute erythrocytosis (polycythemia vera) is an idiopathic, myeloproliferative disorder associated with a normal partial pressure of oxygen (Po_2) and reduced erythropoietin levels. Secondary absolute erythrocytosis is caused by an increase in erythropoietin. Chronic tissue hypoxia, which may accompany residence at high altitudes, chronic pulmonary disease, and heart defects that produce arteriovenous shunting induce a physiologic or compensatory increase in serum erythropoietin that results in absolute secondary erythrocytosis. Inappropriate elaboration of erythropoietin (normal Po_2) and secondary erythrocytosis rarely occur in chronic renal, hepatic, or endocrine disorders, especially those caused by neoplasia.

In domestic animals, absolute erythrocytosis usually occurs secondary to chronic diseases that produce tissue hypoxia. Primary absolute erythrocytosis and inappropriate secondary erythrocytosis caused by hepatocellular carcinoma have been described in horses.[4] Familial erythrocytosis has been described in cattle, and the source of the increase in erythropoietin has not been identified.[5] Clinical signs of erythrocytosis are vague; they include lethargy, weight loss, mucosal hyperemia, and signs of underlying disease.

24.2.1 Box 24-3 Causes of Erythrocytosis in Large Animals

24.2.1.1 RELATIVE ERYTHROCYTOSIS

Dehydration

Endotoxic shock

Strangulating intestinal obstruction

Salmonellosis

Colitis X (E)

Septic metritis

Septic mastitis (B)

24.2.1.2 ABSOLUTE ERYTHROCYTOSIS

24.2.1.2.1 Common Causes

Congenital cardiovascular disease

Residence at high altitudes

Chronic obstructive pulmonary disease

24.2.1.2.2 Less Common Causes

Familial (B)

Chronic hepatic disease

Hepatoma

Leiomyoma

Hemangioblastoma

Pheochromocytoma

Nephroma

Hydronephrosis

Polycystic kidneys

Nephrocalcinosis

B, Bovine; *E*, equine.

Diagnosis of erythrocytosis is based on persistent elevation of the PCV, hemoglobin, and erythrocyte count in the absence of clinical evidence of shock or dehydration and without response to intravenous fluid therapy. Chronic hypoxia can be ruled out by determining the arterial oxygen concentration. Thoracic radiographs and echocardiography can delineate cardiorespiratory function more thoroughly. Examination of the bone marrow is indicated, although erythroid hyperplasia is not specific for primary or secondary erythrocytosis. In the absence of hypoxemia and a demonstrable disease that could lead to appropriate secondary erythrocytosis, polycythemia vera and inappropriate secondary erythrocytosis must be considered. Renal and hepatic disease should be excluded by determining the serum creatinine, hepatic enzyme, and bile acid levels. The only way to clearly differentiate primary from secondary absolute erythrocytosis is to determine the serum erythropoietin. This is a bioassay that is not routinely available, and it is relatively insensitive to minor changes in erythropoietin concentrations.

25 Chapter 25 Alterations in the Leukogram

Debra Deem Morris

The leukogram (white blood cell [WBC] count, differential analysis, and WBC morphology) provides extremely useful laboratory data when considered with the history, clinical signs, and physical findings. To fully use the leukogram, the practitioner must know the types of WBCs, their kinetics and functions, and the pathologic and physiologic conditions that can cause deviations from normal. Normal values for leukogram data are given in Table 25-1.

Mature WBCs include neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Immature leukocytes that may or may not be present in the peripheral blood include band or nonsegmented neutrophils, metamyelocytes, myelocytes, and progranulocytes. These immature forms usually are found only in the bone marrow, but they may be released in response to disease.

25.1 LEUKOCYTES

Leukocytes, or WBCs, are divided into two main categories: polymorphonuclear (PMN) leukocytes (granulocytes) and mononuclear leukocytes. PMN leukocytes include neutrophils, eosinophils, and basophils, which are produced in the bone marrow. The mononuclear leukocytes are the lymphocytes and monocytes. Lymphocytes are produced in the bone marrow (the primary source), lymphoid organs (thymus, spleen, and lymph nodes), and gut-associated lymphoid tissues (Peyer's patches, tonsils). Monocytes, the largest of the WBCs, originate in the bone marrow.

25.1.1 Neutrophils

Neutrophils develop in the bone marrow as myeloblasts, progranulocytes or promyelocytes, myelocytes, metamyelocytes, band cells, and segmented neutrophils. Myeloblasts arise from bipotential committed stem cells (colony-forming unit—granulocyte, macrophage) that are derived from pluripotent hematopoietic stem cells.[1]

Myeloblasts, promyelocytes, and myelocytes are capable of cell division, but metamyelocytes, bands, and segmented neutrophils (about 80% of the bone marrow granulocytes) do not divide.[2] The normal interval for progression from myeloblast to mature blood neutrophil is 4 to 9 days, depending on the species. A functional storage compartment of neutrophils exists in the marrow to prevent marrow depletion by the sudden imposition of a greatly increased peripheral use. The storage pool, which is limited to segmented neutrophils and some bands, varies in size among species and is relatively small in adult cattle.[1] A marginal pool of neutrophils adheres to endothelium throughout the microvasculature. Neutrophils in the circulating pool are the only part of the total neutrophil population enumerated by the peripheral blood neutrophil count. In large animals the marginal neutrophil pool is approximately equal in size to the circulating pool.[1]

After entering the bloodstream, neutrophils have a half-life of 6 to 14 hours, depending on the species. The entire blood pool of neutrophils is replaced two to two-and-one-half times per day. Neutrophils move randomly into the tissues by diapedesis through vascular endothelium and do not return to the blood. Neutrophils migrate into tissues within 2 hours of injury, infection, or inflammation. In the absence of such lesions, the neutrophils are destroyed by macrophages of the bone marrow, liver, and spleen or are lost into body secretions and excretions within 96 hours of exiting the marrow.[2]

The major function of neutrophils is to phagocytize and destroy foreign material, especially pathogenic bacteria. Bacterial products and substances released from activated lymphocytes (lymphokines), macrophages, and cellular damage are responsible for attracting the neutrophils, which move by chemotaxis and bind to the foreign particle.[3] Opsonins are protein components of serum that adhere to foreign particles and make them more liable to phagocytosis.[4] Opsonization by specific antibodies increases the rate and magnitude of ingestion for most bacterial organisms. Once drawn into the cell, the bacteria are enclosed in a phagocytic vacuole, which fuses with lysosomes in the neutrophil cytoplasm that release hydrolytic enzymes to destroy the contents. Degranulation, which occurs within 5 seconds of a phagocytic event, can lead to release of lysosomal enzymes into the surrounding milieu and cause tissue destruction.

Gram-negative bacteria are more resistant to digestion in the neutrophil than gram-positive bacteria because of the structure of their outer wall. *Brucella abortus, Mycobacterium paratuberculosis, Listeria monocytogenes,* and some *Salmonella* serotypes are extremely resistant to lysosomal destruction and may survive and multiply within the neutrophil.

Basophils ($\times 10^3/\mu L$)	0-0.2	0-0.3	0-0.12	0-0.29
Neutrophil/lymphocyte (N/L) ratio	0.3-0.6	0.3-0.7	0.6-3.6	0.8-2.8

25.2 EOSINOPHILS

Eosinophils are produced in the bone marrow and follow the same maturation sequence and kinetics as neutrophils, except that eosinophils arise from the colony-forming unit—eosinophil.[1] There is a large marrow reserve of eosinophils, and their circulatory half-life varies from 30 minutes to 10 hours, depending on the species. Eosinophils also are found in many body tissues, particularly the gut, subcutis, uterus, and respiratory tract, where they have a half-life of 12 days.

Eosinophils are most important in controlling parasitic infections and in regulating inflammatory and allergic reactions. Eosinophils are less efficient phagocytes than neutrophils and provide little host resistance to bacterial infection but are important in protective parasitic immunity.[2] Eosinophils are believed to regulate immediate (type I) hypersensitivity and inflammatory responses by inactivating histamine, leukotrienes, platelet-activating factor,

and other chemical mediators involved in these processes. Other, less characterized effects of eosinophils include tissue damage, augmentation of coagulation and fibrinolysis, and inhibition of granulopoiesis.

25.3 BASOPHILS

Basophils are relatively scarce in the blood of large animal species. The blood basophil resembles the tissue mast cell and is believed to perform similar functions. Basophils are produced in the bone marrow by mitosis of basophilic promonocytes through the same sequential stages of maturation as neutrophils. Basophils have a mean circulatory half-life of about 6 hours. They then enter tissues, where they survive for approximately 10 to 12 days.[1] Mast cells, found in many body tissues, originate from undifferentiated connective tissue mesenchymal cells, especially near blood vessels. There is evidence in some species that mast cells also originate from a precursor in the bone marrow.[1]

Basophils and mast cells contain stored intragranular substances that mediate their function in allergic and inflammatory processes. The most important function of basophils and mast cells is to elicit an immediate hypersensitivity reaction through secretion of vasoactive mediators, including histamine, leukotrienes, platelet-activating factor, and others. Vasodilation, pooling of fluid in tissue spaces, and systemic reactions may occur, with signs of dyspnea, urticaria, coughing, and even severe anaphylactic shock. Eosinophils are attracted to these areas to neutralize the histamine and attenuate the inflammatory response.

25.3.1 Lymphocytes

Lymphocytes are produced in the bone marrow, lymph nodes, thymus, spleen, and Peyer's patches. They are classically divided into two groups: T cells, or thymus-derived lymphocytes, and B cells, or bone marrow—derived lymphocytes. Null cells have been identified in humans and in some animals that lack specific markers for T or B cells.[1] Both T- and B-cell populations are present in the peripheral blood of large animal species, with T cells making up the majority. B cells are few during fetal life but steadily increase to make up about 20% of circulating lymphocytes in most adult domestic animals.[1] Observations in cattle indicate that various inflammatory states are associated with an increase in B cells and a decrease in T cells. Leukemic cows infected with bovine leukosis virus (BLV) and those with persistent lymphocytosis have a higher number of B cells, which constitute up to 97% of lymphocytes.[1] Lymphocytes can recirculate and continue to undergo mitosis. Information on domestic animals is unavailable, but most blood lymphocytes in humans have an average lifespan of 4.3 years.[1]

B lymphocytes transform into plasma cells that produce antibodies under the regulation of T lymphocytes. T lymphocytes are primarily responsible for delayed-type hypersensitivity (DTH), graft and tumor rejection, autoimmunity, and resistance to certain intracellular pathogens. Some types of T cells have a direct cytotoxic function to destroy foreign cells, and null cells express natural killer activity. Lymphocytes produce important immunologic mediators called *lymphokines,* which include macrophage-activating factor, interferons, and interleukins.

The number of lymphocytes in the peripheral blood reflects a balance between cells leaving and entering the circulation; thus changes do not necessarily mean altered lymphopoiesis. In addition to consideration of the total number in the leukogram, lymphocytes can be evaluated by measuring the ratio of T cells to B cells (normal range is 1:1 to 3:1), antibody levels and response to vaccination, in vitro lymphocyte stimulation tests, and skin tests for DTH.

25.3.2 Monocytes

Monocytes are produced in the bone marrow from the colony-forming unit—granulocyte, a macrophage, which differentiates into either myeloblasts or monoblasts (precursors of monocytes).[1] Monoblasts undergo mitosis to promonocytes, then divide one to two more times to produce monocytes. Once released into the blood, monocytes circulate for 1 to 3 days, then enter body cavities and tissues and transform into macrophages. Tissue macrophages survive in tissues for weeks to years. Once in tissue, these macrophages are described as “fixed” or “free.” Free macrophages are found in the peritoneal and pleural cavities, in joints, in alveolar spaces, and at areas of inflammation. Fixed macrophages include Kupffer's cells of the liver, osteoclasts, microglial cells, and macrophages found in the spleen, bone marrow, and lymph nodes.

406

407

The blood monocytes and tissue macrophages constitute the mononuclear phagocyte (reticuloendothelial) system.[1,2] The functions of tissue macrophages include sustained phagocytic activity to remove dead and damaged tissue; microbicidal action against some bacteria, viruses, fungi, and protozoa; regulation of the immune response in both afferent and efferent limbs; tumor defense; regulation of hematopoiesis; tissue repair and remodeling; and secretion of monokines, lysosomal enzymes, and other substances, such as coagulation factors, that have wide-ranging biologic importance. The tissue macrophages are better equipped than neutrophils to combat intracellular organisms and those that cause granulomatous inflammation such as fungal infections, listeriosis, brucellosis, Johne's disease, tuberculosis, and salmonellosis.

Interleukin (IL)-1 and tumor necrosis factor are important macrophage-derived mediators of the inflammatory response.[5] These and other cytokines are released when macrophages are exposed to bacterial products (especially endotoxin), antigens, and injured tissue. IL-1 stimulates bone marrow release of neutrophils and attracts them to areas of bacterial infection or inflammation. Tumor necrosis factor is responsible for many of the physiologic derangements associated with endotoxemia that end in shock, tissue injury, and death.

25.4 GENERAL PRINCIPLES OF LEUKOGRAM INTERPRETATION

When interpreting the leukogram, the practitioner must consider the established normal values for the species, the animal's age and condition, and the species-specific WBC responses. Leukocytosis may be attributed to physiologic or pathologic causes, whereas leukopenia always is considered pathologic.[1,6]

25.4.1 Physiologic Leukocytosis

Physiologic leukocytosis occurs when epinephrine is released, as with stress, excitation, anxiety, or exercise. The elevated WBC count is transient and caused by both neutrophilia and lymphocytosis, although it is primarily the result of temporary mobilization of the marginal neutrophil pool.[2] Corticosteroids, either exogenous or endogenous, cause neutrophilia and lymphopenia. Younger animals may have higher lymphocyte and total WBC counts than those considered normal for adults.[1]

25.4.2 Neutrophilia

Bacterial infection is the most common cause of pathologic neutrophilia (Boxes 25-1 and 25-2). In the acute stage of the infection, a left shift (presence of increased immature neutrophil granulocytes in the peripheral blood) may appear.[1,6] Left shift with concomitant mature neutrophilia is called a *regenerative left shift*. Rebound

neutrophilia often follows neutropenia associated with endotoxemia, and it is usually a good prognostic indicator. Neutrophilia is most pronounced while bacterial infections are being localized, especially with abscess formation. Chronic localized infections rarely are attended by a left shift, and in cattle the neutrophil count may increase only minimally or not at all. Horses with chronic bacterial infections often show only a mild mature neutrophilia attended by lymphopenia and a normal total WBC count.

Neutrophilia may also accompany inflammation caused by neoplasia or severe injury or may arise during the postoperative period. Less common causes of neutrophilia include parasitic and mycotic infections, tumors that cause secretion of endogenous corticosteroids, toxins, and some metabolic diseases such as pregnancy toxemia.

25.4.2.1

Box 25-1 Causes of Neutrophilia in Horses

25.4.2.1.1

Common Causes

Excitement, exercise

Stress, exogenous corticosteroid administration

Chronic pneumonia, pleuritis

Strangles (*Streptococcus equi* infection)

Chronic peritonitis, abdominal abscess

Other internal abscessation

Chronic salmonellosis or colitis

Thrombophlebitis

Purpura hemorrhagica (vasculitis)

25.4.2.1.2

Less Common Causes

Bacterial endocarditis

Cellulitis

Pyelonephritis

Chronic hepatitis, cholangiohepatitis

Cholelithiasis

Lymphosarcoma

Other internal neoplasia

Pituitary adenoma (equine Cushing's syndrome)

Autoimmune hemolytic anemia

Granulocytic leukemia

Systemic fungal infections

25.4.2.2

Box 25-2 Causes of Neutrophilia in Ruminants

25.4.2.2.1

Common Causes

Stress, exogenous corticosteroid administration

Chronic pneumonia

Chronic traumatic reticuloperitonitis

Peritonitis

Internal abscessation

Caseous lymphadenitis (O, C)

Mycoplasmal or chlamydial polyarthritis (O, C)

Chronic pyelonephritis

Chronic metritis

Liver abscesses

Enteritis

Umbilical abscessation

Chronic salmonellosis

Septic arthritis

25.4.2.2.2 Uncommon Causes

Autoimmune hemolytic anemia

Toxins

Pregnancy toxemia (O, C)

Bovine granulocytopathy syndrome

C, Caprine; *O*, ovine.

In large animals the total WBC or neutrophil count may not reflect chronic inflammation; for this reason, examination of neutrophil morphology is paramount in interpreting the leukogram. Bacterial infections, especially those caused by gram-negative organisms, often result in neutrophil cytoplasmic and nuclear alterations, which are referred to as “toxic changes.” These changes occur in the bone marrow and include cytoplasmic foaminess, vacuolation, and/or basophilia; reddish purple “toxic” granules; bluish cytoplasmic inclusions called Döhle bodies; and bizarre giant forms with or without polyploidy. The changes do not accompany other causes of neutrophilia. 407 408

25.4.3 Neutropenia

The usual causes of neutropenia in the large animal species are bacterial septicemia and endotoxemia caused by gastrointestinal disease, metritis, or coliform mastitis (Boxes 25-3 and 25-4). Some viral diseases and anaphylaxis also cause neutropenia.

A degenerative left shift, generally associated with neutropenia, occurs when immature neutrophils appear in the peripheral blood in greater numbers than mature neutrophils. In species other than cattle, degenerative left shift is an extremely poor prognostic sign. Because cattle have a small bone marrow reserve of neutrophils, immature neutrophils appear quickly in the blood during acute inflammatory diseases and often exceed the mature neutrophils. A marked fall in the WBC count commonly is seen in cattle during the developmental stage of an acute localizing inflammatory process such as mastitis or metritis. Once neutrophil production has intensified,

the left shift disappears and mature neutrophilia intervenes. Neutropenia that persists longer than 4 days is a sign of inadequate granulopoiesis, which sometimes occurs subsequent to severe toxemia. Neutropenia apparently is rare in goats.

25.4.3.1

Box 25-3 Causes of Neutropenia in Horses

25.4.3.1.1

Common Causes

Acute salmonellosis

Acute toxic colitis

Acute peritonitis (ruptured viscus)

Gram-negative septicemia, endotoxemia

Neonatal septicemia

Acute pleuritis

Acute metritis

Proximal enteritis (duodenitis, proximal jejunitis)

Equine influenza

Equine herpesvirus type 1 infection

25.4.3.1.2

Less Common Causes

Equine ehrlichial colitis (Potomac fever, *Ehrlichia risticii* infection)

Equine ehrlichiosis (*Ehrlichia equi* infection)

Idiopathic aplastic anemia

Equine viral arteritis

Radiation toxicosis

Myelophthisic disease (e.g., eosinophilic leukemia)

Common Causes

Gram-negative septicemia, endotoxemia

Septic metritis

Septic (coliform) mastitis

Diffuse peritonitis

Ruptured uterus with peritonitis

Ruptured abomasal ulcer

Acute salmonellosis

Acute pneumonia

Toxemia- or toxin-induced bone marrow suppression

Fat cow syndrome (fatty liver)

Clostridial infection

25.4.3.2.2

Uncommon Causes

Bovine virus diarrhea

Bracken fern toxicosis

Trichloroethylene toxicosis

Radiation toxicosis

Idiopathic aplastic anemia

The severity of toxemia is reflected by the number of “toxic” neutrophils and the degree of toxic changes. In diseases that cause severe toxemia, precursor cells in the bone marrow become vacuolated and fail to divide, thereby contributing to the existing neutropenia. This bone marrow hypoplasia subsequent to severe infection and inflammation is seen most often in cattle.

In rare cases, neutropenia may develop subsequent to myelophthisic disease, idiopathic aplastic anemia, myelofibrosis, or bone marrow suppression by drugs, chemicals, or ionizing radiation. Lymphosarcoma may involve the bone marrow in rare cases.

25.4.4

Lymphocytosis

Pathologic lymphocytosis is uncommon, occurring occasionally with chronic viral infections and autoimmune disease processes (Boxes 25-5 and 25-6). Lymphocytic leukemia is rare in large animals. Thirty percent of cattle infected with BLV are leukemic (see Chapter 37), and lymphocytosis may persist in the absence of lymphoma or leukemia. Physiologic lymphocytosis associated with epinephrine release caused by excitement or exercise is common in horses under 2 years of age.

25.4.5

Lymphopenia

Causes of lymphopenia include acute viral diseases, endotoxin release, severe bacterial infection, septicemia, rickettsial diseases, malnutrition, tumors that cause increased release of corticosteroids, and immunodeficiency (Boxes 25-7 and 25-8). Persistent lymphopenia is a poor prognostic indicator. Increasing lymphocyte counts represent recovery.

25.4.6

Monocytosis

Monocytosis occurs with chronic inflammation (Box 25-9). Because the monocyte count is not highly responsive to inflammatory disease in large animals, it is not an especially useful part of the leukogram.[6]

25.4.6.1

Box 25-5 Causes of Lymphocytosis in Horses

25.4.6.4.2 Uncommon Causes

Bovine virus diarrhea

Immunodeficiency

25.4.6.5 Box 25-9 Causes of Monocytosis in Large Animals

25.4.6.5.1 Uncommon Causes

Granulomatous disease

Chronic bacterial infections

25.4.7 Monocytopenia

Endotoxin release and viremia may cause monocytopenia. Monocytopenia occurs initially during stress periods associated with corticosteroid release and may be followed by monocytosis.

25.4.8 Eosinophilia

Eosinophilia is uncommon in large animals but may occur with diseases that involve an interaction between antigen, IgE antibody, and mast cells or basophils, such as parasitic infections, allergic respiratory diseases, and dermatoses (Boxes 25-10 and 25-11). Unlike in humans and small animals, visceral larval migrans rarely induces peripheral eosinophilia. Tissue protein breakdown (malignancies, chronic suppurative processes) may cause eosinophilia in rare cases through the release of histamine or eosinophilic chemotactic factor of anaphylaxis from mast cells. Histamine in the blood attracts bone marrow eosinophils to the circulation. For eosinophilia to occur in response to parasitism, a parasite protein must be released and processed by cells infiltrating the tissue site of parasitic lodgment.[1] Thus eosinophilia is unlikely to accompany intestinal parasitism when the parasite is free-living in the lumen.

25.4.8.1

Box 25-10 Causes of Eosinophilia in Horses

25.4.8.1.1

Uncommon Causes

- Internal parasitism
- Cutaneous habronemiasis
- Systemic hypersensitivity reaction
- Lymphosarcoma
- Eosinophilic leukemia

25.4.8.2

Box 25-11 Causes of Eosinophilia in Ruminants

25.4.8.2.1

Uncommon Causes

- Milk allergy
- Atypical interstitial pneumonia
- Acute bovine pulmonary emphysema
- Sarcocystosis
- Toxoplasmosis
- Migrating parasite larvae such as:
  - Lungworms
  - Ascarids
  - Flukes
  - *Trichostronglyus* species

Hypoderma species

Parelaphostronglylus species

Eosinophilic granulocytic leukemia is rare in large animal species but has been reported in horses.[7] The circulation of bizarre, immature eosinophils differentiates this from other causes of eosinophilia.

25.4.9 Eosinopenia

Eosinopenia is difficult to evaluate, because the leukograms of clinically normal animals may contain very few eosinophils. Eosinopenia may occur secondary to an increase in endogenous or exogenous corticosteroids. Eosinopenia also may be seen with active inflammatory processes.

25.4.10 Basophilia and Basopenia

Basophils are rarely seen in the peripheral blood of the large animal species, although they are more frequently encountered than in dogs and cats.[1] Changes in the number of basophils are difficult to interpret. Stress causes a reduction in their number, whereas basophilia may be seen with allergic dermatitis and delayed hypersensitivity reactions.

25.5 APPROACH TO INTERPRETATION OF THE LEUKOGRAM IN HORSES

The equine neutrophil-to-leukocyte (N/L) ratio declines from approximately 2.8 at birth to 1.1 at 1 to 2 months of age and to 0.9 at 6 to 8 months. An N/L ratio near 1 persists through 2 years and increases with age to approximately 2 as lymphocyte numbers are reduced. The total WBC count increases from birth through 3 months of age, is slightly above adult values between 3 months and 2 years of age, and then starts to decline. Physiologic leukocytosis is quite common in horses under 2 years of age.[1]

During chronic and established inflammatory diseases, horses generally have a mature neutrophilia and lymphopenia that may or may not result in leukocytosis.[6] The degree of leukocytosis in chronic suppurative diseases rarely exceeds 20,000/μL. Peracute diseases of the gastrointestinal tract and septicemia (especially in neonates), usually attended by endotoxemia, are characterized by leukopenia and a degenerative left shift, the severity of which is correlated with the prognosis. In the most severe cases the left shift includes myelocytes and neutrophils that show marked “toxic” changes. Survival and recovery are attended by a rebound neutrophilia (with or without left shift) and monocytosis. Neonates have a small neutrophil reserve and have more sluggish granulopoiesis in response to disease.

Lymphopenia and eosinopenia often occur readily in response to stress or corticosteroid administration. Chronic diseases commonly result in a reduction of the lymphocyte count, which may be under 1000/μL during severe systemic stress. The monocyte is not particularly responsive to disease in horses,[1] but the blood monocyte generally decreases acutely and may increase above normal during chronic inflammatory diseases, especially those associated with tissue necrosis.

25.6 APPROACH TO INTERPRETATION OF THE LEUKOGRAM IN RUMINANTS

The general trend is for the WBC count to be higher in calves through 2 years of age and then decline with advancing age. Sheep and goat leukocyte counts increase through 2 to 3 months of age, then decline in adulthood to levels seen at birth. In cattle and sheep, neutrophils exceed lymphocytes at birth, but the ratio is reversed within the first week of life, and this ratio persists as a species characteristic. A reduction in the number of lymphocytes without similar changes in neutrophils produces an N/L ratio near unity in goats over 3 years of age.

Acute inflammatory disease and infection in cattle (e.g., neonatal septicemia, salmonellosis, enteritis, metritis, and coliform mastitis) cause a rapid drop in the WBC count because of migration of mature neutrophils to the site of inflammation, margination of neutrophils, and stress-induced loss of lymphocytes. The bone marrow has a small reserve of mature neutrophils, and immature forms (bands, metamyelocytes) are released into the circulation, creating a degenerative left shift during the first 2 to 3 days of acute inflammation. By the fourth day bone marrow granulopoiesis usually has increased sufficiently to meet the tissue demand for neutrophils, causing a normal leukocyte count with a left shift. If the inflammatory stimulus persists, a mature neutrophilia may develop. Generally the N/L ratio increases without leukocytosis. Severe systemic toxemia or chronic infections (or both) may cause granulopoietic depression and neutropenia.

Approximately 30% of cattle infected with BLV develop a benign persistent lymphocytosis, defined as an absolute blood lymphocyte count over 3 standard deviations above the normal mean for at least 3 months. Although these cells are BLV infected, cattle with lymphocytosis are clinically normal, and most do not develop enzootic bovine lymphosarcoma (EBL).[8] Approximately 50% of cattle with EBL have a mild-to-moderate lymphocytosis, and leukemia is present in 10% to 30% of cases.[1] Lymphocytosis, usually attended by neutrophilia, occurs sometimes as a result of chronic pyogenic conditions such as liver abscess, pericarditis, pulmonary abscess, and traumatic reticuloperitonitis.

The leukogram changes in sheep generally are similar to those of cattle. Parturition and adverse weather conditions induce typical corticosteroid-induced neutrophilia, lymphopenia, and eosinopenia.

Goats differ from cattle and sheep in that the leukogram typically has an equal or slightly greater number of neutrophils than lymphocytes.[1] The total WBC count during inflammatory diseases may attain levels higher than 25,000/μL because of neutrophilia. A regenerative left shift is a common response to subacute or chronic inflammation. Leukopenia is rare.

An inherited syndrome characterized by marked neutrophilia and an increased susceptibility to bacterial infections has been recognized in Holstein-Friesian cattle under 2 years of age.[9] Affected calves have a history of anorexia, weight loss, and failure to thrive, with signs of chronic intermittent pneumonia and diarrhea. Lymphadenopathy, periodontitis, and generalized dermatitis are also features of the syndrome. The neutrophils of these animals are dysfunctional because of a single mutation in CD18 that causes a lack of surface glycoproteins, called β_2-integrins, that are important in cell adhesion processes.[10] Calves that are heterozygous for the defect do not have dysfunctional leukocytes compared with those of clinically normal calves.[11]

26 Chapter 26 Alterations in Blood Proteins

Debra Deem Morris

Janet K. Johnston

Proteins play an integral role in numerous physiologic processes. Not only are they important to the basic structural integrity of most body tissues, but as enzymes and hormones, they also regulate many of the body's biochemical reactions. Hemostasis, resistance to infection, and acid-base balance depend on protein metabolism. Plasma proteins also act as carriers for other plasma constituents, and albumin provides osmotic pressure to help maintain proper intravascular volume and prevent edema. Because of the central role proteins play in the body's homeostasis and the close relationship between plasma proteins and tissue proteins, much information about the body's response to disease can be obtained by measuring the total plasma protein and its fractions—albumin, the globulins, and fibrinogen.

Filtration between intravascular and extravascular space, metabolic demands, hormonal balance, nutritional status, and water balance determine the plasma protein concentration of an individual at any given time. Through colostrum absorption, passive transfer of immunoglobulins causes a rise in the total protein concentration of the newborn (see Chapter 53). With time, however, the passively absorbed immunoglobulin concentration declines through natural catabolic degradation. The rate of decline varies among species and classes of immunoglobulins. The time required to reach levels that are no longer protective depends on the initial concentration of the immunoglobulin. The total protein concentration also declines over the next several weeks, even though immunoglobulins are actively produced (Fig. 26-1). In adults the protein concentration remains relatively stable. Pregnancy alters plasma proteins because fetal development imposes additional stress on the dam's protein reserve,[1] and the concentration and response of each protein fraction to different stressors vary among species.[2,3] In general, however, albumin decreases and globulin (especially α_2-globulin) increases in response to stress.

Several methods are available for determining the concentration of serum or plasma protein. The biuret test is a simple colorimetric technique that has been widely adapted for use in automated chemical analyzers. It is highly specific for protein, especially in the range of 1 to 10 g/dL. Unfortunately the biuret technique is not precise enough for evaluation of very low levels, such as those found in cerebrospinal fluid. Refractometry is a useful method for rapidly determining the protein level in serum, plasma, or other body fluids because the refractive index of a solution is proportional to its protein concentration. Mild hemolysis or icterus of a solution does not interfere with its accuracy; however, turbid or lipemic solutions may alter the transmission of light and provide inaccurate results.

The concentration of the total plasma protein and of the individual fractions varies among species (Table 26-1). When a dysproteinemia is suspected, the total plasma (or serum) protein concentration, albumin-to-globulin (A/G) ratio, serum protein electrophoresis (SPE) results, and plasma fibrinogen concentration should be evaluated. The A/G ratio can easily be calculated from most automated serum chemistry profiles. Changes in the A/G ratio often are the first indication of dysproteinemia. Because this method of albumin measurement can be inaccurate when values are markedly low,[4] the A/G ratio is most accurately obtained from serum protein electrophoresis.

When the practitioner is confronted with dysproteinemia, SPE is necessary to quantitate the individual protein fractions that make up the total. Fig. 26-2 shows normal equine and bovine SPE results. Albumin is identified as a discrete molecular compound by a sharp, narrow-based peak nearest the anode. The sharpness of the albumin peak is a measure of the quality of the SPE procedure and is used to differentiate polyclonal globulin peaks. The α-, β-, and γ-globulins form broad-based peaks during their migration in the electrical field, and, depending on the species, one or two types of the individual fraction normally are present.

26.1 HYPERPROTEINEMIA

Hyperproteinemia can result from an elevation in the concentration of all plasma proteins (panhyperproteinemia) or an absolute increase in globulins (hyperglobulinemia) (Boxes 26-1 and 26-2).

26.1.1 Panhyperproteinemia

An increase in the concentration of all blood proteins most commonly results from loss of the fluid component of the blood. Dehydration (decreased fluid intake or excessive fluid loss or both) causes hyperproteinemia with an associated increase in packed cell volume (PCV); however, a dehydrated, anemic animal will have hyperproteinemia with a normal or subnormal PCV. The A/G ratio will be normal. In large animals a total plasma protein concentration above 8 g/dL can be expected with severe dehydration. Initially dehydration causes withdrawal of tissue fluid into the intravascular space as the body attempts to maintain adequate blood volume. As dehydration proceeds, intravascular fluid is lost; hemoconcentration results, with a relative increase in total protein and progressive peripheral circulatory failure. If renal function is adequate, urine concentration increases and output decreases in an attempt to compensate for the fluid loss; water is absorbed from the gastrointestinal (GI) tract, assuming that GI function is normal.

Kaneko JJ: Serum proteins and the dysproteinemias. In Kaneko JJ, ed: *Clinical biochemistry of domestic animals*, ed 4, San Diego, Calif, 1989, Academic.

A/G, Albumin to globulin ratio.

A decrease in fluid intake can result from unavailability of water, lack of thirst caused by depression or toxemia, or dysphagia.

In rare cases, polyuria with renal failure, exudation from extensive skin wounds, and excessive sweating can cause dehydration. Dehydration most commonly occurs after excessive fluid loss, especially from diarrhea. Other causes of increased fluid loss from the blood include fluid sequestration with an intestinal obstruction, vagal indigestion with internal vomiting, and grain engorgement.

Clinical signs of dehydration include tachycardia, an increase in the capillary refill time, and a decrease in pulse pressure, skin elasticity, and urine output. Improvement with appropriate fluid therapy is evidenced by improvement in clinical signs and a decrease in the PCV and the plasma protein concentrations. A decline in the plasma proteins while the PCV remains elevated often indicates protein loss into a third space (this occurs most commonly in horses with severe colitis) and is a poor prognostic sign. Massive plasma transfusions are indicated in such patients.

26.1.2 Hyperglobulinemia

Hyperproteinemia in a patient with apparently normal hydration usually is caused by hyperglobulinemia, because hyperalbuminemia is a result of dehydration. The most common cause of hyperglobulinemia is a generalized increase in γ-globulins (polyclonal gammopathy). This represents the activity of plasma cells in response to chronic antigenic stimulation. Chronic infection, abscess, amyloidosis, and neoplasia typically result in a generalized increase in γ-globulins. Some immunoglobulins (particularly IgM) migrate in the β-globulin region, and polyclonal increases in β-globulins usually are associated with an increase in γ-globulins. A concomitant decrease in albumin synthesis commonly occurs. Chronic hepatitis, hepatic abscess, and suppurative diseases are usually accompanied by an increase in the γ-globulin concentration. Immune-mediated disease processes (e.g., autoimmune hemolytic anemia and autoimmune thrombocytopenia), lymphosarcoma, and other tumors of the reticuloendothelial system typically demonstrate polyclonal increases in γ-globulin.

26.1.2.1

Box 26-1 Causes of Hyperproteinemia in Horses

26.1.2.1.1

PANHYPERPROTEINEMIA-DEHYDRATION

26.1.2.1.1.1

Common Causes

Acute toxic colitis of unknown cause

Acute salmonellosis

Potomac horse fever

Intestinal clostridiosis

Intestinal strangulating obstruction

Proximal enteritis

Gram-negative sepsis, endotoxemia

Botulism

Choking (esophageal obstruction)

26.1.2.1.1.2

Less Common Causes

Chronic renal failure

Chronic hepatic disease

Guttural pouch mycosis with dysphagia

Equine protozoal myelitis

Salt toxicity

Toxins, poisonous plants

Lead toxicity

Yellow star thistle poisoning (dysphagia)

Dysphagia of unknown cause

26.1.2.1.2 HYPERGLOBULINEMIA

26.1.2.1.2.1 Common Causes

Abdominal (mesenteric) abscess (including “bastard” strangles)

Pulmonary abscess

Chronic pleuritis

Purpura hemorrhagica

Equine infectious anemia

26.1.2.1.2.2 Less Common Causes

Chronic hepatic disease

Strongylosis

Lymphosarcoma

Immune-mediated cytopenia

26.1.2.2 Box 26-2 Causes of Hyperproteinemia in Ruminants

26.1.2.2.1 PANHYPERPROTEINEMIA-DEHYDRATION

26.1.2.2.1.1 Common Causes

Ruminal acidosis (grain overload)

Abomasal torsion

Acute salmonellosis

Peritonitis

Sepsis, toxemia (mastitis, metritis)

Intussusception

Vagal indigestion

Oral or pharyngeal foreign body with dysphagia

Coccidiosis

Diarrhea, undifferentiated

Salt toxicity

Toxins, poisonous plants

26.1.2.2.1.2 Less Common Causes

Renal amyloidosis

Lymphosarcoma

Johne's disease

Pregnancy toxemia

Rabies

26.1.2.2.2 HYPERGLOBULINEMIA

26.1.2.2.2.1 Common Causes

- Abdominal abscess (traumatic reticuloperitonitis, uterine tear, other)
- Chronic pneumonia
- Umbilical abscess
- Lymphosarcoma
- Caseous lymphadenitis (sheep and goats)
- Other abscess

26.1.2.2.2.2 Less Common Causes

- Parasitism
- Pregnancy

An abnormal increase in a single immunoglobulin class is known as *monoclonal gammopathy*. On SPE, the monoclonal peak is as sharp as or sharper than the albumin peak and is the result of a single clone of plasma cells producing an increased amount of immunoglobulin. Monoclonal gammopathies can be caused by multiple myeloma, lymphocytic leukemia, and other tumors of the reticuloendothelial system (e.g., lymphosarcoma). The clinical signs depend on the degree of organ involvement, plasma cell proliferation, and protein production. Increased susceptibility to infection can be expected as a result of decreased production of normal immunoglobulins, leukopenia, and/or impaired granulocyte function. Internal parasitism, especially strongylosis, may cause an associated β-globulin spike that does not usually cause hyperglobulinemia. An increase in both β- and γ-globulin fractions (β-bridging) can occur with intense antigenic stimulation, chronic active hepatitis, or lymphosarcoma.

413 414

The α-globulins are divided into α_1 and α_2 fractions in most species except ruminants. α-Globulins are known as *acute-phase reactants* because their concentration rapidly increases after tissue injury or inflammation. α_2-Antiplasmin rapidly increases,[5] whereas ceruloplasmin[6] increases several days after the onset of inflammation.[7] An increase in C-reactive protein has been associated with pneumonitis, enteritis, and arthritis in horses.[8] The increase does not generally cause hyperglobulinemia.

26.2 HYPOPROTEINEMIA

26.2.1 Hypoalbuminemia

Hypoalbuminemia often exists despite normal total plasma protein levels. The three most common causes of hypoalbuminemia are a decrease in production, an increase in loss by the gut, and renal loss (Boxes 26-3 and 26-4).

Albumin is produced by the liver, has the lowest molecular weight, and is the most abundant of the plasma proteins, accounting for 75% of plasma osmotic activity. In addition to maintaining osmotic pressure, a major function of albumin is to bind and transport plasma components that do not have a specific transport protein. Hypoalbuminemia causes a decrease in the A/G ratio.

26.2.1.1 Box 26-3 Causes of Hypoproteinemia in Horses

Ingestion of caustic chemicals

Strangulation, infarction of intestine

Congestive heart failure

	Pyelonephritis
	Urinary tract blood loss

Starvation, malnutrition, and chronic GI disorders that interfere with digestion and absorption may lead to inadequate provision of amino acid substrate for general protein production. Hypoalbuminemia often precedes the development of panhypoproteinemia with dietary protein deficiencies. In certain cases, diets that appear to be well balanced and to provide adequate protein nutrition may actually be inadequate in demanding conditions.

Although albumin is produced by the liver, synthesis does not usually decrease in acute liver disease. Chronic, diffuse liver diseases such as chronic hepatitis, fibrosis, and hepatic neoplasia may cause hypoalbuminemia. Because the half-life of albumin is prolonged in horses and cattle compared with that in dogs and humans,[9] hypoalbuminemia rarely occurs with large animal hepatic disease.[10] If it does, it often is accompanied by increases in β- and γ-globulins. Because these changes occur late in the course of the disease, they may be of more prognostic than diagnostic value.

Increased metabolic demands such as occur with fever, trauma, surgery, and neoplasia can lead to a state of negative nitrogen balance with excessive albumin breakdown. Chronic antigenic stimulation can also result in increased albumin catabolism to provide necessary amino acids for immunoglobulin production; however, this increased albumin catabolism typically does not result in a change in the total plasma protein concentration.

Excessive protein loss usually occurs through the urinary and GI tracts. Normally urine contains little or no protein, but transient physiologic proteinuria occurs with exercise, stress, convulsions, and excessive protein intake, as well as in neonates; however, none of these factors causes hypoproteinemia.

Clinically significant proteinuria consists primarily of albumin, resulting in subsequent hypoalbuminemia. Because of its small size and low molecular weight, albumin is readily filtered through defects in the glomerular basement membrane. Glomerulonephritis, amyloidosis, and less commonly pyelonephritis cause albuminuria, which may lead to hypoproteinemia.[7]

Protein-losing enteropathy refers to the excessive loss of plasma proteins into the GI tract, with resultant hypoproteinemia. The diagnosis of protein-losing enteropathy usually is made after ruling out protein loss through other routes (urine), increased protein catabolism, and inability to produce protein (liver disease). The clinically important mechanisms of GI protein loss are defective lymphatic drainage, increased mucosal permeability, exudation as a result of inflammation, and ulceration. In a study of horses with diarrhea, albumin was lower in horses that died than in those that survived.[11] Panhypoproteinemia eventually develops, especially when inflammation is a cause.

The most common cause of protein-losing enteropathy in the horse is idiopathic granulomatous enteritis.[12] Tuberculosis and histoplasmosis also cause “granulomatous changes.” Lesions are most commonly located in the small intestine, and weight loss results. Other causes of chronic protein-losing enteropathy in the horse include eosinophilic gastroenteritis, intestinal lymphosarcoma, and strongyle larval migrans. Salmonellosis, nonsteroidal antiinflammatory drug (NSAID) toxicity, and other causes of acute colitis and enteritis may result in hypoalbuminemia and a general loss of all plasma proteins. A decreasing plasma protein level that occurs with an elevated PCV indicates acute protein loss from the gut.

The most common cause of chronic protein-losing enteropathy in ruminants is Johne's disease. Hypoalbuminemia causes hypoproteinemia. *Trichostrongylus* infection, intestinal lymphangiectasia, and intestinal lymphosarcoma can cause a primary hypoalbuminemic hypoproteinemia.

Clinical signs of hypoalbuminemia include edema of the distal extremities, ventral body wall, and face. The albumin level generally must be below 1.5 g/dL in horses and below 1 g/dL in ruminants before these clinical signs occur. Pharyngeal and laryngeal edema may result in upper airway obstruction, necessitating a tracheostomy.

26.2.2 Panhypoproteinemia

Vigorous fluid therapy or excess water intake can cause dilution of the plasma proteins, with subsequent panhypoproteinemia. Panhypoproteinemia occurs most often in animals that have acute protein-losing colitis or enteritis and that are receiving intravenous fluid therapy. Similarly, animals that lose large amounts of sodium through diarrhea and then drink fresh water may become hyponatremic as a result of a relative water excess.

Acute blood loss results in loss of plasma proteins and a dilution of the remaining protein by rapid movement of interstitial fluid into the intravascular space to help maintain intravascular volume. This dilutional effect is intensified by the excess water intake that commonly occurs after acute blood loss. Acute hemorrhage resulting from trauma, severe epistaxis, or internal vascular rupture should be ruled out in a hypoproteinemic, anemic animal.

GI blood loss can result from abomasal or gastric ulcers, blood-sucking parasites (particularly *Haemonchus contortus* in ruminants), viral or bacterial infection, azotemia, neoplastic invasion, or exposure to caustic chemicals. NSAID toxicosis and strangulating GI obstructions and infarctions can result in mucosal necrosis and leakage of plasma proteins into the gut lumen. Although protein-losing enteropathy initially results in hypoalbuminemia, it eventually results in panhypoproteinemia.

Blood loss from the urinary tract can result from congenital vascular disorders, renal trauma, renal calculi, pyelonephritis, neoplasia, or cystic calculi. Coagulation dysfunction, such as disseminated intravascular coagulation (DIC) or immune-mediated thrombocytopenia, may cause blood loss by way of the GI or urinary tract.

Congestive heart failure may cause hypoproteinemia by a number of mechanisms. Extracellular fluid is diluted by the retained sodium and water, and plasma protein is lost into interstitial spaces, ascitic fluid, and the GI tract. Hypoproteinemia also can occur as a result of acute severe peritonitis with massive protein exudation, as is seen with a ruptured GI viscus.

26.3 ALTERATIONS IN PLASMA FIBRINOGEN

Fibrinogen is a large—molecular-weight protein produced by the liver. Its primary function is to serve as substrate for thrombin in the formation of fibrin during hemostasis. Fibrinogen, as an acute-phase reactant protein, increases its concentration during active inflammatory disease and is a useful marker in assessment of the inflammatory response.

26.3.1

Hyperfibrinogenemia

Plasma fibrinogen is nearly always increased during severe inflammatory conditions and may increase with milder inflammation that is not associated with leukocytosis or neutrophilia (Boxes 26-5 and 26-6). After surgical treatment for subchondral bone cysts and osteochondrosis desiccans, horses still had hyperfibrinogenemia 15 days after surgery.[13] Hyperfibrinogenemia generally occurs with infectious, suppurative, traumatic, and neoplastic diseases and subsides as the condition improves. Chronic inflammation is associated with hyperfibrinogenemia, but the degree of hyperfibrinogenemia is not always directly correlated with the severity of the disease. Fibrinogen is an especially useful indicator of inflammation in cattle because of their greater capacity to produce fibrinogen,[14] which is a more sensitive indicator of inflammation than the leukocyte count (see Table 26-1).

415

Septic arthritis

Cholelithiasis

Neoplasia with inflammatory response

Vasculitis (equine purpura hemorrhagica)

Cellulitis

Gastrointestinal inflammation

Salmonellosis

26.3.2

Hypofibrinogenemia

A decrease in the fibrinogen concentration may result from increased consumption of fibrinogen or decreased synthesis. Severe, diffuse liver damage, such as occurs with severe pyrrolizidine alkaloid toxicity, causes a decrease in the fibrinogen concentration, whereas mild to moderate inflammatory liver disease can result in an increase in plasma fibrinogen. With DIC and fibrinolysis a decrease in the fibrinogen concentration would be expected; however, hypofibrinogenemia is not common in horses with DIC. Inflammatory disorders often are the cause of DIC, and a compensatory increase in production masks the increased consumption. In rare cases, rapid removal of fibrinogen from the circulation may occur as a result of primary hyperfibrinolysis. An erroneous finding of hypofibrinogenemia may result if the fibrinogen concentration is quantitated from samples containing clotted blood.

27 Chapter 27 Alterations in the Clotting Profile

Debra Deem Morris

The minimum laboratory data needed to evaluate hemostasis in large animals are platelet count, plasma fibrinogen, prothrombin time (PT), activated partial thromboplastin time (aPTT), and serum fibrin and fibrinogen degradation products (FDPs). Proper collection and preparation of blood samples are paramount in obtaining accurate results (see Chapter 23). If the laboratory does not have normal values for the species in question, plasma from two or more healthy animals should be collected and assayed in a similar manner for comparison. Table 27-1 shows some normal values that have been published.

27.1 THROMBOCYTOPENIA

Thrombocytopenia (a platelet count below 100,000/µL) is caused by one of three basic mechanisms: a decrease in the production of platelets, platelet sequestration, or a shortened platelet lifespan (Boxes 27-1 and 27-2). Reduced production of platelets is the result of a bone marrow abnormality such as infiltration by neoplastic tissue (myelophthisic disease) or aplastic anemia. Occasionally immune-mediated destruction of megakaryocytes causes selectively reduced platelet production. Familial myelofibrosis occurs in some lines of pygmy goats.

Splenomegaly that may occur in acute and chronic infections and in noninfectious inflammatory disorders causes platelet sequestration, although this does not generally predispose the animal to hemorrhage. Congestive splenomegaly occurs when venous outflow is occluded by intestinal displacements or congestive heart failure.

Shortened platelet lifespan is the most common cause of thrombocytopenia in large animals. Excessive consumption of platelets occurs with disseminated intravascular coagulation (DIC), overwhelming septicemia or endotoxemia, and, in rare cases, systemic vasculitides. Platelet destruction by immune-mediated mechanisms is a common cause of thrombocytopenia in horses. Viral and rickettsial diseases may cause consumption or immune-mediated thrombocytopenia (IMTP).

Platelets form the initial hemostatic plug, provide phospholipid and a surface for clot formation, and maintain vascular integrity. Thrombocytopenia is characterized by petechial hemorrhages on the oral, nasal, and/or vaginal mucous membranes and the nictitans, sclerae, and pinnae. Epistaxis, melena, hyphema, or hematuria may occur, although spontaneous hemorrhage is rare unless the platelet count drops below 10,000/µL. Prolonged bleeding from injections or wounds and a propensity to form hematomas with minor trauma are quite common when the platelet count drops below 40,000/µL.

Anemia and mild hypoproteinemia accompany significant, chronic blood loss. Other components of the hemostatic system also should be evaluated (e.g., PT, aPTT, and FDPs), because thrombocytopenia may be only part of a disseminated coagulopathy. Evaluation of a bone marrow specimen (aspirate, core) is necessary to document adequate megakaryocyte numbers if thrombocytopenia is the only laboratory abnormality *or* if pancytopenia is present.

27.2 PROLONGED PROTHROMBIN TIME

The PT is a measure of the extrinsic and common pathways of coagulation (Fig. 27-1). It becomes prolonged when the fibrinogen level drops below 100 mg/dL or with a marked deficiency (less than 50% of normal concentration) of prothrombin and/or clotting factors V, VII, and X. In addition to deficiencies of these factors, functional

abnormalities or factor inhibitors may be reflected by changes in the PT. The most common mechanisms for prolonging the PT are increased consumption of the relevant clotting factors or failure of the liver to produce these factors. Congenital afibrinogenemia in goats may prolong the PT.[1]

Increased factor consumption usually is caused by DIC, which also causes prolonged aPTT and thrombocytopenia(Boxes 27-3 and 27-4). Reduced production occurs as a result of hepatocellular disease or vitamin K deficiency. Vitamin K is necessary for hepatic production of factors II, VII, IX, and X. The action of vitamin K is inhibited by coumarin compounds, which may be found in moldy sweet clover hay or rodenticides. Coumarin derivatives (warfarin) sometimes are used therapeutically in horses.

Clinical signs of clotting factor deficiencies relate to the tendency for spontaneous hemorrhage (e.g., epistaxis, melena, hematuria) or prolonged bleeding after trauma, diagnostic procedures, or surgery. Hematomas or hemarthroses are common after minor trauma or normal exercise. The clotting times are designed primarily for screening purposes and are very insensitive to minor abnormalities of one or more factors. Patients with mild bleeding tendencies may require more specialized diagnostic procedures.

Moldy sweet clover (*Melilotus* species) toxicosis

Disseminated intravascular coagulation (DIC)

27.2.4.2 LESS COMMON CAUSES

Rodenticide (warfarin) toxicosis

Pyrrolizidine alkaloid toxicosis

Rubratoxicosis

Aflatoxicosis

Bitterweed *(Hymenoxys odorata)* toxicosis

Chronic hepatic fibrosis

27.3 PROLONGED ACTIVATED PARTIAL THROMBOPLASTIN TIME

The aPTT screens the function of the intrinsic coagulation pathway (see Fig. 27-1) and is sensitive to deficiencies or abnormal activity of factors VIII:coagulant (VIII:C), IX, XI, and XII. Insufficiencies of prekallikrein and high molecular weight kininogen may prolong the aPTT, depending on the thromboplastin reagent used in the assay. Thromboplastin in which ellagic acid is used as the activator will not demonstrate a prekallikrein deficiency because ellagic acid activates factor XII directly. Kaolin activates factor XII by means of prekallikrein. Of course, the aPTT is abnormal if deficiencies of factors in the common pathway exist. The activated coagulation time (ACT) is a simplified variation of the aPTT that can be tested by mixing whole blood with activator and calcium.

The most common cause of a prolonged aPTT is the increased consumption of clotting factors induced by DIC (Boxes 27-5 and 27-6). Liver failure and vitamin K deficiency prolong both the aPTT and PT, because factors II, IX, and X are tested by both. Inherited deficiencies of factors VIII,[2] IX, and XI[3] and prekallikrein[4] have been described in horses, and these are associated with prolonging the aPTT without affecting the PT. Congenital factor VIII deficiency is sex-linked, occurring only in males.[2,5] A mixed deficiency of intrinsic coagulation was reported in an aged horse with lymphosarcoma.[6] Inherited factor XI deficiency is transmitted in Holstein cattle by an autosomal recessive trait.[7]

27.3.1 Box 27-5 Causes of Prolonged Activated Partial Thromboplastin Time in Horses

27.3.1.1 COMMON CAUSES

Disseminated intravascular coagulation (DIC)

Warfarin toxicosis

Acute hepatic necrosis

27.3.1.2 LESS COMMON CAUSES

Moldy sweet clover toxicosis

Hemophilia A (deficient factor VIII:C)

Congenital deficiencies of factor IX, factor XI, prekallikrein, or high—molecular-weight kininogen

Hepatotoxins (pyrrolizidine alkaloids, rubratoxins, aflatoxins, bitterweed)

27.3.2 Box 27-6 Causes of Prolonged Activated Partial Thromboplastin Time in Ruminants

27.3.2.1 COMMON CAUSES

Moldy sweet clover toxicosis

Disseminated intravascular coagulation (DIC)

27.3.2.2 LESS COMMON CAUSES

Congenital deficiency of factor XI

Rodenticide (warfarin) toxicosis

Hepatotoxins (pyrrolizidine alkaloids, rubratoxins, aflatoxins, bitterweed)

Clinical signs of clotting factor deficiencies are those of hemorrhagic diathesis, as described in the previous section. Cattle deficient in factor XI seem to have complete in vivo coagulation competency. The level of factor VIII:C or factor IX must drop below 5% of normal before spontaneous bleeding occurs. Hemophilia A is a deficiency in factor VIII:C.

A disseminated coagulopathy should be manifested by several abnormalities in the coagulation profile, although variable use, synthetic rates, and the half-lives of clotting factors may result in abnormality of only one clotting time (PT *or* aPTT). Serial analyses should reveal a trend toward prolonged PT and aPTT, with dropping platelet numbers. When a persistently prolonged aPTT is the only laboratory abnormality, hereditary deficiency of one or more clotting factors should be suspected. Specific quantitative assays of intrinsic clotting factors usually are reserved for experienced coagulation laboratories.

27.4 ELEVATED FIBRIN AND FIBRINOGEN DEGRADATION PRODUCTS

Measurable levels of FDPs in the serum generally indicate increased fibrinolysis in response to excessive activation of coagulation (i.e., DIC) (Box 27-7). Severe inflammatory processes, hemorrhagic disorders, or postoperative states that cause extensive intravascular fibrin deposition may exceed the clearance capacity of the mononuclear phagocyte system (MPS) and elevate serum FDPs. Primary (spontaneous) hyperfibrinolysis has not been described in large animals.

Elevated serum FDPs contribute to the hemorrhagic manifestations of DIC by interfering with thrombin activity, fibrin monomer polymerization, and platelet function. Interpretation of this test depends on evaluation of the other components of the clotting profile (platelet count, PT, aPTT) in concert with the patient's clinical signs. A serum

FDP level above 40 µg/mL most often occurs secondary to DIC; however, values below 40 µg/mL do not exclude the diagnosis of DIC, because there may be considerable compensation by the MPS, degradation of FDPs, or both.

27.4.1

Box 27-7 Causes of Elevated Fibrin and Fibrinogen Degradation Products in Large Animals

27.4.1.1

COMMON CAUSES

Disseminated intravascular coagulation (DIC)

Thrombophlebitis

Postoperative state

Severe inflammation

Immune-mediated thrombocytopenia (IMTP)

27.4.1.2

UNCOMMON CAUSES

Massive internal hemorrhage

Primary hyperfibrinolysis

27.5

REDUCED PLASMA ANTITHROMBIN III

The physiologically most important inhibitor of coagulation is the α-globulin called *antithrombin III* (AT-III). This low—molecular-weight glycoprotein contributes up to 70% of the total procoagulant-inhibiting activity in plasma and can neutralize thrombin-activated factors IX, X, XI, and XII, kallikrein, and plasmin. Heparin is a necessary cofactor for the action of AT-III, causing a 200-fold acceleration of the interaction between the inhibitor and its substrates. Plasma AT-III may be reduced by failure of production in the liver, excessive use, loss from the intravascular compartment, or increased catabolism.

Chronic liver disease may result in failure to produce AT-III and a number of other important plasma proteins; however, horses with chronic liver disease were shown to have a higher than normal plasma AT-III level in addition to hyperfibrinogenemia.[8] These findings suggest that AT-III may behave as an acute-phase protein in horses, as has been shown in cats.[9]

In conditions such as DIC, AT-III is consumed as a result of irreversible binding to activated clotting factors. Any pathologic generation of thrombin and other activated clotting factors, such as can occur with trauma, neoplasia, or endotoxemia (all known initiators of DIC), would be expected to cause some reduction in plasma AT-III (Boxes 27-8 and 27-9).

27.5.1 Box 27-8 Causes of Reduced Antithrombin III in Horses

27.5.1.1 COMMON CAUSES

Disseminated intravascular coagulation (DIC)

Protein-losing enteropathy (e.g., granulomatous enteritis, intestinal lymphosarcoma, nonsteroidal antiinflammatory drug toxicosis)

Chronic glomerulonephritis

27.5.1.2 LESS COMMON CAUSES

Acute toxic enteritis

Acute hepatic necrosis

Starvation

Venous thrombosis

27.5.2 Box 27-9 Causes of Reduced Antithrombin III in Ruminants

27.5.2.1 COMMON CAUSES

Disseminated intravascular coagulation (DIC)

Renal amyloidosis

Johne's disease

27.5.2.2 LESS COMMON CAUSES

Starvation

Venous thrombosis

Hepatic failure

Diseases that cause massive proteinuria or protein-losing enteropathy result in reduced plasma AT-III, in addition to loss of other plasma proteins. Because of the small size of AT-III (molecular weight approximately 65,000), it is lost in approximately the same proportion as albumin. Starvation or sepsis resulting in massive protein catabolism may cause a reduction in plasma AT-III.

The major clinical sequela of AT-III deficiency is a tendency to develop venous thrombosis. A hypercoagulable state with nephrotic syndrome has been recognized in humans,[10] dogs,[11] and cattle.[12] Venous thrombosis is commonly recognized in horses with severe toxic colitis or endotoxemia; whether this involves AT-III is not known. The contribution of AT-III consumption in DIC to the clinical manifestations of this syndrome is difficult to evaluate; however, use of AT-III concentrates in human patients with acute DIC has improved survival in some circumstances.[8] As with all components of the hemostatic system, plasma AT-III must be evaluated in light of other clotting data.

27.6 HYPOFIBRINOGENEMIA

Hypofibrinogenemia may result from impaired hepatic synthesis, increased consumption with DIC, degradation during primary hyperfibrinolysis, or uncompensated loss during massive hemorrhage (Boxes 27-10 and 27-11). A reduction in plasma fibrinogen is rare under any circumstances in large animals. This protein is produced exclusively by the liver, and it functions as an acute-phase reactant, being rapidly released in response to a variety of inflammatory and procoagulant stimuli. The equine liver seems to have a remarkable reserve capacity to produce fibrinogen, because hypofibrinogenemia is a feature only of acute fulminant hepatic necrosis, which is attended by DIC. 420 421

27.6.1 Box 27-10 Causes of Hypofibrinogenemia in Horses

27.6.1.1 UNCOMMON CAUSES

Acute hepatic necrosis

Acute severe disseminated intravascular coagulation (DIC)

Severe hepatic fibrosis

27.6.2 Box 27-11 Causes of Hypofibrinogenemia in Ruminants

27.6.2.1 UNCOMMON CAUSES

Hereditary afibrinogenemia (goats)

Acute severe disseminated intravascular coagulation (DIC)

Hereditary afibrinogenemia has been recognized in a family of Saanen dairy goats.[1] This incompletely dominant trait causes a hemorrhagic diathesis in newborn kids that is characterized by umbilical bleeding, recurrent hemarthroses, and bleeding into the skin and mucous membranes. Heterozygotes have hypofibrinogenemia.

27.7 OTHER TESTS OF HEMOSTATIC FUNCTION

Other tests of hemostasis are performed less routinely in large animals because of lack of specificity or sensitivity, technical difficulty, or expense. Some of these tests may be useful in a particular disease situation.

27.7.1 Thrombin Time

The time required for a standard thrombin solution to clot plasma is a measure of the rate of fibrinogen to fibrin conversion. In large animals a prolonged thrombin time usually indicates the presence of FDPs that interfere with fibrin polymerization.

27.7.2 Factor Assays

(See previous discussion of prolonged aPTT.) For consumptive states such as DIC, factor analyses rarely provide significantly more information than the PT and aPTT. Factor VIII:C functions as an acute-phase reactant and may be increased by inflammatory disease. Specific factor analyses are indicated for the diagnosis of hereditary factor deficiencies.

27.7.3 Platelet Factor 3

The platelet factor 3 (PF_3) test is an indirect assay for the presence of serum antibodies directed against platelets. Because of its low sensitivity for the diagnosis of IMTP, it is no longer routinely available.

27.7.4 Plasminogen

The zymogen precursor of plasmin is reduced in the plasma during states that cause pathologic increased fibrinolysis such as DIC. Plasminogen levels have been explored in horses with colic.[13]

27.7.5 α_2-Antiplasmin

α_2-Antiplasmin (α_2-AP) a plasma glycoprotein, is the main physiologic inhibitor of fibrinolysis. In humans, α_2-AP is decreased by severe liver disease (reduced production) and with DIC (consumption). Limited experimental studies in ponies suggest that α_2-AP may be reduced significantly with chronic DIC.[14]

27.7.6 Fibronectin

The soluble form of fibronectin is a large glycoprotein that promotes clearance of plasma particulates by the MPS. Fibronectin initially is consumed by binding to fibrin breakdown products and platelet microaggregates; however, it is replenished rapidly in the acute-phase response. A persistently low fibronectin level is associated with a high mortality rate in humans with DIC.

27.7.7 Eicosanoids

During activation of coagulation, thromboxane A_2 (TxA_2) and prostacyclin are produced and released by platelets and endothelial cells, respectively. TxA_2 is a potent vasoconstrictor and aggregates platelets, whereas prostacyclin has the opposite effect. Plasma concentrations of thromboxane B_2 (TxB_2), the stable hydrolysis product of TxA_2, are elevated during acute, severe DIC in humans. Although not actually evaluated in DIC, both eicosanoids are increased in horses and cattle with endotoxemia.

27.7.8 Protein C

The protein C pathway provides the second major anticoagulant mechanism that regulates hemostasis. Protein C is activated by thrombin, then proteolytically destroys factors V and VIII. In humans, plasma protein C may be reduced by liver failure or by disseminated coagulopathy, inducing a tendency for thrombotic disease. The same may be true in horses.[13]

28 Chapter 28 Collection and Analysis of Bone Marrow

Andrea A. Bohn

28.1 BACKGROUND

The hematopoietic system is composed of erythrocytes, leukocytes, and platelets, their precursor cells, and the tissues that support the continuous cycles of cell differentiation required for maintenance of oxygen delivery, protection from infectious agents, and hemostasis. A single pluripotent stem cell is the precursor for all hematopoietic cells. From this cell arise stem cells directed toward various cell lineages. Postnatally, hematopoiesis to replenish circulating erythrocytes, granulocytes, monocytes, and platelets predominantly occurs in the bone marrow. Although lymphocytic precursor cells continue to travel from the bone marrow to the thymic cortex and enteric mucosa for differentiation postnatally, most circulating lymphocytes are associated with the extramedullary lymphoid organs.

Constantly replenishing blood cells, the bone marrow is one of the most active tissues in the body. Blood cell turnover is rapid; for example, neutrophils have a circulatory half-life of approximately 10 hours. The lifespan of platelets, on average, is approximately 7 to 10 days, and the lifespan of large animal erythrocytes is approximately 5 months, with slightly shorter half-lives reported in some breeds.[1–3] Readers are referred to a veterinary hematology textbook for more in-depth information on the hematopoietic system.[4]

28.2 INDICATIONS FOR BONE MARROW ASPIRATION OR BIOPSY

Bone marrow evaluation provides important diagnostic information on the hematopoietic status of an animal; it is typically performed to evaluate hematopoiesis and to detect evidence of neoplastic or infectious disease (Box 28-1). The complete blood count (CBC) is the most common method used to evaluate the hematopoietic system, but a more comprehensive evaluation includes bone marrow aspiration and/or biopsy. Bone marrow aspiration is commonly used to evaluate the cause of cytopenia. Unexplained nonregenerative anemia, neutropenia, thrombocytopenia, and pancytopenia are indications for bone marrow aspiration. In these cases, bone marrow evaluation is used to determine if the cytopenia is more likely a result of lack of production or of consumption or destruction of the cell in question. If an animal's clinical presentation and other laboratory data provide a reasonable explanation for cytopenia, a decision to perform the procedure may not be justified. For example, if another disease process is present that could explain nonregenerative anemia, such as a chronic inflammatory disease or chronic renal failure, bone marrow aspiration is not indicated in most cases.

Another common reason for bone marrow aspiration is the observation of atypical cells, unexplained immature cells, or abnormal blood cell morphology on a peripheral blood film. In these cases bone marrow is evaluated for the diagnosis of leukemia, myelodysplastic syndromes, and infiltrative disease. Potential infiltrative disease is sometimes detected radiographically, and the presence of lytic or proliferative bone lesions can also be an indication for bone marrow aspiration. Because abnormalities within the bone marrow are not always reflected in the peripheral blood, it may be prudent to perform bone marrow aspiration if a neoplastic or infectious process is clinically suspected but cannot be found elsewhere. This suspicion may arise from detecting an unexplained hypercalcemia or monoclonal gammopathy, conditions that are often associated with neoplasia; identifying a fever of unknown origin; or recognizing the probability of an infectious agent that may have bone marrow involvement.

Even though complication rates are low, bone marrow aspiration should not be performed indiscriminately, and, as for all testing, the clinician should consider what question is being asked and if bone marrow evaluation is the appropriate diagnostic test for answering that question. Examination of a peripheral blood film often provides clues as to the necessity of bone marrow evaluation. In general, cytopenia should be persistent and confirmed before bone marrow evaluation is performed. Rechecking a low cell count by drawing a new blood sample, especially if initial results do not fit with the clinical presentation of the animal, is recommended. An ethylenediamine tetraacetic acid (EDTA)–associated pseudothrombocytopenia has been reported in horses,[5] which can be ruled out by drawing blood into a heparin or sodium citrate tube for platelet counts. A low platelet count can also be artifactual if platelet aggregation occurs during blood collection. The presence of clumped platelets on a peripheral blood film is an indication that platelet aggregation has occurred and that a low platelet count should be viewed with skepticism. Repeated CBCs can also be used to assess persistence of an abnormality. It can take up to 5 days for the bone marrow to respond to acute anemia and for regeneration to be evident in the peripheral blood. Bone marrow aspiration is typically not indicated when there is evidence of regeneration in the peripheral blood. Evidence of erythroid regeneration in the peripheral blood includes an increase in the number of reticulocytes or polychromatophilic cells, basophilic stippling, and macrocytosis. Because the changes typically associated with regenerative anemia are rarely seen in horses, bone marrow aspiration is often the only way to assess erythropoiesis in this species. Evidence of regeneration in granulocytes includes the presence of a left shift and toxic changes. 422

423

28.2.1

Box 28-1 Indications for Bone Marrow Evaluation

To assess regeneration in anemic horses

To investigate cause of cytopenia

Unexplained nonregenerative anemia

Unexplained neutropenia

Unexplained thrombocytopenia

Pancytopenia

To investigate for neoplasia

Atypical cells in peripheral blood

Lytic or proliferative bone lesions

Hypercalcemia

Monoclonal gammopathy

To investigate for infectious disease

Fever of unknown origin

Lytic or proliferative bone lesions

Cytologic evaluation of a bone marrow aspirate is more commonly performed than core biopsy because results can be attained more quickly and the morphology of the cells is superior, allowing a more accurate assessment of cell types. The disadvantage of an aspirate versus biopsy is that architecture cannot be assessed with an aspirate and it can be impossible to confirm whether a poor cellular sample is a result of a pathologic process or an unsatisfactory sampling. The core biopsy provides a better assessment of bone marrow cellularity and is necessary for the confirmation of myelofibrosis, generalized bone marrow suppression, or necrosis. The core biopsy also provides a more accurate assessment of metastatic neoplasia because architecture can be assessed. When collecting a bone marrow sample for cytologic evaluation, some clinicians will also collect a core biopsy to store in formalin in the event that histologic evaluation is later recommended.

If a bone marrow sample is being submitted for evaluation, it is recommended to always submit a concurrent peripheral blood sample for a CBC because interpretation of the bone marrow is dependent on CBC results and changes can occur quickly in the blood.

28.3 BONE MARROW COLLECTION

28.3.1 Sites

Hematopoietically active bone marrow is most consistently found in the flat bones (sternum, ribs, pelvis, vertebrae) and proximal ends of long bones (humerus, femur). The most commonly described sites for bone marrow aspiration in large animals are the sternum, ribs, and iliac crest (Figs. 28-1 and 28-2). Which location is chosen may depend on species, age, and temperament of the animal as well as available facilities.

Fig. 28-1 Equine skeleton depicting sites for bone marrow aspiration: the sternum, iliac crest, vertebral ends of ribs *8* to *18*, and first lumbar vertebra.

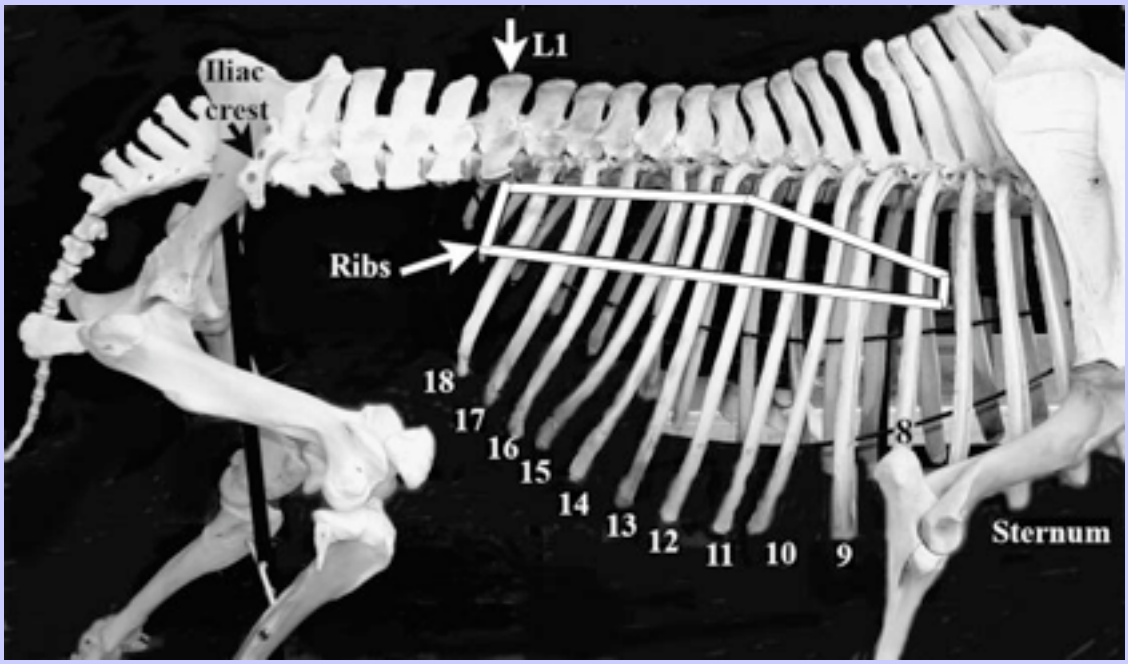

Fig. 28-2 Bovine skeleton depicting sites for bone marrow aspiration: the sternum and vertebral ends of ribs *8* to *11*.

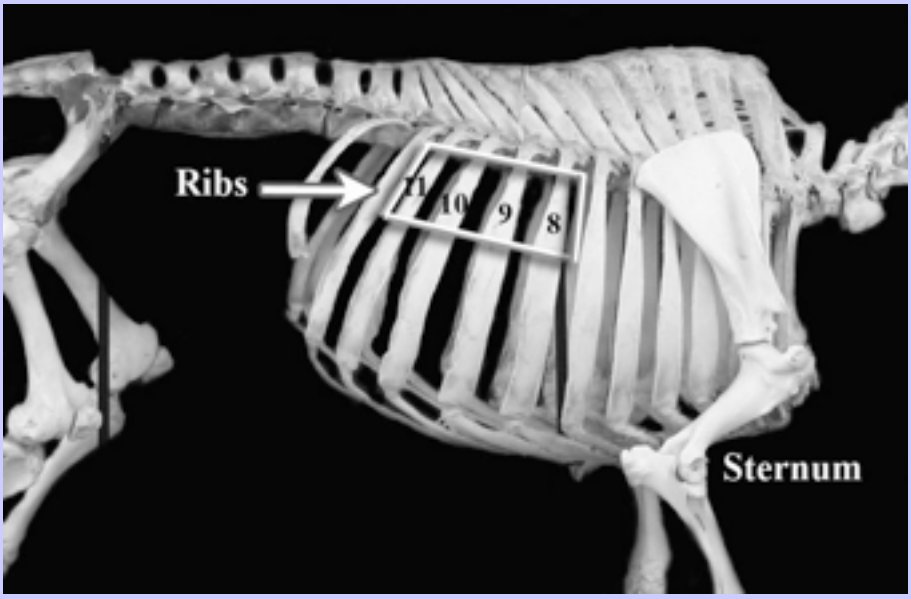

Fig. 28-3 Lateral view of equine sternum. The ventral sternum is the most popular site for sampling bone marrow in the adult horse *(bracket),* but the cranial sternum can also be used. The aspirate site of the cranial sternum is reached by going one hand width below *(dotted line)* and one hand width lateral to its cranial tip. From there, the needle is advanced in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse *(arrow)*.

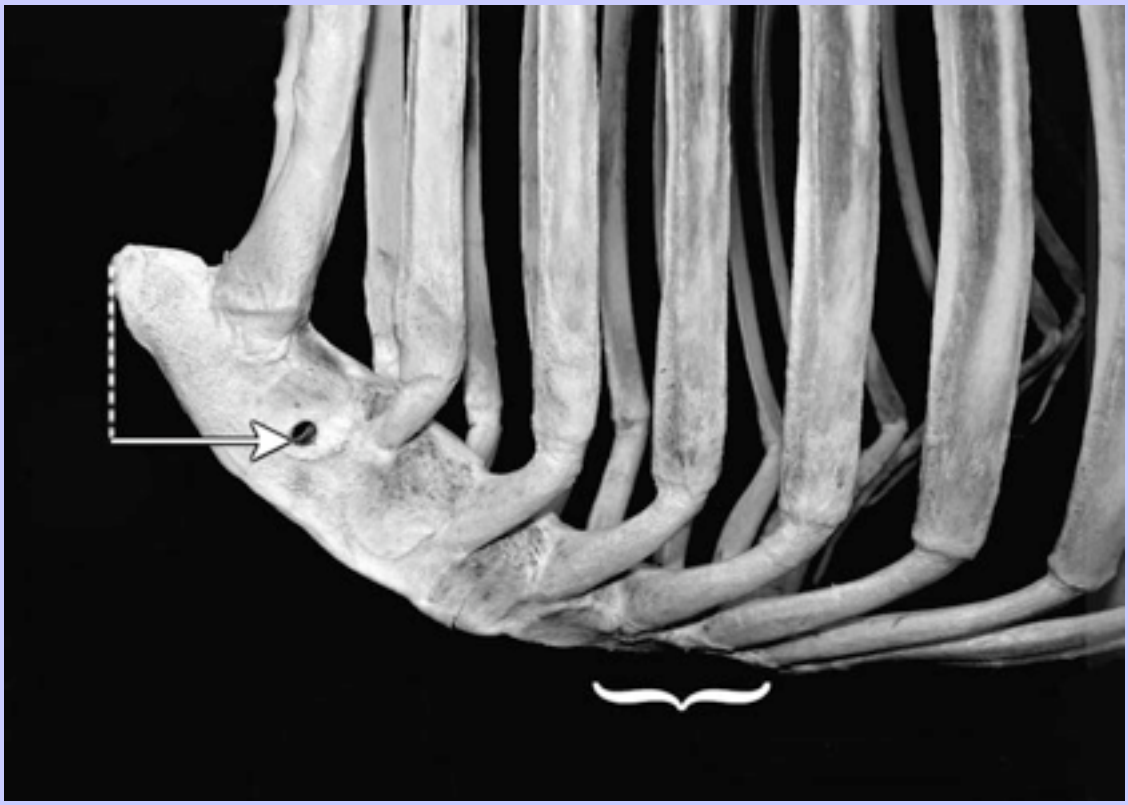


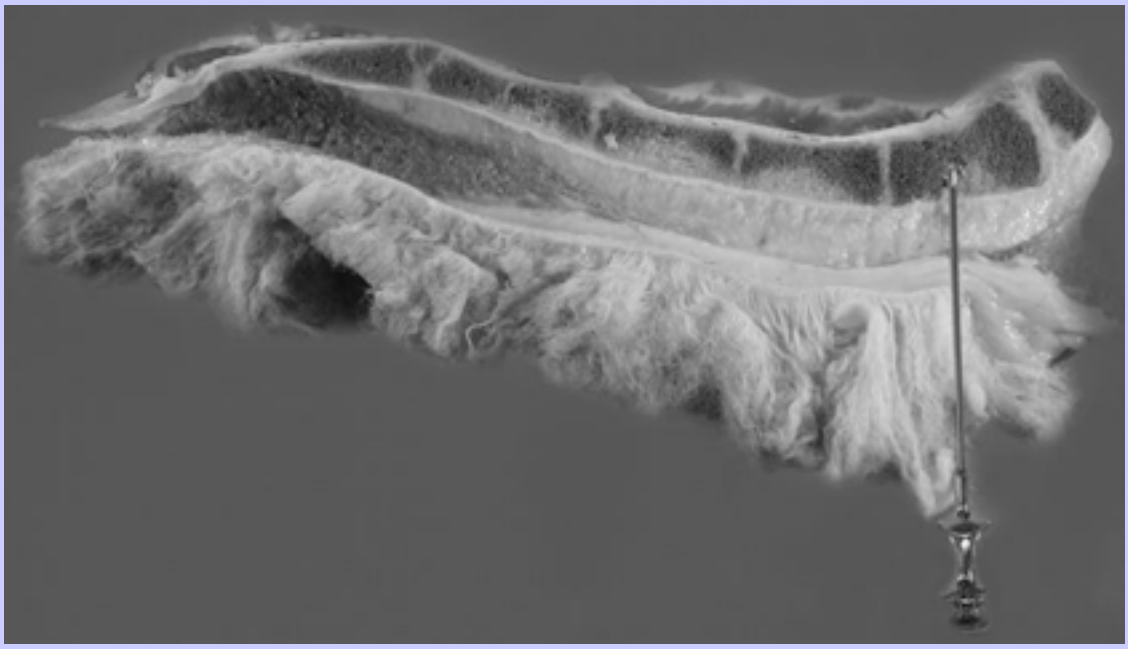
The ventral sternum is the preferred site in adult horses, small ruminants, and camelids (Figs. 28-3 to 28-6). It is one of the preferred sites in cattle (Fig. 28-7). The advantages of the sternum are that it is covered by only a thin layer of bone, it has areas not covered by thick muscles, and samples can be reliably obtained from the site. The disadvantages of the sternum are that it is near vital organs and that the operator is in an awkward position when working on a standing animal. A procedure for sampling the cranial aspect of the sternum has also been described in horses[6] (see Fig. 28-3). There is more muscle to go through with this approach.

The ribs are one of the preferred sites for bone marrow aspirates in cattle. The dorsal ends of ribs 8 to 11 can be accessed for sequential aspirations[7] (see Fig. 28-2). Ribs can also be used in the horse, but the needle slips off the bone more easily. In calves, sheep, and goats the marrow cavity of the rib is small and more difficult to hit,[8]

and in camelids the rib marrow is less consistent in location than the sternum.[9] Successful collection from ribs has been described in camels, with the fifth to eighth ribs as the best sites.[10] 423 424

Fig. 28-4 Ventral view of equine ribcage and sternum. *Arrows* depict optimal sites for sternal bone marrow aspiration or biopsy, on midline between the elbows of the horse.

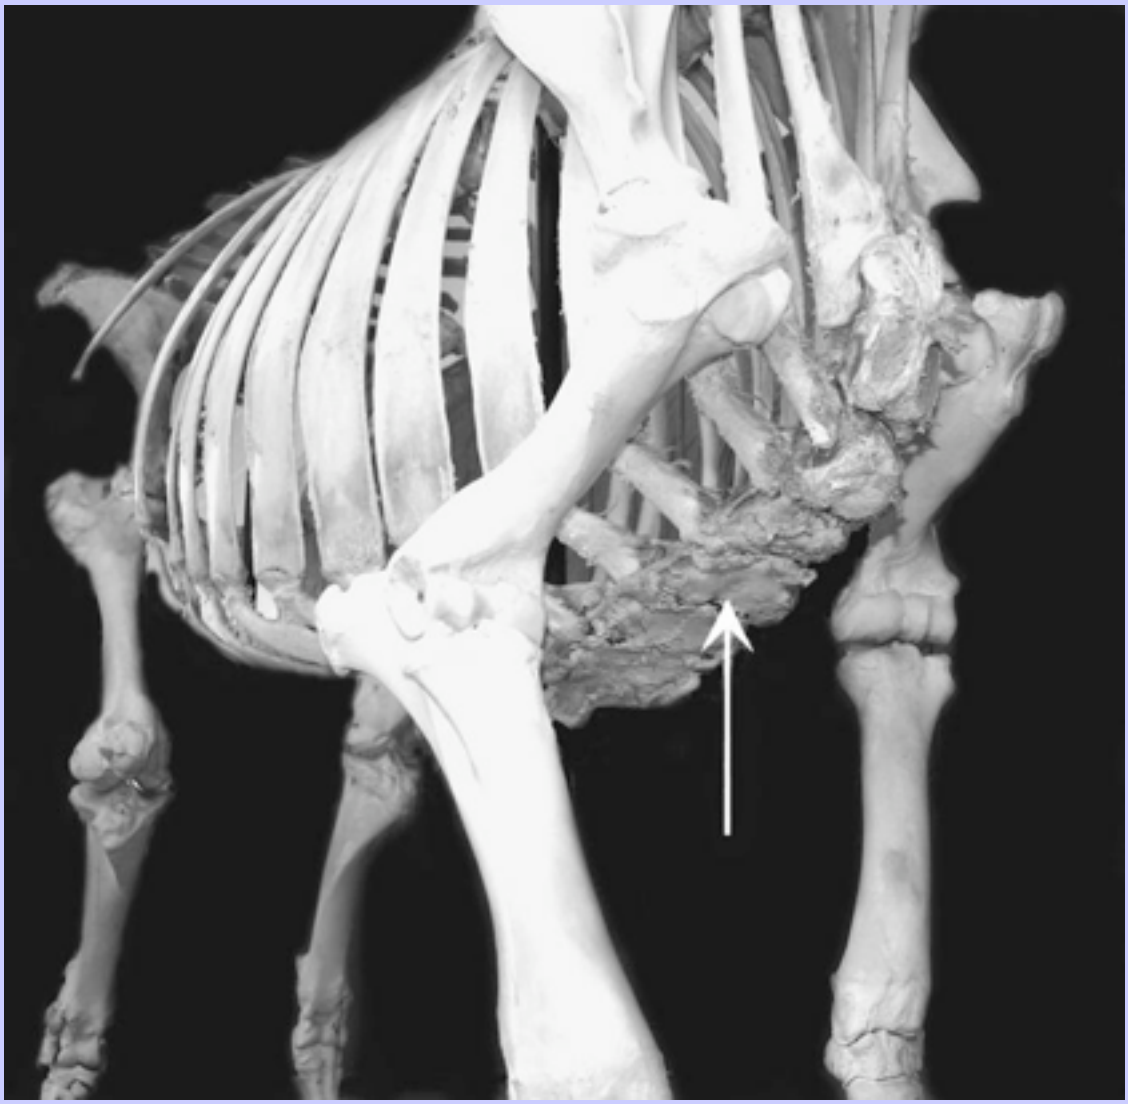
Fig. 28-5 Cross-section of sheep sternum. The needle is entering the second sternebra. The second through fourth sternebrae are recommended as optimal sites for bone marrow collection.



The iliac crest is the site often used in foals for bone marrow sampling and can also be used in young adult horses up to a couple of years in age[11] (Fig. 28-8). Samples can also be obtained from older horses at this site, but the needle must be inserted more deeply, needle placement is more critical, and it becomes difficult to obtain a successful sample in horses more than 9 years old.[12] The wing of the ilium is generally considered too thin for bone marrow aspiration in camelids,[9] although successful bone marrow aspiration from the iliac crest of a 2-year-old alpaca has been reported[13] (Fig. 28-9). The iliac crest can also be used in sheep (Fig. 28-10).

Fig. 28-6 Llama sternum. The llama sternum can be sampled at ventral midline, inserting the needle vertically through the callosity, or from a lateral approach, inserting the needle dorsal to the callosity.

Fig. 28-7 Bovine sternum. The third and fourth sternebrae are recommended for bone marrow collection. The *arrow* is pointing to the fourth sternebra.



Another site informally described for horses is the spinal process of the first lumbar vertebra (Fig. 28-11). It is usually vertical, whereas the adjacent processes tend to be more angled. The tip of the process is wider than the shaft and has a thin layer of bone. The needle is advanced straight down into the marrow cavity, which is narrow, but if the needle is close to correct placement, the walls of the process help guide the needle into the marrow cavity. The advantage of this site is that the operator is not working under the horse. The spinal process is reported to be a poor site to sample in the cow.[14]

Fig. 28-8 Equine pelvis. To obtain bone marrow, the needle should be placed near the center of the tuber coxae *(arrow)* and advanced toward the opposite coxofemoral joint *(dotted line)*.

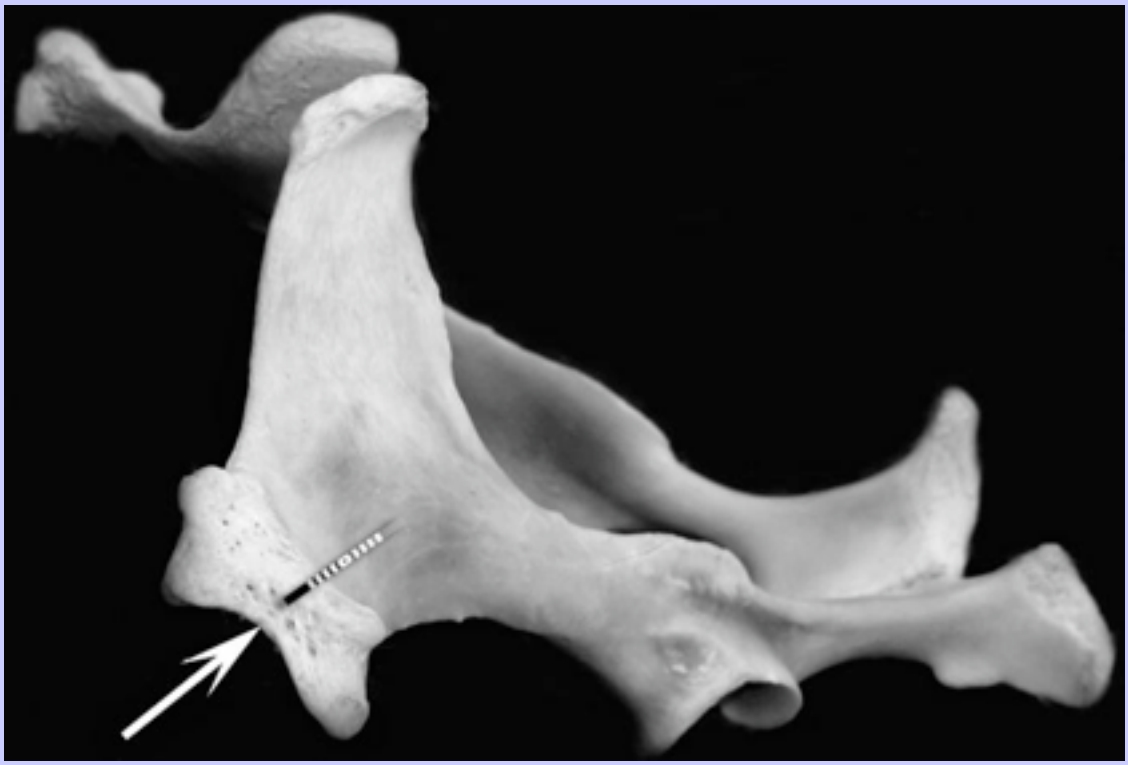


Fig. 28-9 Llama pelvis. The wing of the ilium *(arrows)* is generally considered too thin for easy bone marrow collection in camelids.

28.3.1.1

APPROACH TO THE STERNUM

In the horse, bone marrow aspiration is typically performed in the standing animal. Sedation or a twitch may be used if necessary. The preferred site is on the ventral midline in the cleavage between the deep pectoral muscles where a line connecting the points of the elbows would cross[15] (Figs. 28-4 and 28-12). The

manubrium of the sternum can also be sampled in horses by finding the cranial end of the sternum and going one hand width below and one hand width laterally from the end (see Fig. 28-3). From this spot the needle is advanced through the muscle in a horizontal plane at a 45-degree angle to the longitudinal axis of the horse.[6]

Sternal bone marrow can be sampled from adult cattle standing in stocks or a squeeze chute. It may be necessary to use techniques to prevent kicking, such as jacking the tail, or sedation. Unruly adult cattle and large calves can be cast and held in lateral recumbency. The upper front leg of the cast animal is held extended along the neck, exposing the sternum, after the other legs are secured with a rope.[16] Calves that weigh less than 300 lb can be placed in dorsal recumbency and secured by assistants or with ropes.[8] The needle should be placed on the midline and inserted perpendicular to the third or fourth sternebra. The appropriate sternebrae is located by palpating the third or fourth rib and following it to the sternum.

Fig. 28-10 Bone marrow aspirate from the ileum of a sheep. This sheep was undergoing necropsy, and the wing of the ileum has been dissected out.

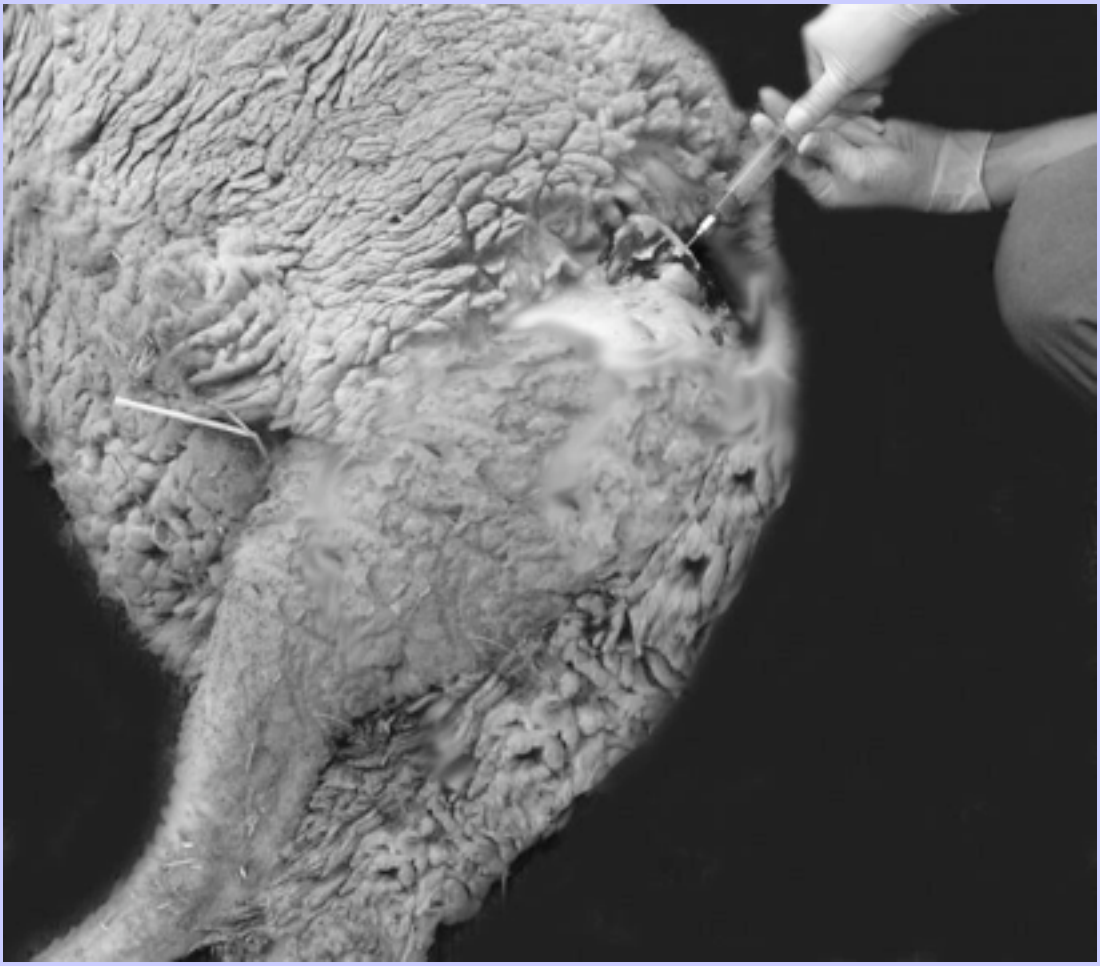

Fig. 28-11 First lumbar vertebra of a horse. Although not widely used, the spinal process of L1 *(arrow)* is another site from which bone marrow can be obtained in the horse.

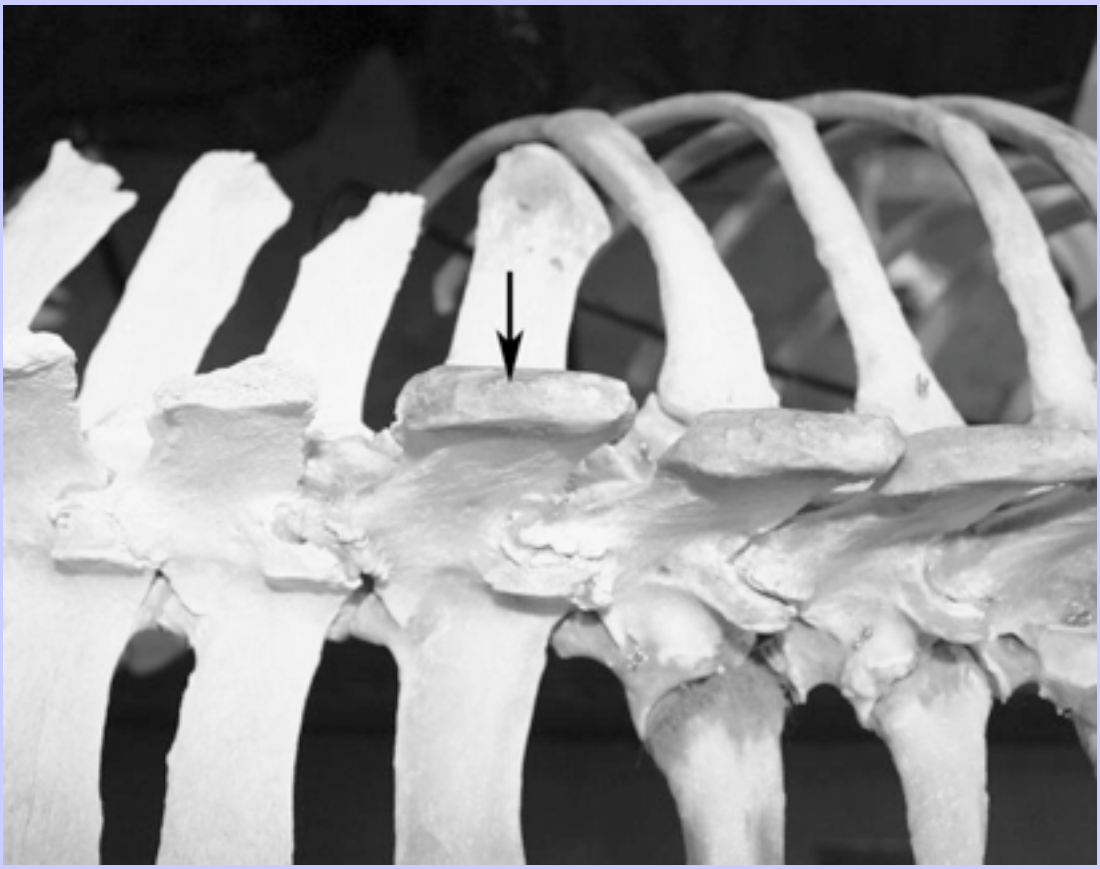


For the sternum of a small ruminant to be sampled, the animal is placed in dorsal recumbency with legs secured, or it can be restrained in a sitting position with an assistant standing behind, supporting the animal and holding a foreleg in each hand.[8] The location of the appropriate site is midline, between the front legs. The second through fourth sternebrae can be used in sheep (see Fig. 28-5). A prominence may be felt between the first and second sternebrae. The appropriate sternebrae can also be located by palpating ribs and following them to their articulations.[17] In sheep, the needle will advance approximately 0.5 cm into the bone (2.5 to 3.8 cm from the skin) before entering the marrow cavity.[17]

425

426

Fig. 28-12 Bone marrow aspiration in a horse. The animal was placed in a stock and sedated. **A,** The ventral sternum between the horse's elbows is clipped and surgically scrubbed. **B,** After local anesthetic, a stab incision is made on midline. **C,** A spinal needle is inserted to collect marrow.

The sternum of llamas can be sampled with the animal either standing in a chute or in left lateral recumbency, usually sedated[18] (see Fig. 28-6). The sample can be taken by inserting the needle vertically through the callosity on the ventrum of the sternum or with a lateral approach, approximately 3 to 4 cm dorsal to the callosity with the needle directed medially and slightly dorsally to engage bone.[9] Marrow will be approximately 2.5 cm deep in an adult. The sample is normally more dilute with blood than in other species.[9]

When the ventral sternum is sampled, unless a lateral approach is used, the needle should be placed on the midline, as near to the center of the bone as possible, and advanced perpendicular to the bone. A sudden reduction of resistance may be felt when the marrow cavity is entered, but because the sternal cortex is so thin, especially in horses, there may be no obvious change. Care needs to be taken to not enter the thoracic cavity. Because a change in resistance may not be felt, once the tip of the needle is firmly seated in the bone an aspiration attempt should be made.

28.3.1.2

APPROACH TO THE RIB

The vertebral end of the rib more consistently contains marrow than the sternal end of the bone[19,20] (Fig. 28-13). Palpation can be used to find the rib that has the least amount of fascia covering it. In the horse, the eighth to eighteenth ribs can be used, going as high as possible but below the latissimus dorsi and serratus posticus muscles[19] (see Fig. 28-1). In cattle, place the needle approximately 3 inches ventral to the ninth or

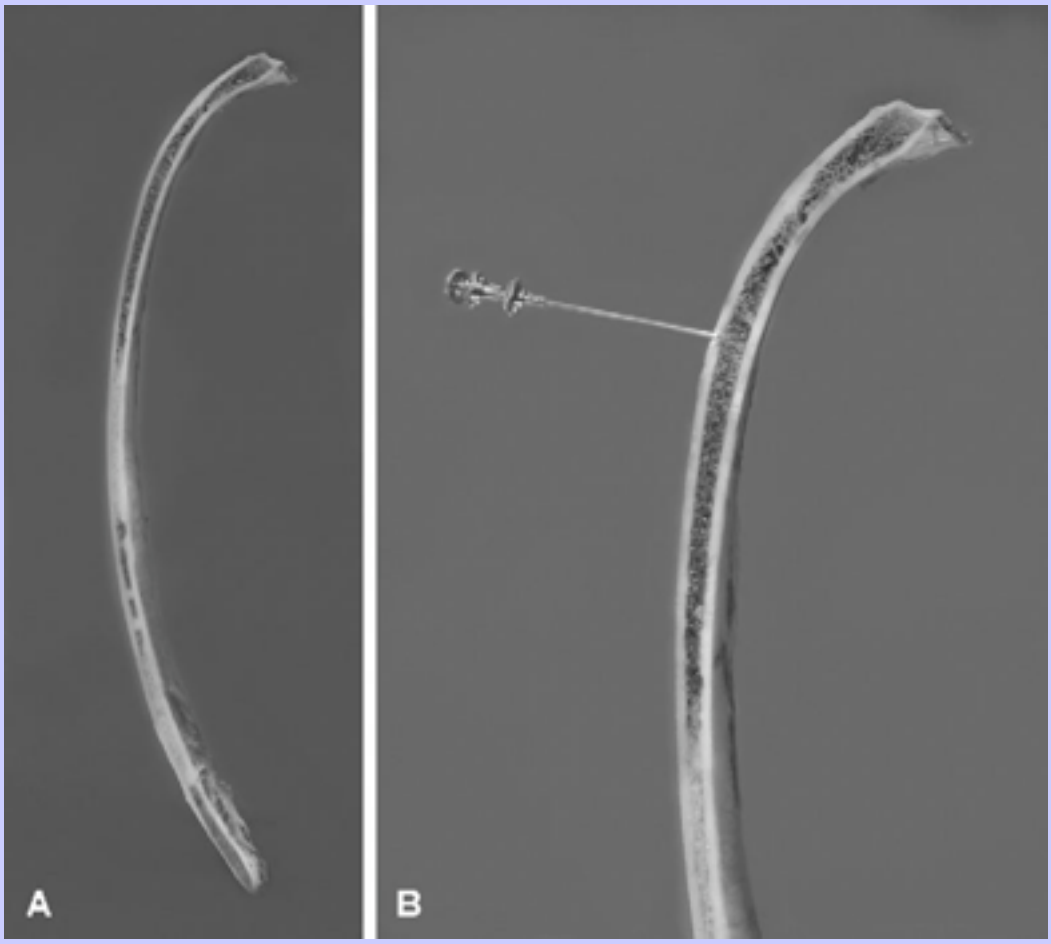
tenth costovertebral junction[14] (Figs. 28-2 and 28-14). The needle should be perpendicularly inserted at the middle of the rib, midway between the anterior and posterior borders (see Fig. 28-14, *A*). To help keep the needle from sliding off the bone, a scalpel can be first inserted until it touches the bone to be used as a guide.[11]

28.3.1.3 APPROACH TO THE ILIAC CREST

The iliac crest is often used in foals (see Fig. 28-8). The needle should be placed midway between the two tuberosities of the tuber coxae and somewhat toward its posterior border. With regard to angle, the needle should be pointing at the coxofemoral joint of the opposite side. Bone marrow will be hit when the needle is inserted approximately ⅛ inch for foals, whereas in adult horses bone marrow may be more than 2 inches deep. The main benefit of using this method is that there is no risk of inadvertently entering the thoracic cavity.[12]

426
427

Fig. 28-13 Cross section of bovine rib 10. **A**, Bone marrow is more consistently present in the vertebral end. **B**, Rosenthal bone marrow needle is inserted into the rib approximately 3 inches below the costovertebral junction.



28.3.2 Preparation for Bone Marrow Aspiration or Biopsy

Bone marrow aspiration should be performed as a sterile procedure. After the animal has been restrained and the site of approach identified, hair should be clipped and the area surgically scrubbed (see Fig. 28-12, *A*). Local anesthetic is injected at the site where the needle will be inserted, from the skin to the periosteum (see Figs. 28-14, *B* and 28-15, *A*) A small stab incision is typically made with a scalpel to aid the needle's approach to the bone (see Fig. 28-12, *B*). If the rib is to be sampled, the scalpel blade can be held in place to act as a guide for the needle. It is important to be organized and have all supplies ready so that the procedure will flow smoothly and the sample will not clot before it can be processed (Box 28-2; Fig. 28-16).

How the sample will be ultimately handled will dictate some of the available supplies needed: glass slides, Petri dish, EDTA blood tubes, and/or anticoagulant. One option is to prime the syringe that will be used for aspirating the sample with anticoagulant. To prevent clotting, 1 to 2 mg of EDTA is recommended per milliliter of blood. One to two drops of a 3% to 15% EDTA solution should be adequate. The EDTA solution can be aspirated from a purple-topped blood tube. Priming the syringe with anticoagulant, although it adds a preparatory step, decreases the worry that the sample will coagulate and allows more time for processing the sample. If the syringe is not primed, as soon as the sample is seen in the syringe, the syringe needs to immediately be disconnected from the needle and the sample quickly processed before it has a chance to clot. If a reticulocyte count is to be performed to assess erythroid regeneration, supravital stains such as new methylene blue and brilliant cresyl blue, require mixing with a portion of anticoagulated, liquid sample before slides are made; therefore placing at least some of the bone marrow sample in an EDTA tube is recommended.

The sample in the syringe may be processed by expressing it directly onto several clean glass slides, into an EDTA blood tube, or into a Petri dish or watch glass. The Petri dish or watch glass must contain anticoagulant if no anticoagulant was used in the syringe. The anticoagulant commonly used is EDTA, which can be used in solution or as a salt, but other anticoagulants such as sodium citrate are also effective. Samples placed in an anticoagulant should be immediately gently mixed.

28.3.3 Collecting the Sample

The goal of bone marrow aspiration is to obtain a good sample of hematopoietic cells with minimal blood contamination. Anatomically, within the bone marrow, hematopoietic cells are extravascular and found in spaces dissected by venous sinuses and a central vein.[21] To collect the sample, a bone marrow or spinal needle with stylet should be used. Commonly used needles include Rosenthal, Illinois sternal-iliac, and Jamshidi bone marrow needles (Fig. 28-17). Some needles come with a guard that can be adjusted to prevent deeper penetration than desired. The needle used should be 16 gauge or larger and at least 1½ inches long. Larger needles may be needed, depending on the site of aspiration and the age and size of the animal.

After an animal has been properly prepared, the bone marrow needle is inserted through the skin, perpendicular to the bone (see Fig. 28-12, *C*). Once the needle contacts bone, it can be advanced using manual pressure and a clockwise-counterclockwise twisting motion (see Fig. 28-14, *C*). One hand can be used to stabilize the needle angle and placement while the other hand is on the needle hub pushing and turning the needle.[15] If the needle is going through dense bone, a wood mallet can also be used to advance it.

Fig. 28-14 Bone marrow aspirate of a cow. The animal was placed in a head-gate and sedated, and a tail jack was applied. **A,** The area over the vertebral end of rib 11 has been clipped and surgically scrubbed. The cranial and caudal edges of the rib are palpated approximately 3 inches down from the costovertebral junction, and the midpoint of the rib is identified for aspiration location. **B,** At the chosen aspiration site, lidocaine is injected from skin to periosteum. **C,** After a stab incision has been made and the Jamshidi-type bone marrow needle inserted through the skin, the needle is forcibly pushed forward through cortical bone as it is rotated in a clockwise-counterclockwise motion. **D,** After a decrease in resistance is felt, the stylet is removed. **E,** A syringe is attached to the needle, and a few sharp pulls on the plunger are needed before sample is noted in the hub of the syringe.

Fig. 28-15 Core bone marrow biopsy of a horse. The animal was placed in a stock and sedated; the ventral sternum between the elbows was clipped and surgically scrubbed. **A,** Lidocaine is injected from the skin to the periosteum. **B,** After a stab incision, the Jamshidi bone marrow biopsy needle is advanced into cortical bone. Here the stylet is about to be removed before the needle is advanced further. **C,** Core biopsy sample.

28.3.3.1

Box 28-2 Supply Check List for Bone Marrow Collection

Clippers

Surgical scrub

Lidocaine

Syringe and needle

Sterile gloves

Scalpel blade (No. 15 adequate)

Bone marrow needle

>16 gauge, 1½ inches

10- to 20-mL sterile syringe

Glass slides

Jar of formalin for core biopsy

Optional:

Anticoagulant

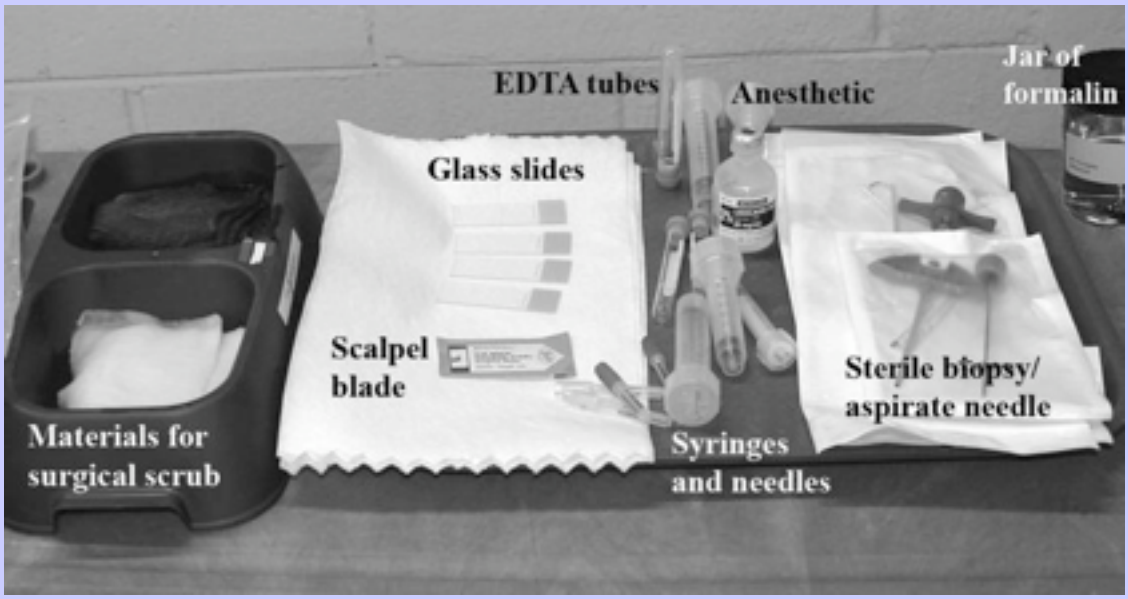
EDTA blood tubes

Petri dish or watch glass

EDTA, Ethylenediaminetetraacetic acid.

Once it is suspected that the needle has entered the marrow cavity, either because of detection of a sudden reduction in resistance or because of needle depth, the stylet should be removed and an aspiration attempted (see Fig. 28-14, *D*). In dense bone, pliers may be helpful in removing the stylet.[8] After the stylet is removed, a 10- to 20-mL sterile syringe is securely attached to the needle, and the plunger of the syringe is pulled back quickly and sharply, creating negative pressure in order to dislodge bone marrow particles (see Fig. 28-14, *E*). Suction can be repeated two or three times. As soon as blood is seen in the hub of the syringe, suction should be discontinued, the needle and syringe removed from the animal, and the sample processed promptly. Additional suction will likely only result in hemodilution of the sample. The first drop of blood is the most cellular, and further aspiration results in lower cellularity of the sample.[22]

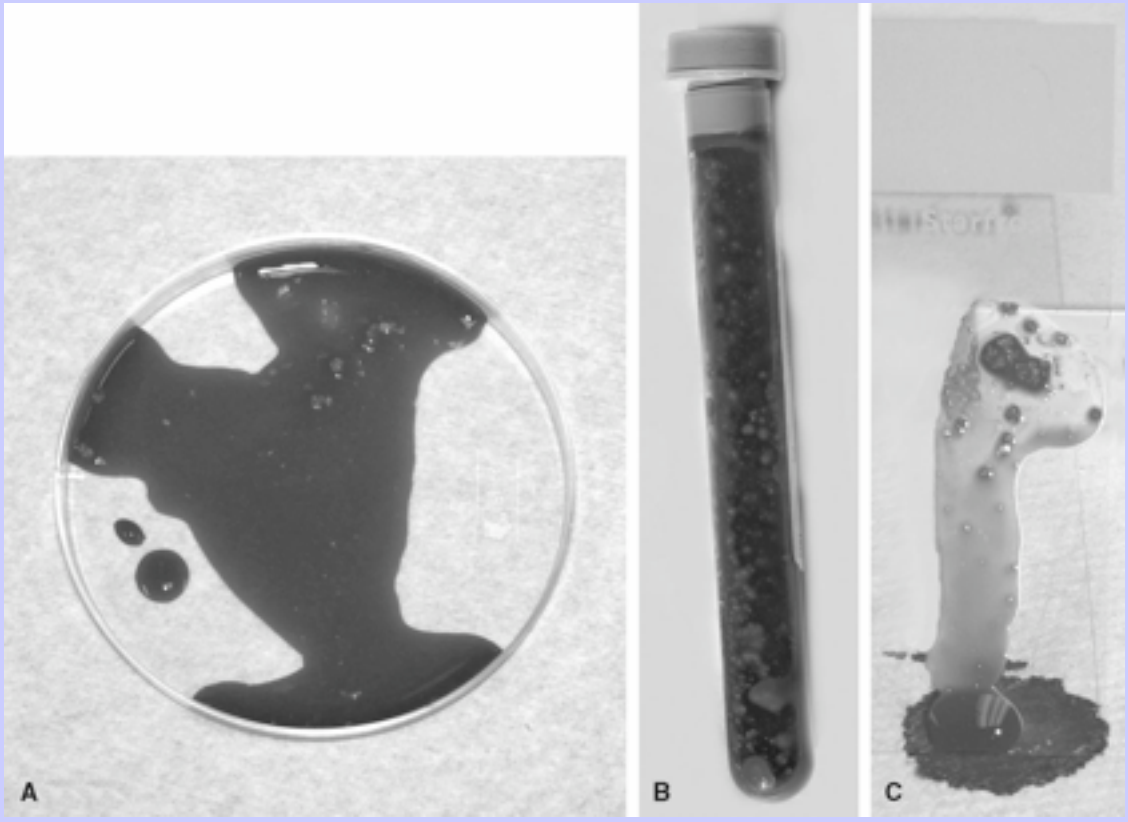
Fig. 28-16 Supply table is set up and ready for bone marrow aspiration. Sterile gloves were opened on an adjacent table.



If the initial aspiration does not obtain any material, remove the syringe, replace the stylet, and carefully advance the needle a little further. If still no sample is obtained after additional advancement of the needle and repeated suction, slowly withdraw the needle while applying suction to the syringe. Ultimately, repositioning the needle to a different site, such as moving a couple of centimeters cranially or caudally, may result in a successful aspiration.[9]

Fig. 28-17 Bone marrow needles with stylets separated. On the *left* is a 14-gauge, 2¾-inch Rosenthal needle. On the *right* is an 11-gauge, 4-inch Jamshidi needle.

Fig. 28-18 Bone marrow spicules (small grayish particles) should be seen in the aspirated sample. **A,** Particles can be picked out of background blood from a Petri dish. **B,** Particles can be seen adhering to the sides of an EDTA blood tube. **C,** Particles will adhere to a glass slide while excess blood runs off.



28.3.4 Processing the Sample

Whether the bone marrow sample is directly applied to glass slides or expressed into a Petri dish or watch glass, processing needs to proceed rapidly to prevent clotting or drying out of the sample. When on the slide, if the sample contains a lot of excess blood, the slide can be briefly tilted so that the fluid portion can run off into an absorbent surface, leaving behind adherent particles for spreading (Fig. 28-18, *C*; Fig. 28-19, *A*). If the sample is placed into an EDTA tube or Petri dish with anticoagulant, spicules (small grayish particles) can be transferred out of the bloody sample using a pipette and placed on a glass slide[23] (see Fig. 28-18).

To spread the sample on a slide, place a second glass slide flat on top of the sample, allowing the sample to form a thin layer between the slides (see Fig. 28-19, *B*). Without additional pressure other than the weight of the slide, gently pull the slides apart from each other horizontally and without vertical separation, which can create suction and rupture cells (see Fig. 28-19, *C*). This typically results in a nicely spread sample with intact particles and nice monocellular layers for evaluation. Several slides should be made. After slides are made, they should be

allowed to air dry, kept away from formalin fumes, and stored at room temperature until staining.

Some bone marrow slides are stained with a Romanovsky-type stain (Wright, Giemsa, Diff-Quick) for cytologic examination, and some should be left unstained in the event that special staining procedures are wanted. It is highly recommended to stain at least one slide right away for microscopic examination in order to determine sample quality and to make sure bone marrow elements are present while the animal is still available and prepped, in the event that the first aspiration is nondiagnostic and additional attempts will be needed (Fig. 28-20). If a hemodilute sample without spicules is obtained, it may be possible to acquire diagnostic information by centrifuging the sample in Wintrobe hematocrit tubes and making smears from the buffy coat. Staining for reticulocytes requires that an anticoagulated, liquid bone marrow sample be mixed and incubated with a supravital stain before slides are made.

Fig. 28-19 Making slides of a bone marrow sample. **A,** Excess blood is allowed to run off the slide onto an absorbent surface while the spicule stays adhered to the slide. **B,** A second slide is laid on top of the sample, causing the sample to spread out between the slides. **C,** The slides are horizontally pulled apart, then allowed to air-dry.

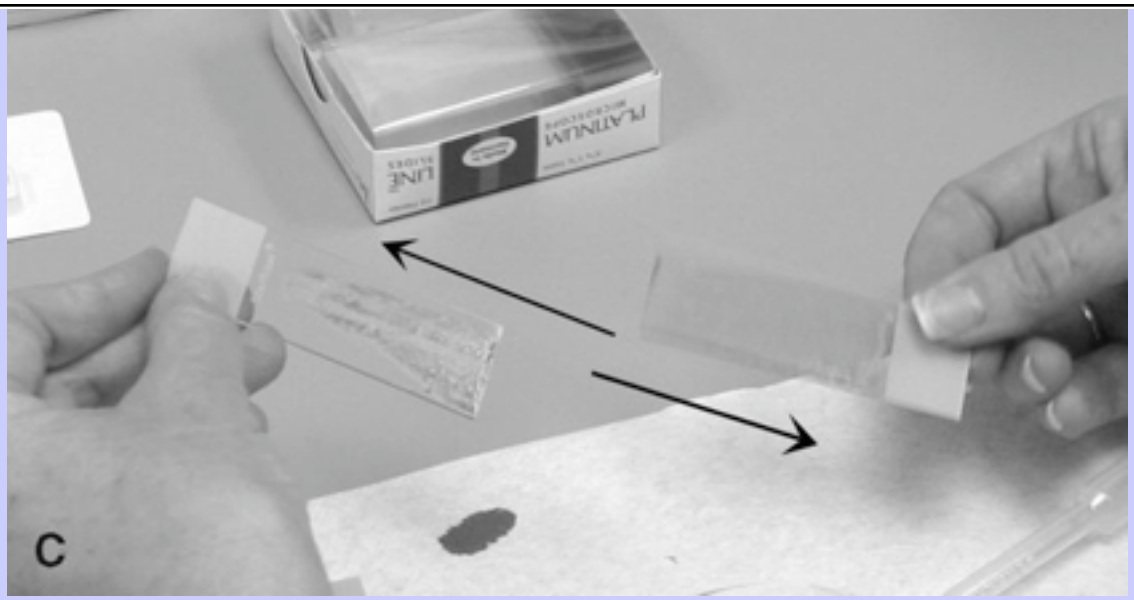


Fig. 28-20 Stained slide of adequate bone marrow aspirate sample. Megakaryocytes *(arrowheads)* and particles *(arrows)* are present. There is also increased cellularity compared with peripheral blood. (Wright-Giemsa stain, 10× objective.)

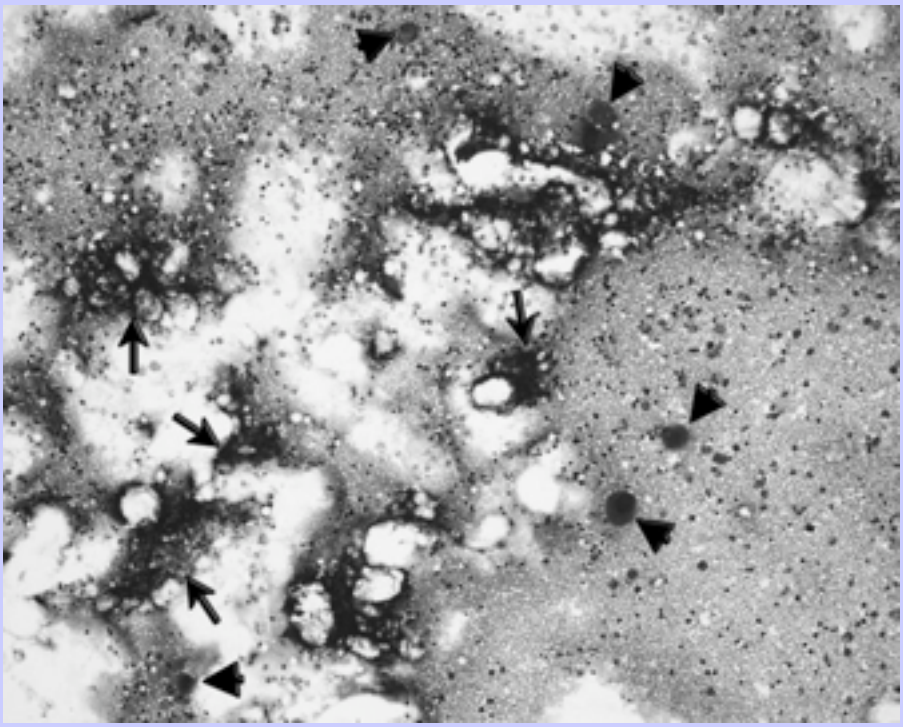


If a core biopsy sample is obtained, the tissue can be gently rolled on a slide to make an impression smear for

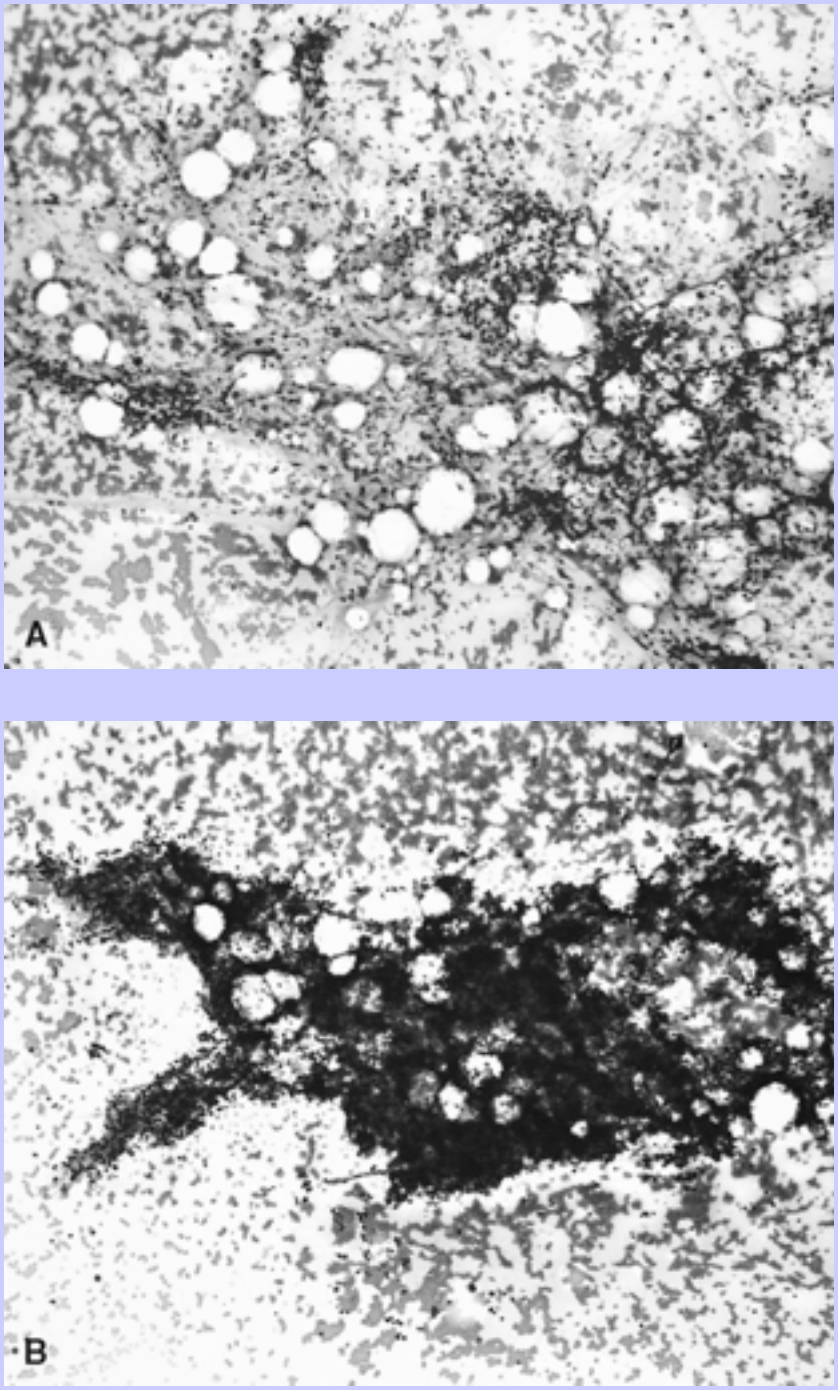
If a core biopsy sample is obtained, the tissue can be gently rolled on a slide to make an impression smear for cytologic evaluation. The biopsy tissue should then be placed in 10% neutral buffered formalin for preservation. A larger gauge needle (10 to 13 gauge) is generally recommended for core biopsy. The Jamshidi needle, designed so that the distal tip tapers to help retain the sample, is the most popular needle for biopsy. The needle and stylet are initially inserted as for aspiration. (see Fig. 28-15, *B*) Once the needle enters the bone marrow, the stylet is removed and the needle advanced further with the same twisting motion. Ideally, the needle is inserted at least an additional 1 to 2 cm, but this may be limited by location. After the needle is advanced to obtain the core, it is rotated and rocked forcibly to help break the core at its base for successful removal. Once the needle is removed from the animal, a probe is inserted into its lumen at the distal tip, pushing the sample out the hub end (see Fig. 28-15, *C*).

Often, bone marrow aspirates are placed into an EDTA blood tube for submission to an outside laboratory. In this case it is still recommended to make slides of the sample to submit along with the fluid sample. If the sample is left in the fluid phase, cells can deteriorate during transit, and it is always helpful for the cytologist to have a freshly prepared sample to examine (of both bone marrow and peripheral blood). In addition, a slide can be stained and evaluated for diagnostic quality before the sample is shipped.

431

432

Fig. 28-21 Bone marrow particles. The particle in **A** is of low cellularity. Only a small proportion of the particle is composed of nucleated cells. The particle in **B** is of high cellularity. At least 75% of the particle is composed of nucleated cells. (Wright-Giemsa stain, 10× objective.)



If repeated aspirates all result in samples of low cellularity, a core biopsy may be indicated. Cytologically, it is

If repeated aspirates all result in samples of low cellularity, a core biopsy may be indicated. Cytologically, it is usually impossible to differentiate low cellularity caused by a pathologic process from that resulting from poor sampling; therefore, a biopsy may be needed for the evaluation of cellularity.

28.4 BONE MARROW EVALUATION

Bone marrow evaluation requires expertise (advanced training and experience), and in most cases it is anticipated that samples will be sent to a trained cytologist for evaluation. To obtain the most information from a bone marrow aspirate, it is important to have a good-quality sample. Even if not reading the sample oneself, it is recommended to stain a slide to confirm that a diagnostic sample was obtained (stain the worst slide; if it is acceptable, one can expect the others to be acceptable, too). Recent CBC results and freshly made blood films are also essential for full interpretation of a bone marrow sample. Relative changes among different cell lines are assessed in the evaluation of hematopoiesis because absolute cell counts are unreliable in bone marrow aspirates.[22] Knowledge of the peripheral blood picture is necessary to assess whether changes (or lack of changes) in the bone marrow are consistent with normal hematopoiesis. Freshly made blood films are important to have when comparing the morphology of cells in the bone marrow with the morphology of those in the peripheral blood. Results from cytologic evaluation of bone marrow should ultimately be correlated with history, clinical presentation, and other laboratory data.

28.4.1 Cytologic Examination

In general, the evaluation of bone marrow includes assessment of the following parameters. On low magnification the cellularity and quality of the sample as a whole are assessed, as well as the cellular density of bone marrow particles. Iron stores are evaluated within the particles. Megakaryocyte numbers are also best assessed at low magnification. On high magnification the sample is evaluated for the presence of myeloid and erythroid cell lines. The cell lines are evaluated for orderly maturation, and cell morphology is assessed for evidence of dysplastic changes. The relative proportion of myeloid to erythroid cells is determined by subjective assessment or by counting cells to derive a myeloid-to-erythroid (M:E) ratio. The sample is also evaluated for the presence of other cell types or infectious organisms. Results from the bone marrow evaluation are then interpreted in accordance with peripheral blood abnormalities.

Cellularity of bone marrow spicules is subjectively determined by assessing how much area of a particle is composed of cells versus fat. Cellularity of normal marrow can vary according to the age of an animal, with higher cellularity in younger animals and lower in older animals. Examples of differing cellularities are depicted in Fig. 28-21. Iron stores are assessed within spicules and typically described as *present, decreased,* or *increased* (Fig. 28-22).

Maturation of bone marrow cell lines follows somewhat of a pyramidal pattern, with cells dividing as they mature, resulting in higher numbers of cells in the more mature cell stages (Figs. 28-23 and 28-24). In bone marrow of healthy animals, rubriblasts and myeloblasts will typically comprise at most a small percentage of the total cell population. Twice as many prorubricytes and promyelocytes may be seen. Numbers of cells in each stage increase up to polychromatophilic rubricytes and metamyelocytes, after which there are relatively stable numbers between the subsequent maturational phases. In general, for each blast there are 16 mature granulocytes or erythrocytes. Mitotic figures are normally present in low numbers.

Fig. 28-22 Bone marrow aspirate. The blue-black granules visible extracellularly and within macrophages represent iron stores *(arrows)*. Iron stores can also be seen as brown crystalline material within particles. (Wright-Giemsa stain, 100× objective.)

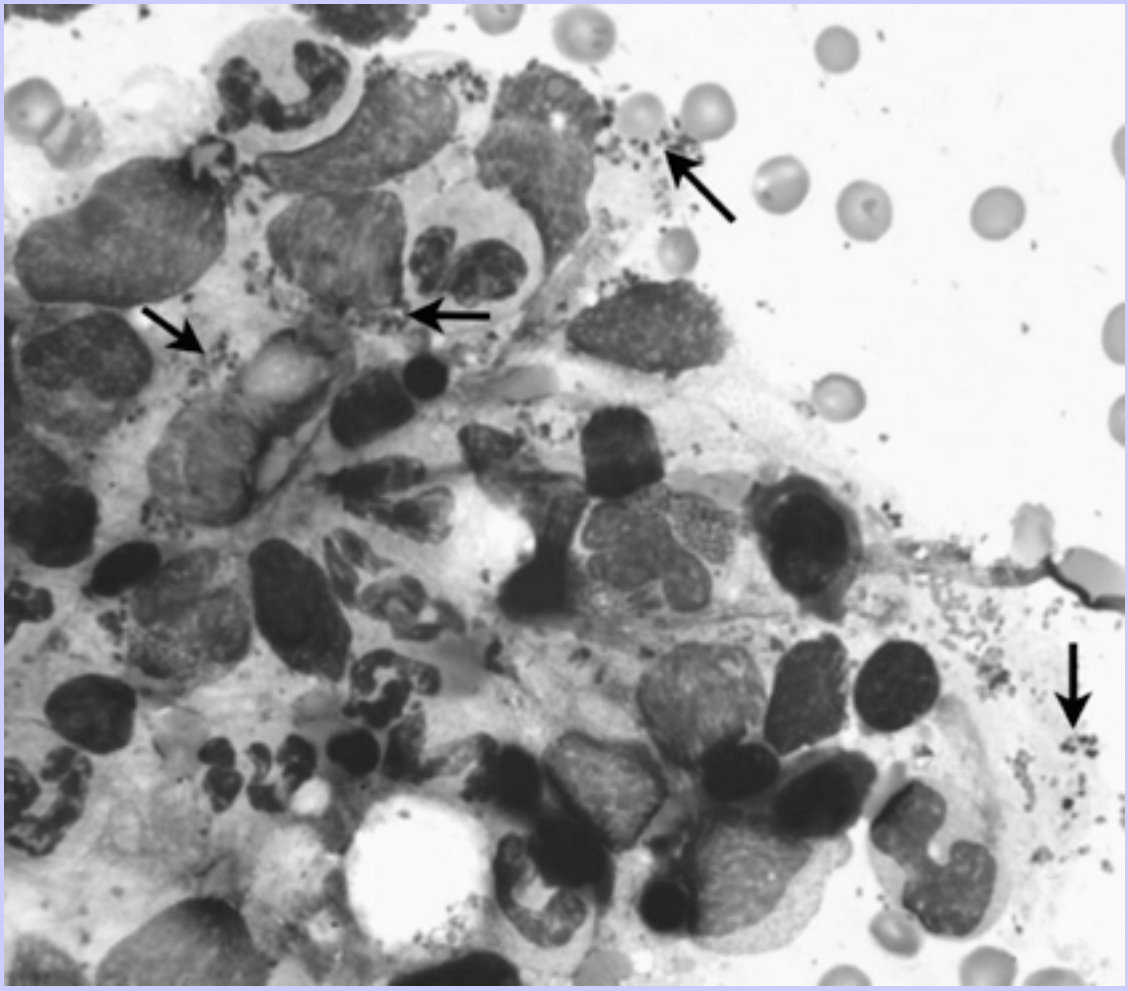


Fig. 28-23 Maturational stages of erythrocytes within the bone marrow. The *left panel* contains rubriblasts in the upper square with prorubricytes below. Rubriblasts are large cells with large nuclei containing coarse-grained chromatin and nucleoli; a perinuclear halo is present within scant deeply basophilic cytoplasm. Prorubricytes have a more mature nucleus; chromatin condensation begins, and no nucleoli are present. The *middle panel* contains basophilic and polychromatophilic rubricytes; chromatin condensation is distinct and the cytoplasm is paler, grayer, or polychromatic. The *right panel* contains metarubricytes with dark, intense chromatin condensation and pink cytoplasm. (Wright-Giemsa stain, 100× objective.)

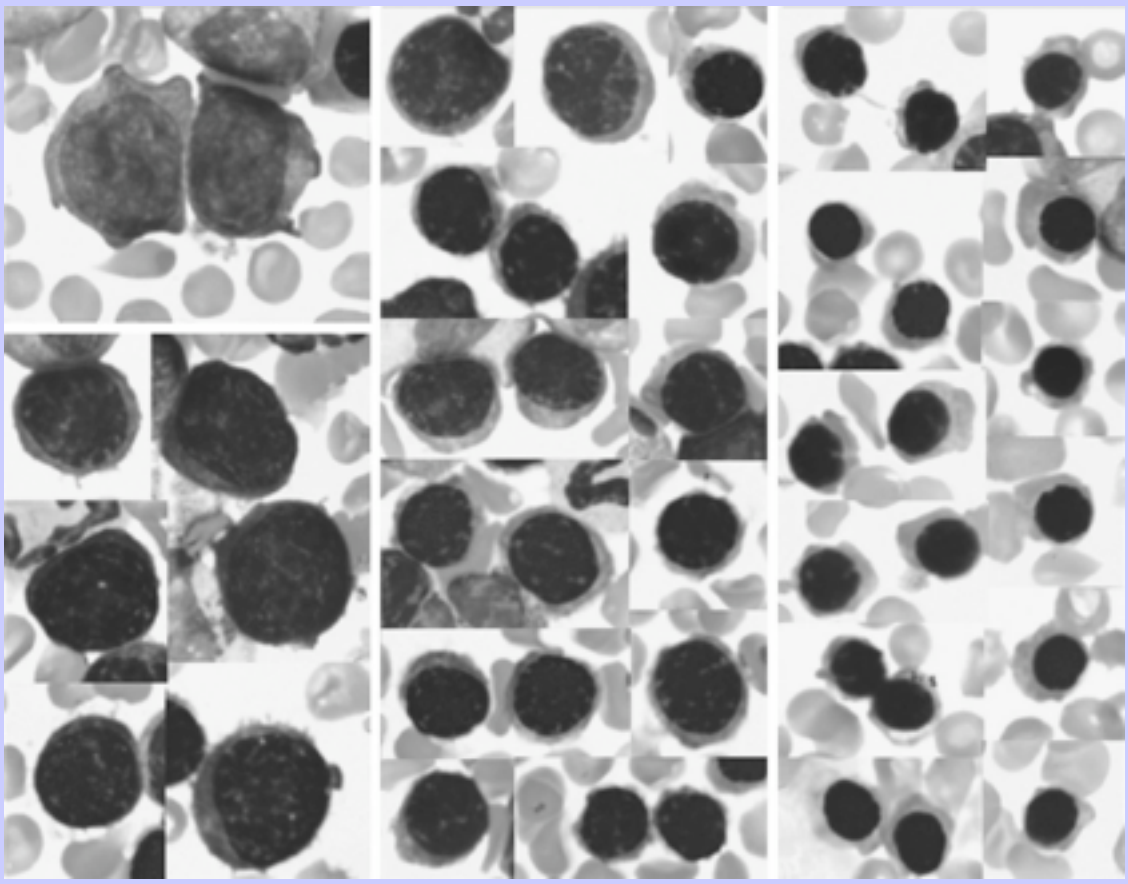


The M:E ratio is most accurately determined by counting a minimum of 500 cells. Nucleated cells of all maturational stages are included in the count and categorized as myeloid or erythroid. The ratio is calculated by simply dividing the total number of myeloid cells by the total number of erythroid cells. It is important to include

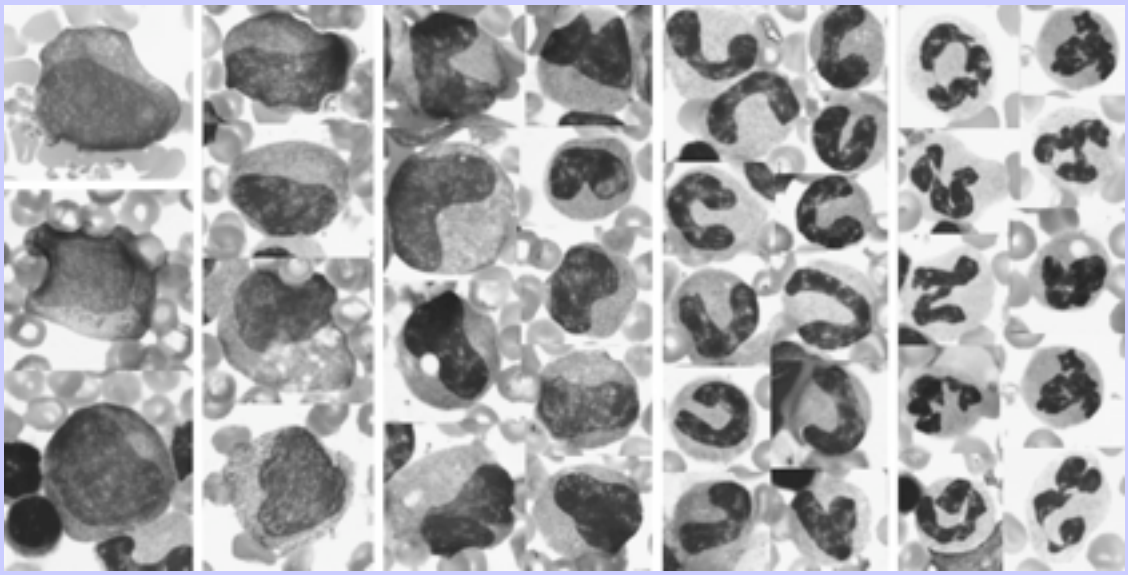
several different areas of the sample to make it as representative of the whole sample as possible. Blood contamination can also affect the M:E ratio, especially if leukocytosis is present. Reported M:E ratio ranges for healthy animals of different species have been variable. In some sources the M:E ratio in cattle is listed as <1, although ranges from 0.27 to 2.59 have been reported.[7,20,24–26] The range of M:E ratios in ten 3- to 6-year-old pregnant sheep was reported as 0.77 to 1.68.[17] The reported range for the M:E ratio in a low number of llamas is 0.9 to 2.9.[18] Llama, alpaca, and vicuna have a lower M:E ratio at high elevation (4200 m) versus low elevation.[2] M:E ratios in horses generally range from 0.5 to slightly greater than 1, with 1.5 sometimes reported as the upper value.[6,27–29]

Evidence of dysplastic changes in hematopoietic cells includes asynchronous maturation between the cytoplasm and nucleus, large cell forms, and abnormal nuclei, such as ring-shaped nuclei. Cell types other than hematopoietic cells should be evaluated as to their presence and proportion of the total cell population. Low numbers of macrophages (<1%), plasma cells (<2%), and small lymphocytes (<10%) are commonly seen in bone marrow samples.

28.4.2 Interpretation

It is easy to make a conclusion about bone marrow cellularity if the sample is highly cellular, but a poorly cellular sample is more difficult to interpret if adequate particles are not present. A core biopsy may be needed to differentiate between a poorly cellular marrow and a nonrepresentative sample. In general the bone marrow will become more cellular in a hyperplastic or regenerative response.

Fig. 28-24 Maturational stages of granulocytes within the bone marrow. The *left panel* contains a myeloblast in the upper square with promyelocytes below. Myeloblasts are large cells with large nuclei containing fine reticular chromatin and nucleoli; the cytoplasm is basophilic and agranular. Promyelocytes contain coarse cytoplasmic granulation; nuclear chromatin is beginning to condense, and nucleoli are present. *Subsequent panels, moving to the right*, contain myelocytes, metamyelocytes, band neutrophils, and segmented neutrophils. Myelocytes have a lower nuclear:cytoplasmic ratio and contain fewer and finer cytoplasmic granules; the nucleus is round to kidney-shaped and contains no nucleoli. As maturation progresses, the cells become smaller, the cytoplasm becomes more eosinophilic, the chromatin becomes more condensed, and the nucleus indents and segments.



In many cases it is adequate to describe iron stores as being present without quantification. When assessing the cause of anemia, an abnormality in iron stores may provide useful diagnostic information. Lack of iron stores would suggest iron deficiency, whereas abundant iron stores are associated with anemia of chronic inflammation. Perl's iron stain (Prussian blue reaction) can be used on bone marrow slides to confirm low iron stores. Llama bone marrows normally contain abundant iron.[18]

No definitive criteria for megakaryocyte numbers have been determined. If thrombocytopenia is not present, any number of megakaryocytes is acceptable. Many megakaryocytes are expected to be seen within individual particles when there is regeneration associated with thrombocytopenia. Higher numbers of immature

megakaryocytes may also be seen; these will be smaller cells (still larger than other bone marrow cells) with a higher nuclear-to-cytoplasmic ratio, deeper basophilic cytoplasm, and fewer lobes to the nucleus. If megakaryocytes are not frequently seen in the bone marrow from an animal with thrombocytopenia, this suggests hypoplasia or destruction of megakaryocytes.

When assessing bone marrow for normal, progressive maturation of cell lines, it is expected that all developmental stages will be present, with greater numbers of the more mature cells. Variation from normal can be seen for a variety of reasons, often reflected by a shift to the left or what appears to be a maturation arrest. A shift to the left is the situation in which all maturation stages are represented but there is a higher proportion of the less mature cells (the proliferating pool) than normal. *Apparent maturation arrest* is a term used maturation appears to terminate at a particular stage; the earlier maturation stages are present, but later stages are poorly represented. Suppression of hematopoiesis can result in abnormalities in maturation progression but often is reflected by a decrease in all stages of maturation. If the number of cells within a cell line is too low, progression of maturation can be difficult to evaluate. Destruction of cells, such as with immune-mediated disease, at a particular maturation stage will result in decreased numbers of cells of the affected type as well as cells at all later stages, which can appear as a maturational arrest. If a disease process results in large demand or rapid mobilization of cells out of the bone marrow, depletion of the more mature cell stages can appear as a maturational arrest. In such cases a left shift also is often associated with the increased demand. Acute leukemia is typically reflected as an apparent maturational arrest or left shift. Therefore it can be difficult to differentiate between hyperplastic marrow in which there has been rapid mobilization of mature cells out of the marrow and a myeloproliferative disorder on cytologic examination alone. In some instances sequential bone marrow aspirations can be useful in helping determine disease pathogenesis. Abnormalities in maturational progression may also be reflected by the presence of dysplastic changes.

The M:E ratio is used to help determine if the erythrocyte or myeloid cell lines are hypoplastic or hyperplastic. An equal number of nucleated erythroid and myeloid cells will result in an M:E ratio of 1. An M:E ratio greater than 1 (or greater than the reference interval) often indicates that granulocytic production exceeds erythroid production, but it could also indicate a decrease in erythropoiesis. Likewise, an M:E ratio less than 1 (or less than the reference interval) often indicates that erythropoiesis exceeds granulopoiesis, but it could also indicate suppression of the latter. Determining which interpretation is appropriate requires knowledge of concurrent CBC results. An increase in the M:E ratio would be appropriate in an animal with neutrophilia, but if the neutrophil count is normal and anemia is present, it would indicate erythroid hypoplasia. In the face of anemia, a decrease in the M:E ratio would indicate erythroid hyperplasia and regeneration, but a decrease in a neutropenic animal that is not anemic would indicate myeloid hypoplasia. In some disease states both the myeloid and erythroid series may be affected, which could potentially exacerbate or mask alterations.

434

435

Whereas most species readily reflect an erythroid regenerative response in the peripheral blood, horses do not. Reticulocytes are rarely seen in equine peripheral blood, and in one investigation it took several days of severe anemia (PCV of 13% to 14%) in horses before a reticulocytosis of 1% to 2% was seen.[30] An increase in mean corpuscular volume (MCV) may be detected in the peripheral blood of horses with chronic anemia or acute, massive hemolytic or hemorrhagic anemias,[29–32] but the best way to assess erythropoiesis in horses is to examine the bone marrow. The number of reticulocytes significantly increases in the bone marrow of horses with regenerative anemia. In the study of acute blood loss in which only 1% to 2% of reticulocytes were seen in peripheral blood, bone marrow reticulocytes went from 4.1% (pre—blood loss) to as high as 66.5%.[30] Reticulocytes typically comprise <2% of erythrocytes in normal bone marrow, and a regenerative response is considered present if reticulocytes comprise <5%.[11] Determining the number of reticulocytes per 1000 erythrocytes after staining with a supravital stain such as new methylene blue is the most reliable method, but an

estimate can be made by counting the number of polychromatophils per 100× oil objective field in a Wright-stained smear (assuming the field of view includes approximately 100 cells; this can vary with the microscope). In the face of anemia, <5 polychromatophils/oil field is considered a good regenerative response and <2 is indicative of erythropoietic suppression.[33] Care should be taken not to dilute the sample with peripheral blood, as this will dilute the number of reticulocytes from the bone marrow.

Other bone marrow parameters that indicate erythrocyte regeneration in horses include a decreased M:E ratio (<0.5) and a left shift of erythroid precursors.[29,33] Depending on the type of blood loss, it could take several weeks to reduce the M:E ratio below the reference interval.[34] With regeneration, a doubling of the proliferating pool of erythrocyte precursors can occur within 3 days of an acute severe hemorrhage, with maximal response at 9 days.[35] The proportion of basophilic and polychromic rubricytes can reach 39% to 55% of all cells in the regenerative equine bone marrow.[29]

Atypical cell populations in the bone marrow can represent a myeloproliferative disorder, an infiltrative neoplastic process, inflammation, or antigenic stimulation. Atypical cell populations can be a result of significant increases in cell numbers of types normally seen in the marrow. Blast cells normally constitute only a small percentage of total cells in the bone marrow. A diagnosis of acute leukemia is typically associated with blast cells that constitute <30% of all cells in the bone marrow,[36] although human medicine has revised its criterion to <20% and some veterinarians are following suit. Cytologic results need to be correlated with other clinical data because granulopoiesis characterized by a marked left shift in bone marrow precursor cells with rapid mobilization of more mature cells from the bone marrow can resemble a myeloproliferative disorder.

Another cause of increased numbers of cells normally residing in the bone marrow is inflammation. Suppurative inflammation can be seen, typically associated with septicemia. Histiocytic or granulomatous inflammation is characterized by increased numbers of macrophages. Both suppurative and histiocytic inflammation can be associated with infectious or noninfectious disease processes. If inflammation is present, the sample should be thoroughly inspected for organisms, and culture may be indicated.

Increased numbers of lymphocytes and plasma cells can be seen with antigenic stimulation or with neoplasia. In general, it is rare to see the proportion of lymphocytes or plasma cells exceed 20% with antigenic stimulation. The morphology of lymphocytes and plasma cells should be well differentiated if they are associated with nonneoplastic processes. Cells associated with neoplasia can also appear well differentiated; therefore cell morphology alone may not be useful in establishing a diagnosis. Clinical presentation and ancillary testing (e.g., serum protein electrophoresis, flow cytometry) can be helpful in interpreting lymphocytoses and plasmacytoses.

The presence of cells not typically seen in the bone marrow or cells exhibiting a high degree of pleomorphism or other criteria of malignancy should raise suspicion of a neoplastic process. Neoplasia can arise from within the bone marrow or can metastasize to the bone marrow from other sites.

Degenerative cells or amorphous proteinaceous debris suggests bone marrow necrosis. This can occur secondary to infarction, neoplasia, or inflammation. Degenerative cells are often unidentifiable.

After cytologic evaluation of bone marrow and correlation with CBC results, a determination can be made as to whether any of the cell lines are hypoplastic or hyperplastic and whether there is evidence of maturational arrest, dysplasia, neoplasia, or inflammation. This information can then be correlated with the clinical information to determine appropriate differential diagnoses and likely disease pathogenesis.

29 Chapter 29 Molecular Diagnostics in Large Animals

Consulting Editors

Nicola Pusterla

Christian M. Leutenegger

29.1 MOLECULAR DIAGNOSTICS IN LARGE ANIMALS

Christian M. Leutenegger

Nicola Pusterla

Of the four classes of organic molecules that compose the basic physical structure of all living beings, nucleic acids are the only molecules that carry replicable instructive information. Nucleic acids differentiate themselves from lipids, carbohydrates, and even proteins in their ability to organize the basic unit of life, the cell. Even minor alterations in DNA and RNA molecules can disrupt the fine balance between health and disease. The field of molecular diagnostics seeks to elucidate the variations and mutations in genetic material that can cause disorder in the otherwise intricately organized body.

The amplified era of molecular diagnostics for infectious diseases began in 1983 when Dr. Kary Mullis of Cetus Corporation first conceptualized the polymerase chain reaction (PCR). He went on to win the Nobel Price in Chemistry for this revolutionizing technology 10 years later.[1,2] Since the inception of PCR technology, infectious disease diagnostics has been at the forefront of molecular medicine, with the promise of detecting contagious pathogens in a safer and more sensitive way to aid in controlling their spread. Infectious disease testing is expected to continue to dominate the molecular diagnostic market for large animals in the foreseeable future. The use of amplified and nonamplified tests to assay the molecular makeup of the host rather than the pathogen is growing. Whereas cancer diagnostics is in its infancy for large animal testing, parentage and forensic testing together with single-nucleotide polymorphism (SNP) detection using in situ hybridization (ISH), fluorescent in situ hybridization (FISH), and sequencing technologies are gaining importance in assessing the presence and prognosis of genetic diseases.

The ability of molecular diagnostic assays to sensitively and specifically detect the primary cause of disease in a short time is unprecedented. Molecular tests are able to detect and sometimes to quantify a specific unknown. Such tests are binary by nature; they provide a yes-or-no answer. The clinically valuable information rests in determining the presence or absence of a specific pathogen in a biologic sample derived from an animal. Because detection of viral, bacterial, rickettsial, fungal, or parasitic nuclear material in a biologic sample gives clinically important information, molecular tests have clinical utility. Molecular probes are able to detect the presence of nuclear material from a given pathogen with an extraordinarily high level of sensitivity and specificity. The low relative complexity of a bacterial or viral genome allows for this type of detection. Comparatively, animals have a larger genome, with genotype associations linked to clinical pathologies. Determining the presence of a gene sequence does not necessarily correlate with a given clinical action, as diseases are generally multifactorial. In contrast, establishing the presence of the neuropathogenic form of equine herpesvirus (EHV) 1 in an equine patient's blood sample has direct association with EHV-1 infection, whether this translates into a symptomatic stage or not. The binary nature of molecular tests, which establishes the presence or absence of genetic material in a sample with a

high degree of accuracy, has high clinical value for infectious disease testing because of its high correlation with clinical signs.

Rapid results have tremendous clinical value in curtailing infection. Molecular methods can provide results in hours compared with days for culture-based or alternative technologies. The high sensitivity and specificity of molecular testing is particularly valuable in early determination of infection and makes it advantageous compared with antibody and antigen testing without amplification techniques. In most cases pathogens enter the host and replicate exponentially; early detection provided by the higher sensitivity allows for earlier clinical intervention. Molecular tests have been shown to produce fewer false-positive and false-negative results. Therefore molecular tests are becoming the gold standard in the laboratory in terms of sensitivity and specificity. Key features for the adoption of molecular diagnostics for infectious agents are as follows:

- Superior sensitivity and specificity compared with most immunoassays
- Automated platforms that significantly increase throughput
- Quantitative assessment of viral load, which is clinically useful
- Fast turnaround time that speeds detection and reduces overall costs
- Simultaneous analysis of multiple analytes

29.2 TECHNOLOGIC SUPERIORITY OF MOLECULAR TESTS

The relative technical superiority of molecular methods makes them likely to partially replace other types of more conventional methods such as culture-based tests or certain direct antigen and antibody tests to determine the presence of an infectious pathogen in a sick animal. Whereas antibody testing is more of a broad screening tool, molecular diagnostics allow accurate detection of the genome of a pathogen in a clinically sick animal. Culture-based tests have a turnaround time of days and are labor-intensive. In addition, certain infectious agents are difficult to culture or biohazardous for laboratory personnel (e.g., *Mycobacteria* species, fungi, *Mycoplasma* species, *Lawsonia intracellularis*). In such instances molecular detection of selected pathogens has already supplanted conventional culture.

436 437

29.3 RAPID AND HIGH THROUGHPUT APPLICATIONS PROMOTE MOLECULAR TESTS

Rapid and specific detection of infectious disease agents is crucial for the prevention or containment of outbreaks. In the case of avian flu, the rapid detection of H5N1 strains of that virus is critical for containment. The avian flu pandemic concerns necessitate rapid and high throughput molecular tests to maintain well-being of animal and human community health. Similarly, West Nile virus (WNV) screening of mosquito pools and birds, and screening for exotic Newcastle disease are additional examples of high throughput applications with predominance for molecular tests.

29.4 INCREASING ADOPTION OF MOLECULAR TESTS BY UNIVERSITY AND COMMERCIAL LABORATORIES

Since the advent of molecular platforms in the diagnostic laboratory, most molecular tests in veterinary medicine are performed by several commercial and public laboratories (Table 29-1). Unlike the market in human molecular

diagnostics, which is dominated by four large players (Roche, Bayer, Gen-Probe, and Abbott), veterinary molecular diagnostics shows significant fragmentation.

29.5 SIMULTANEOUS TESTING OF MULTIPLE PATHOGENS

Parallel testing of multiple infectious agents in highly standardized platforms is a central component of molecular assays; it essentially allows several tests for both DNA and RNA pathogen targets to be performed simultaneously on one sample. This development is a noteworthy driver for molecular diagnostics as it allows acquisition of more meaningful data from a single sample. This so-called *panel strategy* allows an efficient workup of complex clinical syndromes with general symptomatology. These clinical situations do not involve easy diagnostic decision making for the veterinarian. In complex organ-related problems with general or unspecific symptomatology, multiple infectious agents can be responsible for a clinical picture. Even though veterinarians tend to make a single-pathogen diagnosis, it has become more evident in recent years that many syndromes are caused by co-infections. Panel testing on a large scale will uncover unknown dual or triple infections in animals, which can diffuse the clinical picture. It has long been speculated that seemingly clinically irrelevant EHV-2 infections in horses may underlie secondary infections, aggravating and diffusing the clinical picture. More characteristic examples include respiratory infections in companion animals, often initiated by subclinical viral infections that lead the way to secondary infections. In addition, many vector-borne pathogens have a high tendency to persist in infected animals and therefore may facilitate viral infections or aggravate preexisting conditions such as feline immunodeficiency virus or feline leukemia virus infection. Sepsis caused by infectious agents is expected to become an important segment for equine molecular diagnostics, especially in neonatal medicine. Molecular diagnostics enable fast turnaround time with rapid initiation of treatment. In the future, panel testing for the most important sepsis-inducing agents could be complemented by the addition of assays targeting antimicrobial resistance genes. This would allow the modification of treatment regimens in case antimicrobial resistance is detected.

29.6 INDICATIONS FOR USE OF POLYMERASE CHAIN REACTION ASSAYS FOR INFECTIOUS DISEASES

Diagnostic tests such as PCR assays offer the potential for fast and accurate determination of the presence of an infectious agent, which can lead to an improved clinical outcome because of the faster initiation of more etiologic-based treatment and the possibility for quantitative treatment monitoring. Even if molecular-based tests are more expensive than more traditional diagnostic assays, their overall impact will lead to reduction in treatment costs. 438 439

Key indications for use of a molecular test are the speed and accuracy of molecular assays. In comparison with traditional culture for bacteria, rickettsial organisms, fungi, and viruses, molecular testing offers direct detection of the target pathogen within a fraction of the time. Owing to its speed, PCR assays have the potential to replace traditional culture methods for infectious agents that are difficult to culture or not cultivable at all.

Compared with serology testing, molecular tests offer the advantage of detecting an infectious agent before an immune response occurs and a detectable antibody titer is developed. Immunoglobulin M (IgM) analysis in certain applications (such as WNV) can alleviate this problem; however, molecular testing methods are more reliable in picking up early virus replication and allow a faster epidemiologic assessment and earlier patient treatment.

In certain instances, for the discrimination of a clinically relevant EHV-4 infection from a latent infection, the detection of viral DNA is not informative. In such cases the quantitative assessment of viral loads is necessary.[3] Similarly, the choice of RNA or DNA affects the ability to distinguish disease (active virus replication and production of viral transcribed RNA) from nondisease (viral DNA of latently infected cells) status.

29.7 MOLECULAR BIOLOGY TECHNOLOGIES

The main methodologies used for molecular diagnostics include the following:

- Nucleic acid capture, probe hybridization
- ISH, FISH
- Isothermal amplification of nucleic acids[4]
- Transcription-based amplification methods

- Signal amplification by branched-chain DNA
- Qualitative pathogen identification using nucleic acid amplification
- Quantitative assays
- Genotyping assays
- Genotype sequencing assays
- Multianalyte testing panels

Genotyping assays are usually used to test for known mutations associated with inherited genetic conditions such as hyperkalemic periodic paralysis (HYPP) in horses, an autosomal dominant condition that causes potassium-induced attacks of skeletal muscle paralysis. Many of these assays depend on sequence-specific probes designed to hybridize with known genetic variations. For infectious agents, genotyping or speciation is achieved by using highly specific PCR-based or hybridization-based assays or by restriction enzyme fragment length polymorphism (RFLP) assays. In these assays, amplified material is digested with a certain restriction enzyme that characterizes the difference between two target sequences.

29.8 THE POLYMERASE CHAIN REACTION IN VETERINARY MOLECULAR DIAGNOSTICS

Because of its predominance in research and diagnostic applications, PCR assays will be discussed in more detail in later chapters. To give practitioners guidance about what to look for when PCR-based molecular diagnostic assays are offered, we will discuss some aspects such as design guidelines, differences between traditional and real-time PCR assays, sampling, controls, and interpretation of results in greater depth.

PCR testing in its pure form is a three temperature event: denaturation of double-stranded target (or in later cycles PCR products), annealing of target and primers, and extension of the DNA strand from the primer.

29.8.1 Comparing Real-Time Polymerase Chain Reaction with Traditional Polymerase Chain Reaction Testing for Diagnostic Applications

Real-time PCR testing was introduced into the marketplace in 1996 and replaced the tedious gel electrophoresis step to detect PCR products after amplification. In one survey, 98% of equine veterinarians knew about PCR testing and 79% of equine veterinarians at universities knew the difference between conventional and real-time PCR testing.[5] During gel electrophoresis, the PCR products are separated by size and visualized using a dye (ethidium bromide) which intercalates with the double stranded DNA. Real-time PCR detects the PCR products by using an internal probe that is labeled with two fluorescent dyes: a reporter dye and a quencher dye. The fluorescent activity of the reporter dye is absorbed (quenched) by the quencher dye. The probe binds to the PCR products between the two PCR primers. If the primers are extended by the DNA polymerase, the 5′ nuclease activity of the DNA polymerase digests the internal probe (hence hydrolysis probe) and releases the quenched fluorescence. Alternatively, hybridization probes can be used that are not digested during amplification and that allow melting curve analysis. This single change in the protocol regarding how to detect the PCR products revolutionized the use of PCR testing for both research and diagnostic applications. Most of the advantages resulting from this principle originate from the fact that the PCR tube does not have to be opened after a PCR assay for analysis. This principle is called *closed-tube detection*. The advantages are as follows:

1 Because of the closed-tube detection format, PCR products cannot escape from the PCR reaction containers. If escape occurs, it leads to the contamination of the PCR laboratory and subsequently the next PCR reactions. The consequence is false-positive PCR results. Real-time PCR efficiently eliminates this risk of PCR product carryover. There is also a second safety system called AmpErase UNG,[6] which eliminates contaminating PCR products.

2 Real-time PCR is a kinetic PCR principle, underlining the fact that PCR product accumulation is measured during every single PCR cycle in real time. Because of this fact, real-time PCR is a quantitative method.

3 The real-time PCR platform introduced in 1996 consisted of a laser-based thermocycler, software to design real-time PCR assays, reagents, disposables, and protocols. Because of its integrated design, PCR assays generated with the new system were highly standardized.

4 Data analysis is run on an attached computer that collects fluorescent data points. This principle eliminates all laboratory steps after the real-time PCR cycling is finished. Because of the computer-formatted end analysis, results can be fed directly into the information and management systems of diagnostic laboratories. Real-time PCR has also enabled rapid cycling to finish the PCR process in less than 1 hour. Real-time PCR results therefore can be turned around significantly faster than with traditional PCR testing (normally within a 24-hour period).

5 Because of the probe used to detect the PCR products, real-time PCR is also a more specific assay than single-round traditional PCR. Only specific PCR products are detected by the probe. Real-time PCR testing, essentially a liquid-based hybridization method, is considered as specific as Southern blotting, which is a solid-based hybridization method.

6 Because real-time PCR incorporates hot-start enzymes, the specificity is even greater than with regular non—hot-start DNA polymerases. Hot-start enzymes are inactive at ambient temperatures and have to be heated to 95 ° C for 20 seconds to 10 minutes in order for the DNA polymerase activity to begin. Because of the hot-start nature, nonspecific binding of primers does not lead to unspecific PCR products and results in an overall increased specificity of the assay. 439 440

7 In combination, real-time PCR is described to be as sensitive as or more sensitive than double-round (nested) traditional PCR. Analytic sensitivity and limit of detection using real-time PCR testing is normally in the single molecule range, whereas the limit of quantitation with traditional PCR testing is in the range of 10 to 20 molecules.

29.9 PREANALYTIC VARIABLES

In general, molecular diagnostic laboratories provide strict recommendations for sample collection, including shipping instructions. These instructions include specimen type, volume, anticoagulant, and specimen transport, storage, and handling. The sample type is largely influenced by the pathogenesis of the disease and plays a key role in the performance and interpretation of the test results. Veterinarians are advised to adhere to these recommendations, as the quality of the result is directly correlated to the quality of the sample and preservation of the nucleic acid content. Molecular assays often offer the convenience of using a small specimen acquired with a minimally invasive procedure. The diagnosis of herpesviruses is a classic example in which culture and neutralization assays have been largely replaced by PCR testing on a small volume of aspirate or swabs from mucosal surfaces. Molecular tests can detect the presence of small numbers of organisms, and the probability of

detection increases when a larger volume of specimen is added to the amplification reaction. Because molecular assays do not need viable organisms for testing, more flexibility in specimen transport is possible than with culture methods.

Appropriate specimen collection and transport conditions are important to ensure successful extraction of intact nucleic acid and to prevent cross-contamination. Specimen transport and storage conditions are likely to vary among specimen types and between RNA and DNA tests. RNA is more susceptible to degradation. Detailed storage and shipping instructions are crucial if RNA pathogens are part of the diagnostic workup. Practitioners should be aware of these recommendations and consider using appropriate cooling containers when samples are collected in the field. Such samples maintain stability if stored appropriately in a cooled environment. Freezing of fresh specimen often adversely affects the quality and should be avoided if not otherwise instructed by the laboratory.

Sampling errors are among the many preanalytic variables. It is therefore recommended to have the appropriate labeling material available for blood containers or other sample types. Blood or body liquid contamination on the outside of the containers is an obvious cause of sample cross-contamination before the samples are manipulated in the laboratory. Proper collection procedures are essential to prevent artifacts.

29.9.1 Nucleic Acid Extraction

Many commercially available manual and automated methods have been successfully applied to infectious disease testing of a variety of clinical materials. Especially in veterinary molecular diagnostics, the variety of sample types can be challenging for processing through a single platform. Automated or semiautomated platforms are rapid and usually require only a small volume of specimen. In general, these systems are total nucleic acid extraction systems and support the parallel analysis of DNA and RNA pathogens from the same sample. In addition, commercially available automated systems can reduce hands-on labor requirements. Most systems can accommodate sample volumes ranging from 100 µL to 500 µL and even 1 mL of specimen. Nucleic acid binding capacity varies and can be as high as 200 µg per individual extraction position. This maximizes nucleic acid extraction and ensures high consistency.

29.9.2 Interpretation of Results

Interpretation of results obtained with molecular assays for infectious diseases requires understanding of the pathogenesis and biology of the target organisms. Some challenges are unique to molecular tests and are different from considerations in interpreting other microbiologic tests. Such differences are related to the distinction of viable from nonviable organisms and the correlation of nucleic acid detection with presence of disease or disease association.

Interpretation of a negative result includes information about the sensitivity and nucleic acid extraction efficiency. A false-negative result may be caused by a degraded or instable sample. Insufficient or inappropriate sample type, inadequate sampling procedures, and transport problems are additional sources of false-negative results. Sample-specific internal positive controls targeting endogenous genes such as the universal 18S rRNA (ssrRNA) or glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene help to identify these problems. In addition, inhibition phenomena originating from difficult sample matrixes such as feces or environmental samples contaminated with soil (humic acid) have to be controlled with internal positive controls to assess the inhibitory effects.

The factors requiring consideration for the interpretation of positive results include assay specificity and contamination issues. PCR testing or any other target amplification method is subject to these considerations. Real-time PCR testing using closed-tube detection procedures reduces the risk of PCR product carryover as a source of false-positive results.

In general, molecular assays do not provide information about the viability of an infectious agent. Exceptions to this are DNA viruses, bacteria, and parasites analyzed for transcribed genes instead of their genomic DNA. Targeting spliced RNA occurring only if viral genes are actively transcribed provides a means for obtaining information about the replication activity of a virus. In other cases, targeting the ribosomal RNA of parasites such as *Toxoplasma* and *Cryptosporidium* is a means for obtaining viability information and also may increase the analytic sensitivity.[7]

Detection of nucleic acid of a pathogen does not necessarily ensure that the organism is the cause of the disease. A primary example is herpesvirus infections (EHV-1 and EHV-4), in which the detection of DNA may indicate the presence of lytic, nonreplicating, or latent virus. Studies indicated that high viral loads of EHV-4 DNA allow the formulation of a cutoff value to differentiate between lytic and nonreplicating virus.[8] In this particular case, high viral loads were associated with the presence of clinical symptoms and the presence of viral RNA transcripts. Therefore quantitative real-time PCR testing can provide a means to obtain better disease association.

29.9.3 Reporting of Molecular Results

Reporting results for qualitative assays in infectious disease monitoring is easy: a sample either does contain or does not contain nucleic acid of a target organism. Further relevant information includes the nucleic acid extraction efficiency, nucleic acid stability, and sample integrity. 440 441

Reporting results for quantitative molecular infections is more complex. For veterinary medicine, some quantitative applications have been established but are not yet offered as diagnostic assays. Eventually such assays will penetrate into the market with the more widespread adoption of quantitative PCR platforms and more standardized real-time PCR assays.

29.10 REGULATORY CONSIDERATIONS OF MOLECULAR LABORATORIES

Veterinary molecular diagnostics is an emerging market with little regulation. However, standards such as those defined by the American Association of Veterinary Laboratory Diagnosticians (AAVLD) or Molecular Diagnostic Methods for Infectious Diseases (NCCLS; www.nccls.org) are adopted by commercial laboratories aiming to provide a comprehensive diagnostic service. Other sources for guidelines are U.S. Food and Drug Administration (FDA) guidelines (www.fda.gov) for the detection of nucleic acids; ASTM guidelines (*Standard Guide for Detection of Nucleic Acid Sequences by the Polymerase Chain Reaction Technique;* www.astm.org); and Association for Molecular Pathology (AMP) *recommendations for in-house development and operation of molecular diagnostic tests* (www.ampweb.org).

29.11 GUIDELINES FOR CLINICIANS TO SELECT MOLECULAR DIAGNOSTIC LABORATORIES

Veterinarians can use a variety of guidelines to select laboratories for molecular diagnostics. However, there are questions worth asking before samples are submitted. First, it is worthwhile to obtain information about the nature

of the PCR test (traditional versus real-time). Second, questions addressing the quality control and quality assurance system within a particular laboratory should be asked. Third, turnaround time, pricing, and the level of guidance with result interpretation are additional factors worth investigating before samples are submitted.

29.12 SUMMARY

As with any methodologies, quantitative PCR is a work in continuous progress and development. Although all of the methods described in this review use the Nobel Prize—awarded PCR process, the advantages and disadvantages of subtle differences in assay format, accuracy, and reliability of quantitation have to be rigorously compared. The next generation of PCR quantitation will be increasingly automated, standardized, and miniaturized. The time for preparation and the time for amplification will be significantly reduced by using small microtiter-formatted microfluidic cards or silicon-based chip technology.[9–11] Amplification time has been brought down to several minutes by using an advanced nucleic acid analyzer (ANAA) consisting of a battery-powered array of silicon-based PCR microchips with thin-filmed resistive heaters enabling ultrafast amplification.[10]

How could these new systems be incorporated in routine veterinary diagnostics? Veterinary medicine will see a broad adoption of many assays for infectious agents and genetic abnormalities in the near future. The ability to standardize assays will allow high throughput applications that are not possible with traditional molecular methods. For this reason, applications for veterinary medicine may experience not only quantitative but also qualitative growth. These assays will help improve patient management and client satisfaction.

29.13 MOLECULAR TESTING FOR INFECTIOUS DISEASES IN HORSES

Nicola Pusterla

Christian M. Leutenegger

The ready availability of a correct etiologic diagnosis, particularly in contagious infections, enables the veterinarian to make early decisions regarding the patient's care and management and to address appropriate treatment, and allows timely notification and discussion of management issues pertaining to the prevention of disease spread. The last two decades have seen a revolution in the understanding, management, diagnosis, control, and prevention of infectious diseases.[12,13] This period has encompassed the discovery of emerging equine agents, antimicrobials, and vaccines, as well as a wealth of improved diagnostic tests for equine practitioners. Despite these advances, infectious diseases remain a leading cause of equine morbidity and mortality, with resurgence of certain infections (e.g., WNV), an increasing population of elderly, more susceptible horses, and an increasing international equine commerce expanding the geographic distribution of pathogens.[14,15] The focus of rapid diagnosis of infectious diseases also has shifted during this time. The most obvious change has been the appearance and increasing importance of nucleic acid amplification—based techniques, primarily the PCR, at the expense of traditional methods of clinical microbiology.[16] The PCR has become an increasingly important tool in microbial diagnosis in recent years, mainly because of its rapidity, high sensitivity, and high specificity. These superior characteristics have propelled the field of PCR-based molecular diagnostics into the arena of applied diagnostics for infectious agents. Because the number of published and offered PCR assays is steadily rising, there is a need for critical evaluation, comparison of performance, and eventually also standardization of methods to enable equine practitioners to select the optimal method of testing.

29.14 SAMPLE SUBMISSION

Nucleic acid techniques to detect the presence of infectious agents in biologic specimens require stringent quality guidelines. These guidelines aim to ensure the stability of nucleic acids (both genomic DNA and total RNA), which are the target for molecular-based diagnostic methods. Whole blood samples are collected aseptically into evacuated blood tubes containing ethylenediaminetetraacetic acid (EDTA); body fluids (e.g., thoracic, abdominal, joint, cerebrospinal, tracheal wash [TW], bronchoalveolar, and guttural pouch lavage fluids) and tissues should be collected into serum tubes without additives; nasal or nasopharyngeal secretions should be collected with rayon or dacron swabs and are best kept in a sterile serum or conical tube (virus transport medium recommended for the detection of viruses); fecal material should be collected into small fecal cups or serum tubes (Table 29-2 and Fig. 29-1). All samples must be sent cooled on blue ice by express mail overnight to the laboratory. Freezing of samples should be avoided. Short-term storage for a period of 2 to 3 days before shipment (over a weekend) should be in a refrigerated compartment. Each sample should be properly labeled and accompanied by a submission form containing information on the animal, owner, veterinarian, sample, and pathogen(s) to be tested for (most submission forms can be downloaded from the respective laboratory's website). The laboratory should be notified in advance, and inquiry should be made about the availability of the offered tests as well as turnaround time and associated costs. Incoming samples normally are processed the same day, and PCR results usually are available within 24 to 48 hours if the nucleic acid passes quality control.

441

442

Table 29-2 Tissue Samples Commonly Used for the Molecular Detection of Common Equine Pathogens

Pathogen	Tissue Submission
Anaplasma phagocytophilum	Whole blood

29.15 CLINICAL APPLICATIONS

An array of nucleic acid amplification techniques may be offered by laboratories in order to establish an etiologic diagnosis of equine infectious diseases. Several published studies have shown the benefit of nucleic acid amplification techniques compared with conventional microbiologic techniques. Current efforts are aimed at improving the diagnostic efficiency of molecular techniques, both for common and for less common infectious agents. To facilitate a decision about which pathogens should be evaluated for in a specific case, some laboratories offer panels covering specific organ systems (e.g., respiratory, gastrointestinal, neurologic). Such panels test for several common pathogens for each organ system. Some of the diagnostic PCR applications most relevant for equine practice are presented in the following sections, along with their advantages and potential pitfalls.

29.15.1 Respiratory Pathogens

Respiratory pathogens often are contagious, and infections must be diagnosed rapidly in order to prevent a disease outbreak and institute the appropriate management plan. The short turnaround time and reliability of PCR testing makes this molecular technology an ideal tool for the diagnosis of respiratory pathogens.

Equine influenza is commonly diagnosed by virus isolation or detection from nasopharyngeal swabs collected from horses during the early febrile stage of the disease. Virus can be grown from nasopharyngeal swabs by inoculation and incubation of embryonated chicken eggs or passage through Madin-Darby canine kidney cells. Although isolation of the virus is essential to allow antigenic and genetic characterization of the strain, this technology is time-consuming, and successful isolation is to be expected in at best 50% of cases. Furthermore, because mutations have been reported to occur during the process of viral culture, recovered isolates must be viewed critically. In recent years new methods for virus detection, such as antigen detection enzyme-linked immunosorbent assay (ELISA) and PCR assay, have been described; such methods allow a rapid diagnosis in the acute phase of infection. The commercially available Directigen Flu A assay* detects nucleoprotein, one of the type-specific antigens of type A influenza viruses, and was designed for use in cases of human influenza infection. Although this assay has the shortest turnaround time of all antigen tests (i.e., 15 minutes), its sensitivity decreases when low titers of virus are present (e.g., in a partially immune horse with subclinical signs or in a clinical case past the acute onset of disease). In recent years, PCR-based assays with higher sensitivity than virus isolation and antigen-capture ELISA have been described for the identification of equine influenza virus directly from clinical samples (Table 29-3).[17–19]

Amplification of the single-stranded RNA of equine influenza viruses is performed by reverse transcriptase–PCR (RT-PCR) technology, using a one-step, nested, or real-time approach. The hemagglutinin, nucleoprotein, and matrix gene are the commonly targeted genes for these molecular assays. Unfortunately, comparison of the different PCR assays is precluded by the use of different technologies, the lack of standardization among the assays, and variation in targeted genes. Nucleotide and deduced amino-acid sequences of portions of the hemagglutinin gene are now routinely used for phylogenetic characterization of outbreak strains. Furthermore, novel real-time assays can be used as a viable replacement for the more traditional methods of quantifying equine influenza virus in vaccine efficacy studies. Another advantage of assays such as antigen detection ELISA and PCR assay is their ability to detect nonviable virus, a situation that may occur when nasopharyngeal samples are frozen or not adequately stored and/or shipped to a diagnostic laboratory.

Table 29-3 Comparison of Different Viral Detection Methods Using Nasopharyngeal Secretions from Naturally and Experimentally Infected Horses with Equine Influenza Virus

			Detection Method (Mean Detection Days)			
Infection Type	**Number of Horses**	**Collection Type**	**VI**	**DFA**	**RT-PCR**	**Reference**
Experimental	4	Sequential postexposure	4/4 (5.5)	2/4 (3.5)	4/4 (6)	17
Natural	11	Single at peak of disease	5/11	7/11	9/11	18
Natural	171	Single at peak of disease	8/171	14/171	35/171	19

DFA, Directigen Flu A; *RT-PCR,* reverse-transcription polymerase chain reaction; *VI,* virus isolation.

EHV-1 and EHV-4 are important, ubiquitous equine viral pathogens that cause important economic losses in the equine industry. Both are double-stranded DNA alphaherpesviruses that affect the equine respiratory tract and can establish lifelong latent infection after primary exposure. Traditionally, virus isolation has been the gold standard for diagnosing EHV-1 and EHV-4 infections. The sample of choice is a nasal or nasopharyngeal swab, which should be taken early in the febrile phase of the disease. The swabs should be kept in viral transport medium and shipped on ice to a veterinary diagnostic laboratory. Because of the lymphotropism of EHV-1, virus isolation can also be attempted from citrated or heparinized whole blood. Virus isolation requires the maintenance of specific cell culture lines, making this process relatively expensive and time-consuming. EHV-1 can be propagated in a broad range of cell lines; however, EHV-4 grows only in cell lines of equine origin. Virus isolation is often hampered by the fragility of the virus, intermittent viral shedding, and the interference with local antibodies. PCR offers an alternative to virus isolation and has proven to be a sensitive method of detecting EHV-1 and EHV-4 in respiratory secretions, peripheral blood lymphocytes, and other tissues.[20–22] Many conventional PCR assays have been established to study the pathophysiology and improve the diagnosis of these viruses. Conventional one-step or nested PCR assays do have inherent risks of carry-over contamination resulting from postamplification steps required to detect the PCR products. Novel molecular platforms such as the real-time PCR assay have strongly reduced the risk of contamination. PCR assays used in routine diagnostics are based on the detection of viral genomic DNA and are therefore unable to distinguish among lytic, dead, or latent virus. Alternative molecular approaches have recently been established using the real-time PCR to allow discrimination among the different viral states in horses naturally infected with EHV.[23] Discrimination among the different viral states is now possible by (1) targeting several genes (e.g., glycoprotein, latency-associated transcripts); (2) detecting viral genomic DNA and transcriptional activity of the target genes at the messenger RNA (mRNA) level; and (3) using absolute quantification (Table 29-4). Viral threshold loads are used in selected human infectious diseases (e.g., human immunodeficiency virus [HIV], hepatitis C virus [HCV]) to determine disease stage and response to antiviral therapy. The concept of viral DNA threshold has been used diagnostically in EHV-4–infected horses to discriminate between lytic and nonreplicating virus.[23] A similar approach will likely be adopted in the near future for the molecular diagnosis of EHV-1 in order to differentiate

among viral states, as well as to evaluate the efficacy of antiviral therapy and determine the risk of exposure of a PCR-positive horse to other horses. Until such an approach is routinely instituted by veterinary laboratories, the random testing of normal horses for EHV-1 by PCR assay should be avoided, because practicing veterinarians and regulatory officials who receive positive PCR test results on samples they submit may be unaware of the complexities involved in test interpretation, leading them to make inappropriate decisions regarding quarantine of equine facilities or cancellation of competitions.

Table 29-4 Differentiation Among the Viral States of EHV-1 and EHV-4 by Targeting Several Genes and Detecting Either Viral Genomic DNA or Transcriptional Activity of the Target Genes at the Messenger RNA Level

	Viral State		
Target Gene and Nucleic Acid Type	**Nonreplicating Virus**	**Lytic or Replicating Virus**	**Latent Virus**
Glycoprotein B gene using gDNA	Yes	Yes	Yes
Glycoprotein B gene using mRNA	No	Yes	No
Latency-associated transcripts using mRNA	No	No	Yes

gDNA, Genomic DNA; *mRNA,* messenger RNA.

Streptococcus equi subsp. *equi* infection rarely is associated with detection difficulties when conventional cultures are used in clinically affected horses. Culture of nasal swabs, nasal or guttural pouch washes, or exudates aspirated from an abscess remains the gold standard for the detection of *S. equi*. Culture, however, may be unsuccessful during the incubation and early clinical phases of infection, and the presence of other beta-hemolytic streptococci, especially *Streptococcus equi* subsp. *zooepidemicus,* may complicate interpretation of cultures. Available PCR assays are designed to detect the DNA sequence of the *S. equi* M protein (SeM) gene, the gene for the antiphagocytic M protein of *S. equi*. This gene offers enough nucleotide variations between the two *S. equi* subspecies to allow full discrimination in clinical specimens. The test can be completed in a few hours, and results may be available on the same day samples are taken. One of the pitfalls of PCR testing has been its inability to distinguish between dead and live organisms; therefore, in the past, positive results have been considered presumptive until confirmed by culture. Nowadays the viability issue can be addressed by quantitation of the SeM gene or detection of transcriptional activity of the SeM gene at the RNA level. In several studies, PCR proved to be up to three times more sensitive than culture (Table 29-5).[24–26] PCR assay accompanying culture on a nasal swab or guttural pouch lavage may be used in a control program to select possible carrier animals, because PCR testing is capable of detecting *S. equi* DNA in guttural pouch lavages for weeks after disappearance of live organisms. Such is not the case for the nasopharynx, in which the efficient mucociliary apparatus removes organisms and DNA at the same time. PCR should be considered to detect asymptomatic carriers, establish the *S. equi* infection status of asymptomatic horses, and determine the success of elimination of *S. equi* from the guttural pouch. A particular problem in the management of strangles outbreaks is

443

444

the lack of a suitable assay to differentiate between wild and vaccine *S. equi* strains. Recent studies have shown gene variations in the N-terminal region of the SeM gene of various field isolates, allowing epidemiologic analysis of disease transmission.[27] Furthermore, a deletion in the *aroA* gene of a live attenuated strangles vaccine[*] marketed in Europe has allowed the development of a PCR assay able to differentiate between wild and vaccine strains.[27] Such an assay has, however, not yet been developed to differentiate between the intranasally applied attenuated live vaccine[†] marketed in North America and field isolates.

Table 29-5 Comparison of Culture and PCR Assay for the Detection of ***Streptococcus equi*** in Equine Nasopharyngeal Secretions (Swab and Wash), Guttural Pouch Lavage Fluid, and Abscesses After Natural Outbreaks

		Detection Method		
Number of Specimens	**Sample Type**	**Culture**	**PCR**	**Reference**
117	Nasal swabs and washes	15/117	37/117	24
61	Nasopharyngeal swabs	18/61	34/61	25
70	Guttural pouch washes	41/70	53/70	
28	Nasal swabs	4/28	13/28	26
15	Abscesses	5/15	12/15	

PCR, Polymerase chain reaction.

Rhodococcus equi is an important cause of chronic suppurative bronchopneumonia with extensive abscessation in foals 3 weeks to 6 months of age. Culture of the organism from TW fluid currently is considered the gold standard for diagnosis.[28] However, it can be difficult to reliably grow *R. equi* from a single TW sample, possibly because of prior antimicrobial administration or overgrowth by multiple pathogenic bacterial species.[29,30] Hillidge[31] reported that only 62% of foals with positive *R. equi* cultures at necropsy and 64% of those with radiographic evidence of lung abscessation yielded *R. equi* on culture of TW fluid. PCR has been evaluated in order to increase the diagnostic sensitivity of TW fluid samples. Strains of *R. equi* isolated from sick foals uniformly contain an 85- to 90-kilobase (kb) plasmid that carries the gene responsible for expression of a 15- to 17-kDa antigen *(vapA)* of undetermined function.[32,33] Environmental strains of *R. equi* not associated with disease do not contain this plasmid. Therefore detection of the *vapA* gene of *R. equi* in a TW fluid sample from a foal with pneumonia can be considered diagnostic. Both culture and PCR, however, may detect environmental contaminants of *R. equi* in TW fluid, but PCR has the ability to distinguish between virulent and avirulent strains. Foals may have virulent or avirulent strains of *R. equi* present in their airways as contaminants that are not responsible for clinical signs of pneumonia. This situation may be more likely on farms where *R. equi* problems are endemic. In a recent study evaluating the sensitivity of conventional culture, PCR, and serology in 53 foals with pneumonia, PCR of TW fluid was found to be more sensitive and specific for the diagnosis of *R.*

equi pneumonia than the other two available diagnostic tests.[34] PCR should be used in conjunction with standard culture because of the probability of the presence of multiple bacterial pathogens and the inability of PCR to determine antimicrobial sensitivity of *R. equi*. PCR, with its higher sensitivity and specificity, may be useful to rule out *R. equi* pneumonia in culture-negative foals that have failed to improve with standard antimicrobial therapy and have clinical signs consistent with *R. equi* pneumonia. It also may be useful in monitoring response to therapy and deciding when to discontinue therapy in foals that are confirmed to have *R. equi* pneumonia. In clinical situations in which the severity of the respiratory signs of the patient prevents the collection of TW fluid, feces have been shown to be a sensitive surrogate specimen for the molecular detection of *R. equi*.[35] The study determined that fecal PCR assay had a diagnostic accuracy similar to that of culture of TW fluid samples and that false-negative fecal PCR results for *R. equi* were associated with prior use of antimicrobials.

29.15.2 Neurologic Pathogens

Although highly sensitive and specific PCR assays have been developed for detection of viral and protozoal genomes in the cerebrospinal fluid (CSF) of neurologic patients, these methods often are of limited value in the routine diagnosis of these diseases because viremia is often very short-lived or the pathogen has no affinity to the cells of the CSF. Consequently, pathogens are usually no longer detectable at the onset of systemic or CNS signs.

Equine protozoal myeloencephalitis (EPM), caused by the protozoal apicomplexan parasites *Sarcocystis neurona* and *Neospora hughesi,* represents one of the greatest diagnostic challenges for equine practitioners. Detection of the parasite at necropsy is considered the gold standard. Therefore clinical diagnosis is based on clinical findings, exclusion of other neurologic diseases, and the use of serologic assays (e.g., Western immunoblot, indirect immunofluorescent assay) on serum and CSF.[36–38] Molecular diagnostics has also been investigated, but sensitivity was found to be low.[39] Apparently, intact merozoites rarely enter CSF, and free parasite DNA is destroyed rapidly by enzymatic action.[40] Based on its low sensitivity, PCR testing of CSF should not be recommended for routine diagnosis of EPM. In contrast, PCR testing of neural tissue has been shown to be useful as a postmortem test.[41] Detection and isolation of *S. neurona* from peripheral blood has been reported only in experimental studies.[42,43] Therefore molecular detection of *S. neurona* in blood is very insensitive and should not be used in order to document or rule out EPM in a horse with neurologic signs.

444

445

Diagnosis of WNV encephalitis in horses currently is based on observation of compatible clinical signs (e.g., ataxia, paresis, paralysis, hyperesthesia, muscle fasciculation, seizures, fever) and one or more of the following: isolation of WNV from blood, CSF, or tissue; a fourfold increase in plaque reduction neutralization test antibody titers on paired serum samples taken 2 weeks apart; or the detection of IgM antibody to WNV by IgM-capture ELISA.[44,45] Given the nonspecificity of the IgM ELISA (i.e., it does not differentiate between disease and exposure) and the time required to serologically confirm WNV infection, alternative tests able to rapidly detect WNV in clinical specimens are important. RT-PCR using a one-step, nested, or real-time approach has been evaluated to investigate antemortem cases of suspected WNV encephalitis in horses and humans using blood. The diagnostic sensitivity of WNV RT-PCR using either serum or whole blood was very low.[46–48] However, 57% to 70% of CSF samples from human beings with serologically confirmed WNV infection tested positive by real-time RT-PCR.[46,47] The reduced ability to detect WNV in CSF or serum from patients with serologically

confirmed WNV infection is likely a result of the short-lived viremia in dead-end hosts and emphasizes the fact that if WNV is to be detected in blood or CSF the sample should be collected early during the disease process. Investigation of the sensitivity of RT-PCR on CSF from horses with WNV encephalitis has not yet been reported. RT-PCR also has been shown to accurately identify WNV in field-collected mosquito pools, avian tissues, and human and equine brain tissue samples with a degree of sensitivity approaching that of virus isolation in Vero cells.[47–49]

Myeloencephalopathy is an uncommon presentation of EHV-1 infection and should always be considered as a differential diagnosis when a horse develops sudden neurologic signs (e.g., ataxia, paresis, urinary incontinence), especially if multiple horses on the premises are involved or when a recent history of fever, abortion, or viral respiratory disease in the affected horse or herdmates is reported.[50] Diagnosis often is based on history, clinical signs, and xanthochromia and elevated total protein concentration in CSF resulting from vasculopathy. Attempts to isolate virus from the blood or CSF of patients often are unsuccessful because the peak of viral shedding usually has passed by the time neurologic signs appear.[51] However, affected horses can shed the virus in nasal secretions and thus represent a risk of infection for unaffected in-contact horses. This outcome recently has been reported in a hospital setting in which horses developed neurologic disease after having been exposed to horses with EHV-1 myeloencephalopathy.[52] Therefore it is imperative to determine the risk of shedding in a suspected horse in order to initiate an appropriate infectious disease control protocol. PCR assay, as previously shown for viral respiratory diseases, is a fast and sensitive molecular diagnostic tool and should be performed on blood and nasal or nasopharyngeal swabs to document viremia and nasal shedding, respectively.[41,53,54] The dilemma as to whether the virus is in a lytic, nonreplicating or latent state can be addressed by using absolute quantitation or transcriptional activity of the target gene similar to the approach used for EHV-4.[23] Research groups have recently identified a region of variation in the genome of different EHV-1 strains that correlates directly with their ability to cause neurologic disease.[55] The sequence variation occurs in the DNA polymerase gene of the virus, which is involved in initial viral replication within infected cells and may also be involved in establishment of latency and reactivation. Rapid PCR assays have been established to allow differentiation between neuropathogenic and nonneuropathogenic strains.[56] However, such assays have moderate specificity, because 87% of neuropathogenic stains have been shown to harbor the mutation. Therefore such assays should be used judiciously, and the results should always be interpreted in the context of clinical presentation.

29.15.3 Gastrointestinal Pathogens

The detection of equine gastrointestinal pathogens using conventional or molecular tests often is very challenging because these pathogens either are difficult to grow in cell culture systems or can be present in pathogenic or nonpathogenic forms, making interpretation of positive results difficult. Furthermore, the use of fecal material for molecular diagnostics has been associated with false-negative results because of the presence of inhibitory substances in the feces that can interfere with nucleic acid extraction or amplification.[57] However, development and use of specific extraction kits* have improved the yield of nucleic acid from feces.[58]

Neorickettsia risticii (formerly *Ehrlichia risticii*) is the rickettsial agent responsible for Potomac horse fever (PHF), a serious enterocolitis of horses. Because of the nonspecific nature of the clinical signs, a provisional diagnosis of PHF is often based on the presence of typical clinical signs and the seasonal and geographic occurrence of the disease. A definitive diagnosis of PHF, however, should be based on isolation or detection of *N. risticii* from blood or feces of infected horses.[59] Isolation of the agent in cell culture, although possible, is time-consuming and not routinely available in many diagnostic laboratories. The recent development of *N.*

risticii–specific PCR assays has greatly facilitated the diagnosis of PHF.[60,61] These molecular assays have contributed to the investigation of the epidemiology of PHF, allowing the discovery of helminthic vectors and intermediate and definitive helminthic hosts as well as revealing the natural route of infection.[62–64] Nucleic acid of *N. risticii* can be detected in the blood and feces of naturally or experimentally infected horses, but the detection period does not necessarily coincide between the two sample types (Fig. 29-2). Based on these results, we recommend analyzing both blood and feces from suspected horses in order to enhance the chance of molecular detection of *N. risticii*. Another application of PCR has been recently described: the first equine cases of PHF from Nova Scotia using formalin-fixed and paraffin-embedded colon tissue.[65]

An emerging equine gastrointestinal pathogen, *L. intracellularis*, has been described in young horses.[66] This obligate intracellular bacterium is the causative agent of proliferative enteropathy (PE), a transmissible enteropathy known to affect a wide range of domestic and wild animal species.[67] This disease has a worldwide distribution and likely is underrecognized in horses. Antemortem diagnosis can be challenging and is based on interpreting clinical signs (e.g., lethargy, weight loss, subcutaneous edema, diarrhea, colic), clinicopathologic results (e.g., hypoproteinemia), and ultrasonographic findings (e.g., thickened small intestine) and excluding other causes of similar gastrointestinal findings.[68] Currently, culture of the organism is difficult and is not routinely offered by laboratories. Antemortem diagnosis relies on serology and PCR,[69–70] but these tests have not been systematically evaluated in horses. The combination of both tests as well as repeated fecal sampling from target animals for PCR assay will increase the chance of diagnosing the disease. Novel PCR assays, such as the real-time PCR, have increased the sensitivity of molecular detection, compared with initial conventional assays.[71] PCR testing has the advantage of being fast and can yield positive results in the early stage of disease, when antibodies are not yet measurable. Prior use of antimicrobials can negatively affect the molecular detection of *L. intracellularis* in feces. Therefore in a suspected case, fecal collection for PCR testing should be performed before institution of any antimicrobial treatment.

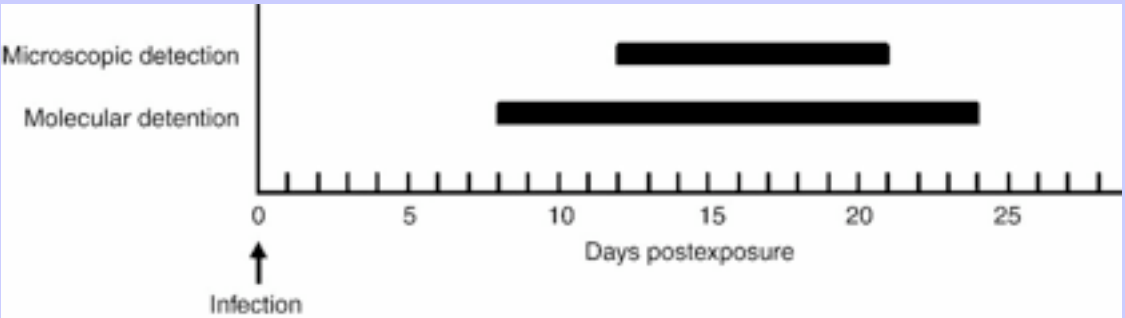
29.15.4 Miscellaneous Pathogens

Equine granulocytic ehrlichiosis (EGE) is caused by *Anaplasma phagocytophila* (formerly *Ehrlichia equi*), a rickettsial pathogen transmitted by *Ixodes* ticks. Diagnosis often is based on awareness of the geographic area for infection, presence of typical clinical signs, presence of abnormal laboratory findings, and identification of characteristic pathogen inclusions in the cytoplasm of neutrophils and eosinophils in a peripheral blood smear stained with Giemsa or Wright stain.[59] PCR has been used for many years to study several aspects of the epidemiology and pathophysiology of EGE.[72,73] For clinical purposes, the material of choice is whole blood. PCR has been shown to be a very sensitive and specific tool, helping with diagnosis especially during early and late stages, when the number of organisms is too small for diagnosis by microscopy (Fig. 29-3).[74]

Corynebacterium pseudotuberculosis is a common cause of external and internal abscesses in horses from arid regions of the western United States.[75] The epidemiology recently has been investigated with the help of PCR technology, and flies have been identified as potential vectors.[76,77] *C. pseudotuberculosis* is easy to grow on culture, and use of PCR testing on clinical samples is restricted to specific situations (e.g., culture-negative aspirates or body fluids).

In recent years PCR assays for the detection of *Salmonella* species in fecal samples from horses admitted to veterinary hospitals have been evaluated.[78–81] All the studies showed that significantly more fecal samples were positive according to PCR assay than according to microbiologic culture. The reasons why some fecal samples, from which *Salmonella* organisms cannot be isolated, are PCR positive need to be determined before PCR assays are routinely used in the hospital setting for the diagnosis of salmonellosis and surveillance programs.

Fig. 29-3 Microscopic and molecular detection period of *Anaplasma phagocytophila* in the blood of horses experimentally infected with *Ixodes scapularis*. From Pusterla N, Madigan JE, Leutenegger CM: Real-time polymerase chain reaction: a novel molecular diagnostic tool for equine infectious diseases, *J Vet Intern Med* 20:3, 2006. Reprinted with permission of the American College of Veterinary Internal Medicine.



Additional PCR assays for *Borrelia burgdorferi*, equine arteritis virus, *Leptospira* species, *Mycobacterium* species, *Clostridium difficile,* and methicillin-resistant *Staphylococcus aureus* have been developed and are being used in the research setting.[82–89] These assays likely will be offered for diagnostic purposes when additional clinical samples from horses have been analyzed.

29.16 MOLECULAR TESTING FOR INFECTIOUS DISEASES IN CATTLE, SHEEP, AND GOATS

Sharon K. Hietala

Beate M. Crossley

The availability of molecular-based diagnostic technologies designed to identify infection or genetic conditions by detecting specific genome targets in the host or agent DNA or RNA has expanded logarithmically in the past decade. Diseases and genetic conditions affecting cattle, sheep, and goats are now commonly studied and diagnosed using molecular techniques, and in particular PCR assays. PCR-based approaches, which by nature can be extremely sensitive for the detection of infectious agents, were once considered useful only in research laboratories based on concerns ranging from the risk of laboratory contamination and false-positive findings to high per-assay costs. With the commercial availability of specialized instrumentation, reagents, and technical training, 446
the criticisms have largely been overcome. Molecular technologies are now generally available for routine 447
diagnostic services provided by state and federal diagnostic laboratories and university laboratories, as well as commercial laboratories. The technical complexity of molecular-based diagnostics, paired with the wide range of assays available to diagnose genetic and infectious diseases of food animals, means that no single laboratory can feasibly provide comprehensive testing for all species and all diseases. Instead, laboratories tend to focus on the diseases or genetic conditions of primary significance to their allied industries and to use the technologies that provide the most rapid, reproducible and economical results for their particular group of clients. Largely based on this specialization within laboratories, molecular-based assays may be developed and put into use without significant effort toward assay standardization and validation. The list of PCR-based assays available for detection of infectious agents in particular has grown significantly in recent years, although with no guarantee that the assays have been suitably designed, tested in the field, or clearly advertised as to their “fitness for purpose.” For molecular-based assays the selection of the genetic sequence (DNA or RNA) used as the target of the diagnostic assay is heavily dependent on the proposed use of the test and on the availability of known genomic sequence(s) for development of the assay. All genomes accumulate mutations over time, with some genes being highly mutable to allow evolutionary advantage—for example, those genes that encode antimicrobial resistance or surface protein conformations used for evading the host immune system. Other genes (e.g., those encoding specific functions such as replication) tend to remain highly conserved and stabile to protect the survival of the organism. Assays used to detect a specific agent—for instance, bovine virus diarrhea (BVD) virus—can be designed to target a conserved region of the genome that is shared by all members of the species. Alternately, assays used to characterize or subtype particular strains or isolates—for example, BVD virus (BVDV) type 1b—can be designed to target regions with significantly more mutability or sequence variation. Assays designed as “fit” for surveillance testing must often sacrifice the ability to discriminate closely related pathogens, such as BVDV, from the genetically related border disease virus in order to have the needed surveillance sensitivity to detect the broad range of potential BVDV isolates. Similarly, assays designed for test and cull or related disease-control programs must have a high diagnostic specificity for detecting only the agent or trait of interest. These assays tend to sacrifice diagnostic sensitivity or detection level in order to minimize the risk of false-positive results. Although molecular diagnostics provides a powerful and rapidly advancing tool, the clinician is advised to use molecular-based assays with appropriate awareness of their individual strengths and weaknesses, including the designated use or “fitness for purpose.”

Unquestionably, molecular technologies will continue to be developed and implemented in veterinary medicine. Although it can be expected that some technologies will replace existing procedures, it should be expected that other molecular tools will be no more than a supplement to traditional diagnostic approaches.

29.17 SAMPLE SUBMISSION

As with any diagnostic technology, the specimen used must be appropriate for the disease or genetic condition, and consideration must be given to the timing and pathogenesis of the disease process and availability of the intact genetic material being targeted by the diagnostic assay. Among the important criteria in the selection and use of molecular-based assays are onset and duration of agent replication in the host, specific tissue(s) affected, and the relative abundance of target DNA or RNA over the course of the infection. In addition to tissues obtained from postmortem investigation or surgical sampling, antemortem diagnostic testing can target genetic material recovered from swabs of mucous membranes or from blood, urine, milk, skin scrapings, or fecal material as appropriate to the disease process.

Because all molecular-based diagnostic tests detect genomic material in one form or another, the isolation and purification of nucleic acids (DNA or RNA) from the diagnostic specimen is critical to the success of the assays. Depending on the tissue or specimen used for diagnostic testing, recovery of nucleic acid in sufficient quantity and quality can be problematic. Common sources of assay failure include substances in the sample that can interfere with the chemistries used in detection or PCR-based amplification steps. Examples include but are not limited to heparin, iron, peroxidases, hemoglobin, and myoglobin, as well as the relative abundance of total DNA or RNA associated with the different specimen types. Another common source of assay failure is destruction of target nucleic acids in the specimen before testing, commonly a result of enzymes associated with postmortem autolysis. Because of the complexities of nucleic acid recovery and target nucleic acid detection, assays developed for use with one matrix, for example whole blood, may not be suitable for use with other matrices, such as milk or feces. Appropriate sample collection buffers, storage temperatures, and shipping requirements are available from the laboratories performing the specific testing.

29.18 MOLECULAR-BASED DIAGNOSTIC TECHNOLOGIES

29.18.1 Hybridization Probes

Nucleic acid fragments, either DNA or RNA, can be detected by hybridizing to a complementary fragment of nucleic acid that has been marked with a reporter dye or enzyme. The short strands of DNA or RNA, generally chemically synthesized and referred to as *oligonucleotides,* are identified as hybridization probes when marked with a reporter dye or enzyme. Radioactively labeled probes, though once the standard, have largely been replaced by enzymatic tags, such as avidin-biotin, peroxidase, and chemiluminescent tags. Target nucleic acids can be detected directly in the diagnostic specimen when sufficiently abundant or may be detected after PCR-based amplification of the nucleic acid target.

29.18.2 Southern, Northern, and Dot-blots

Various techniques are used to immobilize genetic material before detection steps, with or without prior PCR amplification. As a group the techniques are referred to as *blots. Dot-blots* and *Southern blots* refer to DNA bound to nitrocellulose membranes, whereas *Northern blotting* is the terminology used when RNA is immobilized onto membranes. In Southern and Northern blots, nucleic acid fragments are first separated by size

through use of an electric current running through a semisolid gel, a technique referred to as *gel electrophoresis*. The nucleic acid detection step for DNA and RNA blots may include a specific hybridization probe or may simply use the molecular weight of the DNA or RNA fragment. Related terminology includes *Western blot,* which describes protein immobilized on a membrane, and *immunoblot*, referring to detection of the immobilized protein using specific antibody as an immunologic marker.

447

448

29.18.3 In Situ Hybridization

The laboratory technique referred to as *in situ hybridization* allows for localization and observation of a DNA or RNA target within a histologic tissue section.[93,94,100,103] The hybridization probes are typically end-labeled with a radioactive or enzymatic reporter molecule. FISH is a relatively new staining approach that shows promise for future rapid diagnostic applications. ISH using RNA probes (riboprobes) is another rapidly advancing technology, with improved detection sensitivity compared with DNA probes, although it has been used primarily for studying viral infection and gene expression rather than for diagnostic applications. ISH technology can be applied to frozen or formalin-fixed tissues, with best results provided when the tissue is fixed as soon as possible postmortem to avoid loss of target nucleic acids during tissue autolysis. Nucleic acids from veterinary pathogens have been shown to be stabile in formalin-fixed, paraffin-embedded tissues for up to 15 years.[93,99] Because of technical complexity ISH is not yet widely applied to routine diagnostics but appears to be rapidly advancing in that direction.

29.18.4 Polymerase Chain Reaction

PCR is the most commonly applied of the molecular technologies and can be roughly grouped into standard PCR assays and the more rapid real-time or quantitative PCR assays. Both techniques amplify minute quantities of target DNA to levels that are detectable using laboratory instrumentation or special staining procedures. The principle difference in the two approaches is that standard PCR testing is divided into two major processes in the laboratory: the amplification of the DNA target, followed by the detection of the amplified target DNA. Real-time PCR testing combines the two steps so that target detection occurs during the DNA amplification process. The advantages of PCR assays over standard isolation and identification techniques is the significantly reduced time required to obtain a result, with PCR results generally provided in hours compared with days. PCR-based technologies are a particularly powerful tool when designed to detect the presence of organisms that are extremely slow-growing or difficult to culture, such as the *Mycobacterium avium* subsp. *paratuberculosis* (Johne's disease) bacterium, *Leptospira* species, and the bluetongue virus, among others. Because PCR-based assays detect nucleic acids, they do not require that the organism be viable in the sample. This is considered an advantage for those agents that may be easily destroyed during sample transport to the laboratory but a disadvantage where fragments of a pathogen's genome may persist for weeks or months after the animal has become noninfectious. An excellent example of this is the bluetongue virus; PCR can detect nonreplicating viral genome adherent to red blood cells for several weeks after live virus can be recovered from the blood.

29.18.4.1 STANDARD POLYMERASE CHAIN REACTION

Standard PCR testing is used for detection of DNA or RNA and can be applied to mammalian, microbial, or viral genomes. The PCR technique is based on the natural cross-linking of complementary (matching) nucleic acids to form double-stranded DNA. When DNA is sufficiently heated, double-stranded DNA separates into single strands, each of which can then be used as a template for chemically or biologically generating an exact copy. Specific heat-stabile polymerase enzymes are used in the laboratory for the process of DNA replication.

The PCR reaction amplifies DNA using multiple cycles of heating double-stranded DNA to generate a single-strand template and cooling sufficiently to allow the polymerase enzyme to generate a new double-stranded DNA made up of the original strand and its test-tube—synthesized copy. For diagnostic assay purposes, it is necessary to copy only a small but diagnostically characteristic fragment of any particular genome. This fragment is generally referred to as the *PCR target* or *target sequence*. PCR primers are short, chemically synthesized fragments, typically 10 to 30 nucleic acids in length, that are used to mark the beginning and end of the selected target sequence and, as their name implies, are used to prime or start the initial PCR amplification process. The choice of target sequence as well as appropriate primer design is critical to the accuracy and efficiency of PCR-based diagnostic assays. For detecting target RNA, as is needed for the PCR diagnosis of an RNA virus, the technique of RT-PCR is used. The reverse transcriptase enzyme converts target RNA into DNA, identified as cDNA or copy DNA, for use in the PCR steps. The PCR amplification process typically takes 2 to 6 hours to complete and is followed by detection steps that require additional hours to days to complete. Detection of the amplified DNA fragment, often referred to as an *amplicon,* uses techniques that identify the DNA fragment by molecular weight, by marking a specific target sequence in the amplified DNA with a hybridization probes, or by a combination of both (PCR and probe). PCR amplification followed by hybridization probe detection offers increased specificity and thus less chance of a false-positive finding and often provides a tenfold or greater increase in detection sensitivity. Depending on the stringency designed into the assay by balancing temperature, length of replication cycles, enzyme concentrations, and so on, false-negative results will occur when the sequence of the primers or probe does not precisely match the sequence of the target. In some cases PCR assays are very precise and designed to recognize a single nucleic acid polymorphism (SNP analysis) in the target sequence, and in other cases they are intentionally designed with lower stringency to allow some degree of variability among isolates or strains being detected by the assay. Because RNA viruses in general lack the proofreading enzymes found in DNA viruses, bacteria, and protozoa, they are at greater risk for appearance of random mutations at primer or probe sites. PCR false-negative results associated with primer or probe mismatches resulting from random genomic mutations at the primer or probe binding sites are of particular concern for RNA viruses and provide ample justification for a laboratory to investigate with alternate or additional technologies when negative PCR-assay results clearly do not match a clinical or epidemiologic pattern of disease.

29.18.4.2

NESTED POLYMERASE CHAIN REACTION

Nested PCR testing is a PCR technique modification generally used to increase the detection sensitivity of an assay.[92] During nested PCR testing, an initial PCR reaction amplifies a selected fragment of DNA, which is then used as template in a second round of PCR amplification. The second or nested PCR reaction targets one or more unique fragments of DNA within the initially amplified region. The two-step process has the advantages of increasing detection sensitivity and specificity and of diluting the impact of interference from potential PCR inhibitors found in some tissues and clinical materials. Nested PCR assays have been described for WNV, malignant catarrhal fever virus, and *Chlamydia* species, among others. The significant disadvantage of the two-step process comes from handling the first round of amplified DNA in the laboratory. With the high concentrations of target DNA available after PCR amplification, laboratories must take rigorous precautions to mediate the risk of contaminating laboratory workspaces, equipment, and reagents with the amplified DNA. The significant risk and associated costs of laboratory contamination and resulting false-positive results are used in many diagnostic laboratories as justification for charging additional fees or for not offering nested PCR techniques.

29.18.4.3 REAL-TIME POLYMERASE CHAIN REACTION AND REAL-TIME QUANTITATIVE POLYMERASE CHAIN REACTION

Diagnostic assays originally developed using standard PCR approaches are increasingly being converted to real-time PCR and real-time quantitative PCR (qPCR) technology to take advantage of the speed, technical efficiency, and cost reduction often associated with this approach.[96] Because real-time PCR technology completes both amplification and detection in the same reaction tube or well, there is no need for the laboratory to handle amplified DNA and risk workspace contamination. This noteworthy modification of PCR technology has been responsible for a significant expansion in use and general availability of PCR-based diagnostic assays. More important, the combination of amplification and detection in a single reaction vessel has allowed expansion of PCR-based assays into high-throughput, portable, and on-site formats as described for foot-and-mouth disease virus, anthrax detection, and others. Real-time PCR technology offers an additional advantage of supporting quantitative approaches to amplification and detection of the original target in the sample tested. Quantitative PCR testing answers a frequent criticism of standard PCR testing, specifically that detection limits, potentially as low as a single cell or viral particle, may produce a positive finding that is biologically irrelevant to clinical disease. Quantitative PCR technology allows the relative amount of target nucleic acid to be correlated with the associated clinical presentation.

29.18.4.4 MULTIPLEX POLYMERASE CHAIN REACTION

Multiplex PCR technology expands the use of PCR or real-time PCR-based detection from a single target to multiple targets simultaneously from a single specimen.[104,111,119] The ability to include multiple genome targets for a single virus or bacteria in a PCR assay minimizes the risk of a PCR false-negative result caused by genetic diversity within the agent of interest. Inclusion of targets for multiple closely related viruses has been used to differentially detect related pathogens, such as the closely related sheep- and wildebeest-associated forms of malignant catarrhal fever, to subtype BVD viruses, and to differentially detect virulent *Escherichia coli*. Multiplex PCR technology also has broad application in syndrome-based testing in which several pathogens may produce very similar or identical clinical pictures. A single diagnostic specimen could theoretically be used in a multiplex format to detect one or more agents associated with a particular clinical presentation, such as the multiple viral and bacterial agents in shipping fever complex. Prototypes of this approach have been developed but are not yet widely deployed, and there are technologic limits to the number of PCR assays that can be combined without significant loss of assay performance. In real-time PCR formats, three to five unique assays have been the practical limit, based on the technical limitations of commonly available equipment and detection dyes.

29.18.5 Isothermal Amplification

Isothermal amplification techniques use alternate chemistries to PCR technology and are carried out at a single temperature. Among the isothermal amplification technologies that have been used for the detection of veterinary pathogens are nucleic acid—based amplification (NASBA), loop-mediated isothermal amplification (LAMP), rolling circle amplification, and direct signal amplification systems.[102,112] None of these technologies has seen widespread diagnostic application, possibly because of the complexity of initial assay design, but they may offer future PCR alternatives that can be more automated, portable, or developed as fully integrated self-contained testing units.

29.18.6 Genechips and Microarrays

Arrays of DNA or RNA fragments, variously referred to as *genechips* and *microarrays,* consist of thousands of oligonucleotides attached in a specific pattern to a solid surface, typically a glass slide or silica chip.[97,98,101,108,120] The sample nucleic acids compete with fluorescently labeled competitor oligonucleotides for binding to the chip. A fluorescent detector and computer software are then used to analyze the patterns of fluorescence, indicating where nucleic acids have (or have not) been bound to the chip. Microarrays have been used primarily as research tools focused on detecting and understanding gene expression. The practical application to veterinary medicine includes studies such as the evaluation of genetic resistance to naturally occurring nematode infections, including *Haemonchus, Trichostrongylus,* and *Ostertagia* in sheep. Microarray technology has not seen wide use in veterinary diagnostic laboratories, largely because of the large initial investment required for equipment. However, examples of diagnostic microarrays have shown promise, and it is expected that, once established, the technology will be cost-effective on an individual-animal basis. In human diagnostic medicine, microarrays designed with genetically conserved sequences for all major groups of microorganisms have been used to identify or "mine" for unknown pathogens. This approach was used to detect and identify the severe acute respiratory syndrome (SARS) virus before it was initially recovered and characterized by virus isolation techniques. Alternately, genotyping arrays have been designed to target specific virulence-associated genes, allowing differentiation of disease-associated subtypes of organisms from other members of the same or closely-related species, for example enterotoxigenic *E. coli* and multidrug resistant *Salmonella* strains.

29.18.7 Liquid Array

An alternative to genechip technology is liquid array technology, in which the nucleic acids are captured by oligonucleotide probes bound to a microbead rather than to a flat surface. Bead sets are internally labeled with different colored dyes used to distinguish the specific agents being measured. Liquid array systems employ flow cytometry, laser technology, and signal processing to recognize the internal color of the beads and measure associated surface-binding of a target-specific fluorescent hybridization probe. The bead-based modification to microarray technology allows a laboratory to create a flexible diagnostic-test panel in a single assay by adding or removing target beads based on the unique clinical presentation, diseases suspected, or species specificity of interest. In theory, 100 different targets are detectable in a single assay. Liquid array technology was successfully demonstrated during a U.S. National Animal Health Laboratory Network pilot project in 2006, in which bovine oral swab samples were simultaneously screened for the presence of seven different bovine viral pathogens capable of producing vesicular-type lesions. Among the viruses included in the panel were foot-and-mouth disease viruses, bovine virus diarrhea viruses, bovine herpesvirus type-1, malignant catarrhal fever virus, bluetongue virus, and bovine papillar stomatitis virus.

29.18.8 Restriction Fragment Length Polymorphism, Random Amplified Polymorphic DNA, and 16s RNA Typing

Molecular techniques provide a valuable tool for genotypic characterization or subtyping of viral, bacterial, and parasitic agents. Subtype characterization[90,91,110,115] is essential for taxonomic classification, differential detection of virulent strains, identification of genetic sources of antimicrobic resistance or virulence factors, recognition of vaccine escape mutants, epidemiologic investigation of disease outbreaks, identification of interspecies transmission of specific pathogens, and so on. RFLP is a technique useful for subtyping of

pathogens based on genetic sequence variation within specific genes.[106] Target DNA, which may or may not previously have been PCR amplified, is digested using one or more well-characterized restriction enzymes. Characteristic profiles or patterns produced by the different sized DNA fragments remaining after enzyme digestion are detected by gel electrophoresis. RFLP has been used to investigate interspecies transmission of enterotoxigenic *S. aureus* associated with intramammary infections in cattle, sheep, and goats.[118] Random amplified polymorphic DNA (RAPD) analysis is a technique that has proven useful in detecting genetic variation and for strain typing.[107] Rather than amplifying a specific region of a genome, RAPD relies on random amplification of genomic DNA using short arbitrary sequences as PCR primers. RAPD does not require prior knowledge of an organism's DNA sequence for specific primer design and can be applied to very small amounts of template DNA. The RAPD technique has been applied, for example, to rapid differentiation of pathogenic from nonpathogenic coccidia of sheep, including *Toxoplasma gondii* and *Sarcocystis* species. Identification of nonculturable, slow-growing, and atypical bacterial species using sequence analysis of the 16s ribosomal RNA (rRNA) gene has become recognized as a valuable diagnostic tool in recent years. The basis of the 16s RNA typing technique is the highly conserved nature of the 16s rRNA gene within bacterial species as well among species of the same genus.[95,113,119] Automation developed to support 16s rRNA amplification, sequencing, and data analysis is available to and currently in place in selected veterinary diagnostic laboratories. Although the technique is not currently cost-effective for routine identification of all microbial isolates in a clinical setting, the technology is used for identification of atypical, slow-growing, and rarely encountered species. As 16s rRNA databases continue to be updated to include pathogens of veterinary and zoonotic interest, it is likely that the technology will see broader application.

29.18.9 Sequence Analysis

Nucleic acid sequence analysis is used to identify and compare the exact nucleic acid sequence of a gene fragment, gene, or possibly entire genome for forensic purposes, to investigate disease outbreaks, to track evolutionary changes in rapidly mutable microorganisms, or for precise phenotype or genotype analysis of animals or organisms. For example, nucleic acid sequencing of the sheep prion protein (PrP) gene allele has been used as a flock management tool associated with scrapie control.[109] Although at times controversial, rapid PCR-based genotyping of sheep has been used for selective breeding programs targeting the genetic alleles associated with “scrapie resistance.”

29.19 GENETIC DISEASES

Diseases that are linked to genetic mutations in specific breeds, such as bovine leukocyte deficiency (BLAD) and complex vertebral malformation (CVM) in Holstein cattle, β-mannosidosis in cattle or goats, and Spider Lamb Syndrome in sheep can be controlled by selective breeding using PCR-based testing to identify carriers of the defective gene. Similarly, susceptibility to certain diseases, such as scrapie in sheep, as noted previously has been linked to specific genetic haplotypes that can be detected by molecular analysis.[116] DNA testing for genetic selection, parentage confirmation, coat color, and related management purposes is also available for cattle, sheep, and goats. For genetic testing the appropriate sample is typically whole blood, from which genomic DNA is extracted; the gene of interest is amplified by PCR, then mutations are detected by sequence analysis, microsatellite target testing, and restriction enzyme analysis to identify the mutations in the gene of interest.[105,117]

29.20 SUMMARY

With molecular diagnostics, as with any new technologic advance, there was initial hesitation or mistrust of the techniques, followed by a rush to take advantage of new diagnostic tools. With routine implementation of PCR and associated molecular diagnostic techniques have come significant advantages in diagnostic sensitivity and specificity, in the speed with which a laboratory diagnosis can be reached, and in the potential for in-depth genome-level investigation of disease occurrences. At the same time, molecular techniques have introduced a new level of complexity to diagnostic medicine. The use and interpretation of molecular-based diagnostic results require sufficient understanding of the techniques used in order to judge the reliability and the relevance of the findings. Molecular techniques have become, and will continue to grow as, extremely valuable diagnostic tools, but like any tool in diagnostic medicine, they must be used with caution and with a clear understanding of their strengths, limitations, and appropriate application to specific clinical investigations.

30 Chapter 30 Diseases of the Cardiovascular System

Virginia B. Reef

Sheila M. McGuirk

30.1 PERFORMING THE ELECTROCARDIOGRAM

No single electrocardiographic lead system has been universally accepted for use in large animals. Bipolar leads (I, II, III, base-apex, X, Y, and Z of the orthogonal lead system) and unipolar leads (aV_F, aV_R, aV_L, thoracic) have been described, but the amplitude, duration, and configuration of the different waveforms vary widely, depending on an animal's breed, size, body type, and sex. In addition, there is lability of certain waveforms within each animal depending on the level of exercise, excitement, or organic heart disease. Large animals have a deeply penetrating Purkinje system, and depolarization from ventricular endocardium to epicardium occurs explosively and in many directions at once. This period of ventricular activation is responsible for the electrocardiographic criteria indicative of ventricular enlargement in small animals but contributes little to the generation of the QRS complex of large animals. Thus establishing specific diagnostic criteria for chamber enlargement in large animal species has been difficult because changes in the QRS complex are not sensitive or specific for ventricular enlargement.

Therefore the electrocardiogram (ECG) is used primarily to detect cardiac arrhythmias. For this purpose a single-channel machine can be used, and the lead system chosen can be any that generates distinctive P, QRS, and T complexes. If an arrhythmia is detected, another lead can then be obtained to further characterize the QRS and T complexes and confirm their origin. The lead system should be easy to apply, and the tracing free of artifacts created by muscle tremors, skin movement, shifting of weight, and changes in limb position. Two such leads commonly used for the diagnosis of cardiac arrhythmias are the base-apex lead[1] and the Y lead of the orthogonal lead system.[2] The base-apex lead is attached by placing the positive electrode from one of three standard bipolar leads (lead I, II, or III) on the left thorax in the fifth intercostal space at the level of the elbow or at the location where the apex beat is most readily palpable. The negative electrode is attached to the skin of the right jugular furrow two thirds of the way from the ramus of the mandible to the thoracic inlet or at the top of the right scapular spine. The ground electrode can be attached to any site remote from the heart. Electrical contact is improved by clipping hair or wetting the skin with alcohol. The base-apex lead ECG is recorded by switching the machine to the bipolar lead that has been attached to the horse and recording the ECG (Table 30-1). Lead Y is attached by placing the positive electrode over the xiphoid and the negative electrode cranially to the front of the chest.

Continuous electrocardiographic recording over a 24-hour period (Holter monitoring) or with radiotelemetry is also useful for evaluating horses with arrhythmias. Continuous recording of the ECG can be performed with contact electrodes, electrode patches that are held against the skin with a surcingle, or electrode patches attached to shaved skin with a cyanoacrylate adhesive and protected underneath a surcingle.[3,4] The contact electrodes or electrode patches held against the skin with a tight surcingle appear to work best for obtaining a continuous ECG recording. With bipolar contact electrodes, the positive electrode is placed over the left cardiac silhouette or over the sternum and the negative electrode is placed over the dorsum to the left of the withers where the electrode will lie flat and remain in contact with the skin.[3] The electrodes are kept moist with alcohol. The electrodes are then covered with moist sponges to maintain contact and are held in position with a tight surcingle. With electrode patches the electrodes are taped to a small square of cardboard to provide them with some rigidity. The best recording is usually obtained with the left arm electrode placed on the sternum, the right leg electrode on the right side in the fifth intercostal space at the level of the point of the shoulder, and the right arm electrode placed on the left side in

the fifth intercostal space at the level of the point of the shoulder. These electrodes are then held in position with a tight surcingle after removal of the plastic that covers the conducting material overlying the electrode. The electrodes are connected to a recorder (reel-to-reel, cassette, or digital) that records the animal's heart rhythm for the entire monitoring period (Holter monitor) or a telemetry device that sends the ECG signal back to the receiver to be displayed on a monitor. The continuous 24-hour Holter monitor is useful for diagnosing arrhythmias that occur intermittently or for monitoring cardiac rhythm during exercise. Radiotelemetry electrocardiography is useful for monitoring cardiac rhythm during treatment or during exercise.

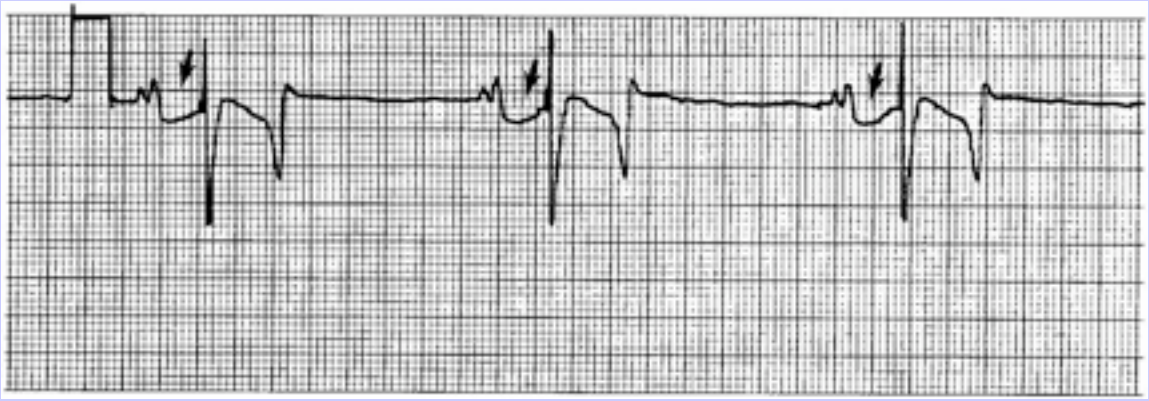
Table 30-1 Standard Bipolar Electrocardiographic Leads

Lead	Positive Electrode	Negative Electrode
I	Left arm	Right arm
II	Left leg	Right arm
III	Left leg	Left arm

453

454

Fig. 30-1 Base-apex lead ECG recorded from a horse. *Arrows* point to the atrial repolarization wave (Ta) frequently seen in normal horses. It follows the notched P wave and precedes the QRS complex. Paper speed 25 mm/sec, calibration 1 cm/mV.



In the base-apex lead the P wave is positive in most horses and ruminants. The P wave is most frequently bifid in horses. In many horses a T_a wave, indicative of atrial repolarization, occurs as a negative deflection after the P wave (Fig. 30-1). The QRS complex begins with a small positive deflection (rS) and is followed by a large negative deflection, which terminates in the ST segment. The T wave is variable and can be positive, negative, or biphasic in horses and ruminants. Frequently the appearance of the T wave is variable within one recording. Fig. 30-2 illustrates a typical base-apex ECG recorded from a cow and a horse at a 25-mm/sec paper speed with the gain set at 10 mm/mV.

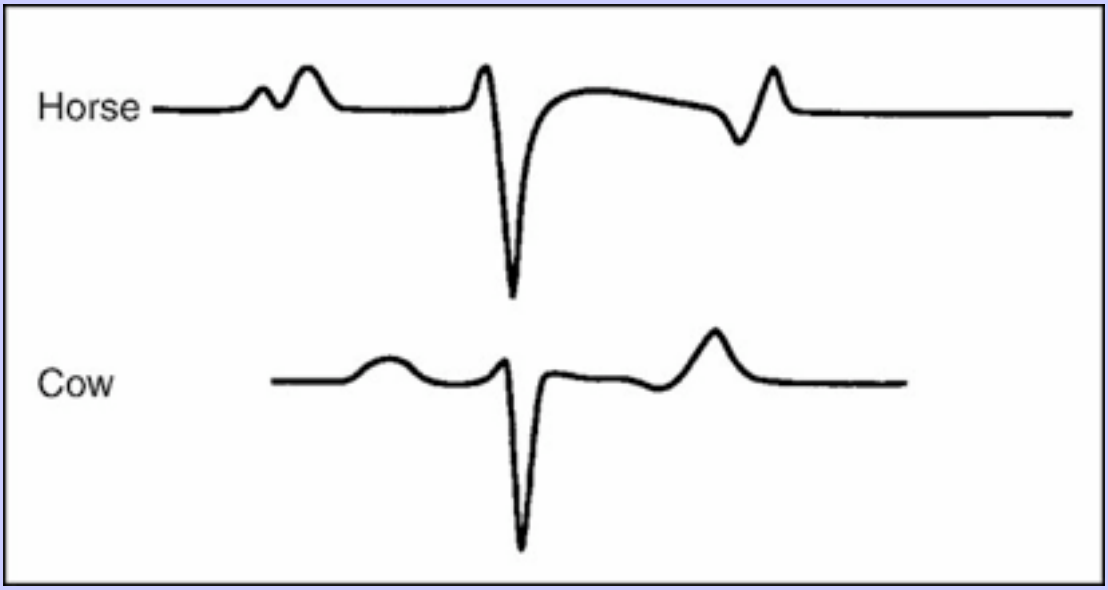
When a systematic approach is used to analyze the ECG, diagnosing arrhythmias is not difficult. The following step-by-step approach can be used:

1 Identify all the QRS complexes. Each QRS complex should be followed by a T wave, and the QT interval should be similar for all QRS configurations, unless there is a marked change in heart rate. Identify the remaining complexes. Are P waves, “F” (flutter) waves or “f” (fibrillation) waves present? Are there any artifacts?

2 Determine the atrial and ventricular rates. Are they identical? Is one too fast or too slow? This determines whether there is a tachycardia or bradycardia.

3 Are the P-P and R-R intervals regular? Determine whether an irregular rhythm has underlying regularity that is interrupted by irregular intervals or whether the rhythm is consistently irregular. Second-degree AV block and atrial and ventricular premature beats are arrhythmias with underlying regularity, whereas atrial fibrillation, sinus arrhythmia, and sinus arrest are truly irregular rhythms.

Fig. 30-2 Schematic representation of a typical base-apex lead ECG recorded from a cow and horse. In horses the P and T waves may be variable in appearance.



4 Are P waves present? If so, is there a P wave preceding every QRS complex? If not, there are premature depolarizations, escape beats, or atrial fibrillation. Are all P waves followed by QRS complexes? If not, second-degree AV block may be present. Is the resultant P-R interval constant? If not, there may be a wandering pacemaker or first-degree AV block.

5 Are all P waves and QRS complexes identical or normal in contour? If not, this signifies more than one pacemaker, premature depolarizations, or escape beats.

30.2 USE OF ECHOCARDIOGRAPHY IN LARGE ANIMALS

Echocardiography is a noninvasive diagnostic tool that uses sound waves in the range of 1.5 to 10 MHz to visualize the heart in motion, using either a single icepick (M-mode) or a two-dimensional (B-mode) image. Noninvasive evaluation of blood flow in the heart and great vessels is performed with pulsed wave, color flow, and continuous wave Doppler echocardiography. Precise localization of abnormal flow within the heart and great vessels is performed with pulsed wave and color flow Doppler echocardiography, whereas continuous wave Doppler echocardiography is used to determine the peak velocity of blood flow and to noninvasively estimate pressure gradients. In contrast to M-mode and two-dimensional echocardiography, in which the best image is obtained with the ultrasound beam perpendicular to the structures being imaged, optimal Doppler signals are obtained with the ultrasound beam parallel to the blood flow being evaluated. For accurate peak blood flow velocities to be recorded with continuous wave Doppler echocardiography, the ultrasound beam should be as close to parallel as possible (less than a 20-degree angle) to the direction of blood flow being measured. This alignment is difficult or impossible to achieve in most large animals with valvular heart disease; therefore accurate peak blood flow velocities often cannot be obtained from large animals with valvular heart disease. Noninvasive estimations of pressure gradients are inaccurate in these instances. Alignment of the ultrasound beam parallel to shunt flow is possible with most ventricular septal defects (VSDs) because of the typical location of the VSD in the membranous portion of the interventricular septum. A more extensive review of the theory and application of echocardiography in horses and cattle has been published.[5–11]

Echocardiography is particularly useful in evaluating large animals with cardiovascular disease because the examination is noninvasive and can be performed in most standing, unsedated animals in a timely fashion. Diagnostic criteria for valvular, myocardial, pericardial, and congenital lesions of the heart are well established, and the information obtained assists the practitioner in confirming a diagnosis, assessing the extent of the disease, determining the severity of cardiac dysfunction, monitoring the response to treatment, and providing an accurate prognosis. Large animal echocardiographic equipment should provide satisfactory resolution of images at depths of 26 cm or greater. Portable ultrasound machines are available that can display depths of up to 36 cm for equine and bovine cardiology. These machines are available with pulsed, continuous wave, and color flow Doppler. However, Doppler echocardiography is used mainly in specialty practices and referral institutions because performing and interpreting a complete echocardiogram, including Doppler, requires a significant amount of training and expertise and state-of-the-art color flow Doppler equipment remains fairly expensive, although it has decreased in price.

454
455

Echocardiographic examination is performed in a systematic way, using standardized images to obtain information about chamber size, wall thickness, myocardial function, valve appearance, valve function, great vessels, blood flow, and presence of abnormal structures or echodensities. The standard equine or bovine echocardiogram is performed from the right parasternal window (the right fourth intercostal space in horses and third intercostal space in ruminants) with a 2.5-MHz transducer. Higher-frequency transducers should be used to examine younger animals, South American camelids, and small ruminants. Both long- and short-axis views of all cardiac structures should be evaluated. The cardiac valves should be carefully examined for any abnormalities of structure or function (thickening, prolapse, ruptured chordae tendineae, fenestrations, flail valve leaflet, vegetative lesion, or high-frequency vibrations). The relative size, shape, and relationship of the cardiac chambers and great vessels should be assessed, and an evaluation of myocardial function and blood flow performed. Standard measurements of left ventricular internal diameter, left ventricular free wall thickness, interventricular septal thickness, and right ventricular internal diameter should all be obtained at end diastole and peak systole from the M-mode echocardiogram. The diameter of the aortic root and left atrial appendage, the distance between the interventricular septum and the peak opening of the septal leaflet of the mitral valve (septal to E point separation), and the left ventricular ejection time (ET) should also be determined. End-diastolic measurements are obtained at the Q wave

of the ECG, whereas peak systolic measurements are made from the peak downward deflection of the interventricular septum. Calculations of fractional shortening (FS) and ejection fraction (EF) can then be performed to assess left ventricular function using the following formulas:

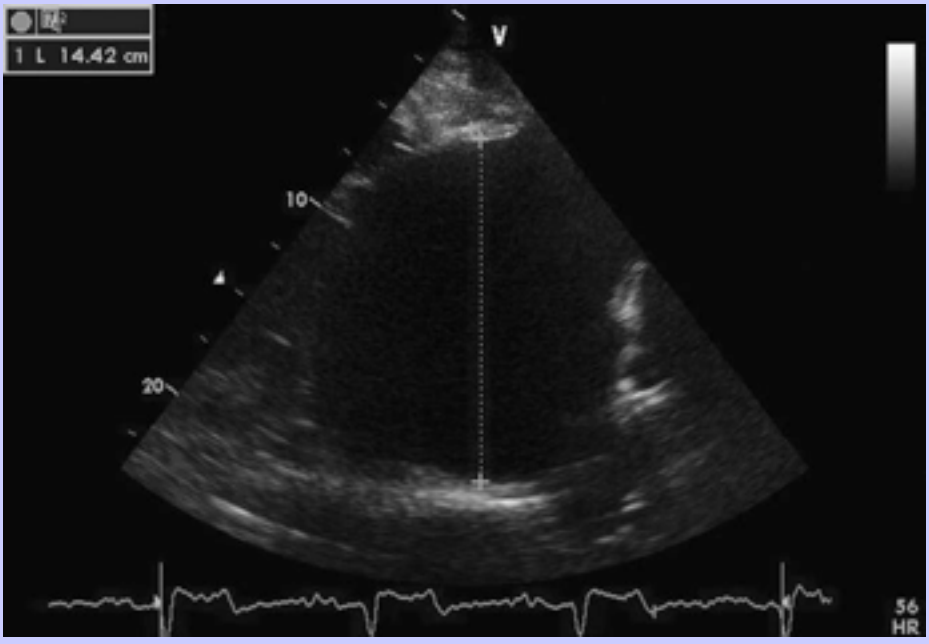
$$FS = \frac{LVID_d - LVID_s}{LVID_d} \times 100$$

$$EF = \frac{LVID_d - LVID_s}{LVID_d} \times ET \times 100$$

in which $LVID_d$ is the left ventricular internal diameter at end diastole (cm), $LVID_s$ is the left ventricular internal diameter in systole (cm), and ET is the left ventricular ejection time (sec).

Echocardiograms should also be performed from the left cardiac window when the entire heart cannot be successfully imaged from the right side; atrial fibrillation is present; abnormalities of the mitral valve, aortic valve, pulmonic valve, aorta, pulmonary artery, left atrium, left ventricle, or outflow portion of the interventricular septum are detected; or murmurs originating from the mitral, aortic, or pulmonic valves are detected or a pericardiocentesis is planned. The maximal diameter of the left atrium should be obtained from the left cardiac window at the level of the left coronary artery, parallel to the mitral valve (Fig. 30-3). The diameters of the aorta and pulmonary artery should be measured from similar locations in the vessel on the two-dimensional echocardiogram and compared. Echocardiography should be considered a useful diagnostic test to evaluate patients with the following complaints, physical examination findings, or tentative diagnoses:

Fig. 30-3 Two-dimensional echocardiographic image of the left atrial diameter obtained from the left parasternal long axis window in a horse with mild left atrial enlargement secondary to cardiomyopathy and mitral regurgitation.



1 Cardiac murmur, to determine whether the murmur is functional or pathologic

a Any grade 3/6 or louder holosystolic or pansystolic murmur on the right or left side of the thorax

b Any holodiastolic decrescendo murmur

c Any continuous machinery murmur

2 Congenital heart defects, especially atrial and VSDs

3 Acquired valvular heart disease

4 Cardiac enlargement

5 Cardiac arrhythmias not associated with high resting vagal tone

6 Unexplained exercise intolerance or intolerance attributed to cardiac causes

7 Muffled heart sounds, pericardial friction rubs, or pericardial effusion

8 Myocarditis or myocardial dysfunction

9 Congestive heart failure (CHF)

10 Pulmonary hypertension

11 Cardiovascular neoplasia

12 Prominent third heart sound

13 Aortic rupture or other abnormalities of the great vessels

14 Ionophore toxicity or exposure to other myocardial toxins

Color flow or pulsed wave Doppler echocardiography should be used to map the size and location of a turbulent jet associated with an intracardiac or extracardiac shunt, valvular regurgitation, or stenosis (rare) and to semiquantitate its severity. Continuous wave Doppler echocardiography can then be used to measure the peak velocity of blood flow in the jet, estimating (noninvasively) the pressure difference between cardiac chambers using the Bernoulli equation and assessing the hemodynamic significance of the lesion. This can be accurately performed in most patients with a VSD but is difficult to impossible to accurately perform in many patients with valvular insufficiencies because of the limited windows available for interrogating blood flow in large animals and the inability to align the ultrasound beam to within 20 degrees of the abnormal blood flow. Contrast echocardiography, a technique involving microbubble-laden injections of saline, carbon dioxide, or indocyanine green, can also be used to demonstrate valve dysfunction and the direction of intracardiac shunts (VSD and atrial septal defect [ASD]) and extracardiac shunts (patent ductus arteriosus [PDA], truncus arteriosus).

455

456

30.3 CARDIAC CATHETERIZATION IN LARGE ANIMALS

Cardiac and great vessel catheterization can be performed in standing, unsedated large animals to determine the following data:

- Pressure and waveforms (shape of the pressure curve)
- Oxygen tension, oxygen saturation, oxygen content
- Cardiac output and other indicators of ventricular size and function

Cardiac catheterization is also used for special diagnostic studies such as angiocardiography, nuclear angiocardiography, and indicator dilution studies. These data are used to determine the direction and size of intracardiac and extracardiac shunts, chamber size and contractility, and valvular and myocardial function. Much of this same information can now be obtained noninvasively with echocardiography and can help the practitioner establish a diagnosis, more accurately assess the prognosis, and provide a direction for therapy.

Cardiac catheterization is usually reserved for specialty practices and referral institutions because of the equipment needed and the skills required for acquiring and interpreting accurate data. Results are not always specific, but catheterization can add quantitative measurements that increase the accuracy of the diagnosis and prognosis of certain cardiac conditions.

30.3.1 Blood Pressure Measurements

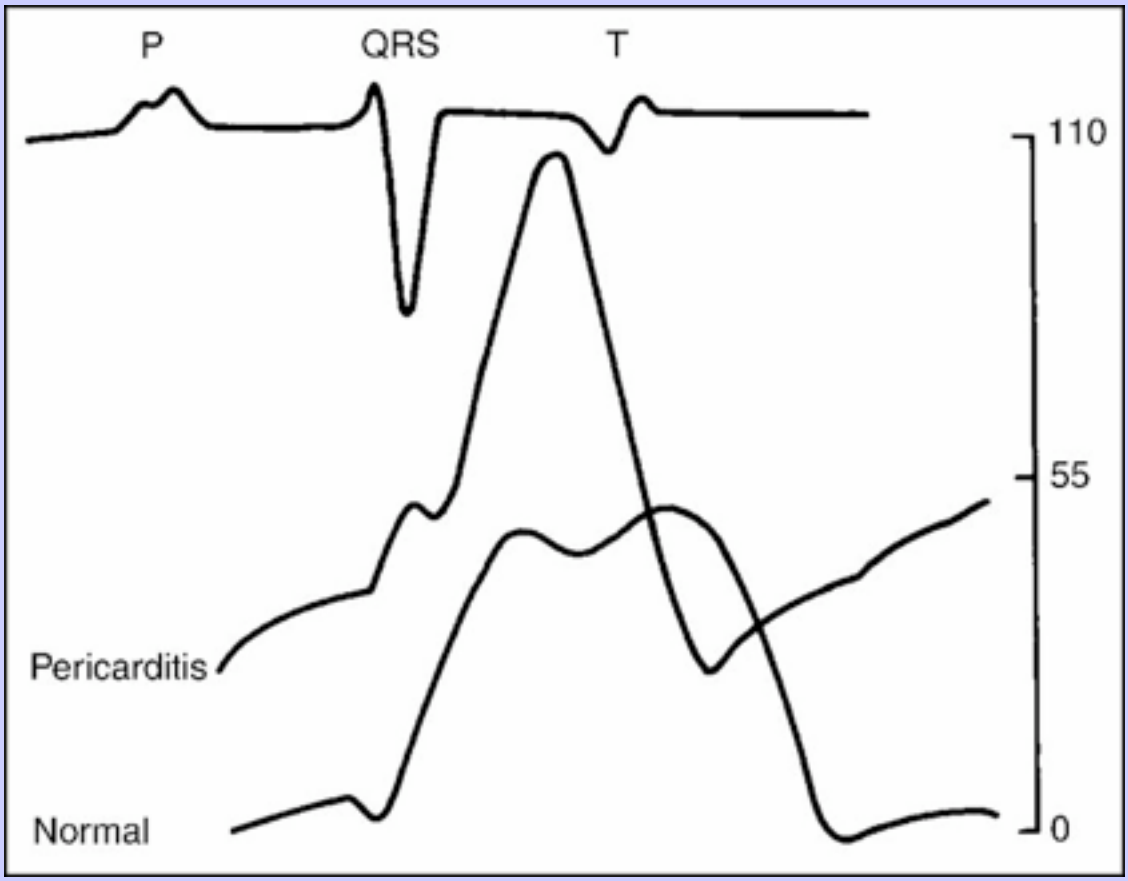
The normal pressures for cattle and horses are listed in Table 30-2.[12–15] The values for horses represent a summary of data from numerous authors as cited in the references given. The accuracy of pressure recordings is greatly influenced by the choice of catheter and the recording equipment used. The pulmonary arterial wedge pressure is an indicator of the left atrial mean pressure, as long as balloon inflation of the catheter occludes flow in the segment of the pulmonary artery that is catheterized. Pulmonary arterial wedge pressure is superior to central venous pressure as a monitor of left ventricular function and fluid therapy.

Table 30-2 Cardiac Pressure Measurements in Normal Horses and Cattle*

	Horses[12]	Cattle[13]
RA	12 to 28/22 to 5 (4 to 10)	(5)
RV	30 to 59/24 to 14 (9 to 25)	42 to 56/0 to 1 (19 to 28)
PA	34 to 48/14 to 22 (16 to 30)	33 to 46/19 to 21 (24 to 31)
PAW	13/3 (8)	(5 to 21)[11]
LV	140 to 148/15 to 17	(120 to 144)[12]
AO	131 to 144/86 to 100 (110 to 115)	
CA	142 to 157/98 to 119 (113 to 124)	160 to 208/110 to 147 (135 to 175)

* Pressure ranges are reported as systolic/diastolic (mean) in mm Hg unless otherwise designated. *AO,* Aorta; *CA*, carotid artery; *LV,* left ventricle; *PA,* pulmonary artery; *PAW,* pulmonary arterial wedge; *RA,* Right atrium; *RV,* right ventricle.

Fig. 30-4 Schematic representation of ventricular pressure curves recorded from a normal horse and a horse with pericarditis, showing the relationship between pressure changes and the ECG. With pericarditis, the ventricular end-diastolic and systolic pressures are elevated and pressure declines sharply in early diastole.



The shape of the pressure curve in the ventricles, aorta, or pulmonary artery may have diagnostic significance in conditions such as constrictive pericardial disease (Fig. 30-4); pulmonic stenosis (giant A wave), rare as an isolated defect in large animals; or tricuspid or mitral valve regurgitation (large V wave). These conditions are more commonly assessed by echocardiography. An abnormal rise in pressure going from one chamber to the next indicates a stenotic lesion (uncommon in large animals) at the level of the pressure gradient. The size of the pressure gradient can be used to determine the severity of the lesion.

30.3.2 Blood Oxygen Measurements

Blood oxygen measurements are taken from the chambers on the right side of the heart to detect abnormal elevations indicative of a left-to-right shunt (ASD, VSD, PDA). Criteria for oxygen step-ups have not been established for large animals, but human guidelines have been accepted for qualitative assessment of shunts.[16,17]

In humans, oxygen content step-ups of the following magnitude are considered abnormal and indicative of a left-to>right shunt[18]:

- ≥1.9 volume percent from the superior vena cava to the right atrium
- ≥0.9 volume percent from the right atrium to the right ventricle
- ≥0.5 volume percent from the right ventricle to the pulmonary artery

Oxygen content depends on the hemoglobin concentration; therefore oxygen saturation, which is independent of hemoglobin concentration, may be a more accurate indicator of shunts in anemic or polycythemic patients. Changes in the animal's physiologic status during sampling (cardiac output, ventilation, oxygen consumption), incomplete mixing of shunted blood, and variable time intervals between sampling can be potential sources of error. Several samples within a single chamber improve the reliability of results. Small shunts and shunts in animals with low systemic arterial oxygen tension may not be detected by this technique.

456

457

Shunt calculations can be made once oxygen saturation or content has been measured in each of the right heart chambers, the pulmonary artery, and a systemic artery. For a left-to-right shunt, the pulmonary flow/systemic flow ratio (QP/QS) is determined as follows:

$$QP \Big/ QS = \frac{SAo_2 - MVo_2}{SAo_2 - PAo_2}$$

in which SAo_2 is the arterial blood oxygen content, MVo_2 is the mixed venous blood oxygen content, and PAo_2 is the pulmonary artery oxygen content. A 2:1 QP/QS represents a 50% left-to-right shunt, indicating that 50% of the pulmonary flow is from the left side of the heart. For a right-to-left shunt, the QP/QS is determined as follows:

$$QP \Big/ QS = \frac{SAo_2 - MVo_2}{PVo_2 - MVo_2}$$

in which PVo_2 is the pulmonary venous oxygen content (assumed to be 98% of oxygen capacity plus 0.3 mL of dissolved oxygen).[19]

30.3.3 Cardiac Output and Ventricular Function Assessment

Cardiac output is determined by indicator dilution methods (usually by dye dilution or thermodilution or, more recently, by lithium dilution), by the Fick method, or by using two-dimensional or Doppler echocardiography. The Fick method requires the use of a face mask and simultaneous determination of mixed venous and arterial blood samples. Dye dilution and thermodilution results are comparable when 30 to 40 mL of 5% dextrose are injected rapidly at 32° F (0° C).[17] Lithium dilution compares favorably with thermodilution in anesthetized horses and foals.[20,21] Volumetric echocardiography using the Bullet method achieves results similar to those obtained with the lithium-dilution method in anesthetized foals.[22] Transthoracic Doppler echocardiography was closely correlated with thermodilution in standing horses.[23] Cardiac output values in the resting horse range from 32 to 40 L/min.[24] Cardiac index is the cardiac output divided by a measure of body size (the body weight in kilograms) and is expressed in mL/kg/min.[24] The normal cardiac index for the adult horse ranges from 72 to 88

mL/kg/min.[24,25] Cardiac output values of 20.9 to 23.6 L/min have been reported in normal anesthetized horses.[20] In cattle a cardiac index of approximately 110 mL/kg/min has been reported.[15] Cardiac output measurements in clinical patients vary with heart rate, excitement, hydration, and many other factors and are best determined in the pulmonary artery. Electronic integration and computation of area under curve by means of battery-powered units that can display results instantly provide the most reliable results.[26]

Cardiac output results or indicator dilution curves can provide quantitative and qualitative assessment of cardiac shunts. Characteristic changes in the temperature-time curve (thermodilution methods) or dye concentration-time curve indicate the presence of a left-to-right, right-to-left, or bidirectional shunt. Calculation of the cardiac output in the chamber just proximal to the shunt and distal to it can give a quantitative estimate of the size of the shunt.[17]

30.3.4 Angiocardiography

Angiocardiography is used in neonates or animals small enough to have the entire cardiac silhouette visualized on a single radiograph cassette. The contrast medium must be injected rapidly, and in most cases this is done with a pressure injector. Specialized radiographic requirements include rapid film change capabilities, rapid image sequence acquisition, or cineradiography. Angiocardiography is used to confirm the presence of an intracardiac shunt (ASD, VSD) or extracardiac shunt (PDA, truncus arteriosus) or valve dysfunction, to visualize chamber size, or to estimate contractility. Angiocardiography is performed in anesthetized animals.

30.3.5 Nuclear Angiocardiography

In nuclear angiocardiography, specialized equipment captures sequential digitized images of the right side of the heart, lung, and left side of the heart after rapid injection of radiographic tracer into peripheral circulation. A more extensive review of this subject has been published.[27] Nuclear angiocardiography can be used to confirm valvular dysfunction, which is manifested by chamber enlargement or prolonged washout of affected vessels or cardiac chambers and is quantitated by the regurgitant fraction. It also can reveal enlargement of chambers and prolonged washout resulting from cardiac failure. The presence of intracardiac or extracardiac shunts can be demonstrated by the simultaneous visualization of left- and right-side cardiac chambers or slow washout downstream of the shunt. In addition, nuclear angiocardiography can be used to calculate cardiac output and EF and other indices of cardiac function.

30.4 CONGENITAL CARDIOVASCULAR DISEASE

The cause of congenital cardiac defects has not been established, although hereditary factors may be responsible for some defects. In humans, additional factors such as maternal infection, age, and nutritional status have been identified. Fetal anoxia from placental insufficiency, fetal infection or metabolic dysfunction, or other causes may contribute to the development of congenital cardiac defects. The same factors may apply in animals. Congenital cardiac defects in large animals can occur alone or in combination. The most commonly reported is VSD.[28–33] Multiple cardiac anomalies including PDA,[34,35] tetralogy of Fallot,[36,37] truncus arteriosus,[38,39] total anomalous pulmonary venous connection,[40] and Eisenmenger's complex in calves[41] have been reported. Congenital anomalies of the tricuspid,[38,42–44] mitral,[45] and pulmonic valves[38,46,47] are uncommon. Congenital abnormalities of the aorta are reported in calves and foals but are also uncommon.[33,48,49] ASD occurs more commonly in calves than in foals

and is frequently accompanied by other defects. [33,39,50,51] Hypoplasia of the left and right ventricles has been infrequently reported in calves and foals.[33,52,53]

Congenital cardiovascular disease should be suspected in a young patient if examination reveals a holosystolic (pansystolic), holodiastolic, or continuous murmur or a murmur with a palpable thrill or wide radiation over the thorax. Cyanosis at rest or with exercise in a patient with a cardiac murmur warrants consideration of a right-to-left cardiac shunt, obstructive pulmonary disease, or severe stenosis of the structures of the right side of the heart. The presence of any of these findings in a young animal with a history of lethargy, weakness, or failure to thrive constitutes grounds to suspect congenital cardiovascular disease.

30.4.1 Ventricular Septal Defect

30.4.1.1 Definition and Etiology

457

458

A VSD is an opening in the interventricular septum that creates a communication between the left and right ventricles. In large animals most defects occur in the membranous septum and are imaged ventral to the septal leaflet of the tricuspid valve and the right and/or noncoronary leaflet of the aortic valve.[29–33] VSD can occur as a single defect or as part of a complex anomaly. Many cardiac malformations such as tetralogy and pentalogy of Fallot, truncus or pseudotruncus arteriosus, common atrioventricular canal defect, tricuspid atresia, and double outlet right ventricle include a VSD. The cause of VSD is unknown, although it has been documented to be a heritable defect in Limousine[33] and possibly Hereford[54] cattle. The defect is thought to result either from failure of fusion of a part of the endocardial cushion and the muscular ventricular septum or failure of fusion of the truncal and conal septa.[55]

30.4.1.2 Clinical Signs and Differential Diagnosis

The clinical signs of an isolated VSD vary and depend on the size of the defect, the direction of the shunted blood, and the presence of concurrent valvular or myocardial disease. In isolated VSD the blood flow is shunted from the left ventricle to the right ventricle through the defect in the interventricular septum. The size of the shunt depends on the size of the defect and the pressures in the left ventricle, right ventricle, and pulmonary artery.

VSD is suspected when there is a loud, harsh, plateau-shaped pansystolic murmur with its point of maximal intensity (PMI) in the tricuspid valve area and a slightly softer, more crescendo-decrescendo holosystolic murmur that is loudest in the pulmonic valve area. The murmur on the left side has its PMI in the pulmonic valve area, associated with a relative pulmonic stenosis (increased blood flow across a normal pulmonic valve). A palpable cardiac thrill usually is present over the tricuspid valve region, and occasionally there is splitting of the second heart sound. The murmur may be the only clinical sign identified if the defect is small. On the other hand, poor growth, lethargy, dyspnea, exercise intolerance, and signs of CHF can be exhibited by animals with a moderate to large VSD. This usually develops by the time the animal is 5 years old. Occasionally there is a diastolic murmur of aortic insufficiency associated with a large VSD, the location of which compromises the support of one of the aortic valve cusps.[31,32] Cardiac arrhythmias, particularly atrial fibrillation, may be associated with VSD when there is cardiac enlargement or failure.

If the systolic murmur is loudest on the left side of the thorax, a subpulmonic VSD or a complex anomaly with pulmonic stenosis (or some form of right ventricular outflow tract obstruction) should be suspected.[31,32,56]

The pulmonic murmur is usually louder than the tricuspid murmur in large animals with tetralogy of Fallot. Large animals with tetralogy of Fallot may have cyanosis at rest (uncommon in horses) or with exercise or exertion. Cyanosis is also a distinguishing feature of Eisenmenger's complex, a defect in which right-sided heart resistance to blood flow causes the shunt associated with VSD to become right to left. Congenital abnormalities of the mitral and tricuspid valves cause a loud systolic murmur audible on both sides of the thorax. The PMI of the left-sided systolic murmur is more caudally located (in the mitral to aortic valve area) than the relative pulmonic stenosis murmur. Usually, the murmur of mitral regurgitation is the loudest of the 2 murmurs. In addition, congenital mitral or tricuspid valve dysplasia is rare in large animals. An innocent flow murmur of neonates can usually be distinguished from VSD by its crescendo-decrescendo shape, PMI at the left heart base, lack of radiation, and low to moderate intensity.

30.4.1.3

Clinical Pathology

Echocardiography is the diagnostic technique of choice for identifying a VSD. With two-dimensional echocardiography the VSD can be imaged directly (Fig. 30-5) and the shunt size, location, and direction demonstrated with pulsed wave Doppler, continuous wave Doppler, color flow echocardiography, or the injection of microbubbles. Careful scanning of the interventricular septum should be performed with two-dimensional echocardiography to directly image the VSD and measure its maximal diameter in two mutually perpendicular planes.[31,32] The typical membranous VSD (≤2.5 cm in both planes) is missed if the long-axis view of the left ventricular outflow tract is not examined. The membranous VSD is located underneath the septal leaflet of the tricuspid valve and the right or noncoronary leaflet of the aortic valve. If a membranous defect is not found, the entire septum should be carefully scanned in all imaging planes to detect the VSD. The subpulmonic location, more common in calves, is easy to miss. This defect is usually best imaged in the short-axis view, scanning the interventricular septum between the left and right ventricular outflow tracts. With a left-to-right shunt a high-velocity turbulent jet is depicted from the right parasternal window, originating in the left ventricle, traversing through the hole in the interventricular septum into the right ventricle with color flow Doppler echocardiography (blood flow toward the transducer), whereas a negative contrast jet is imaged in the right ventricle with a right-sided injection of microbubbles.[31,32] A left ventricular injection of microbubbles is necessary to visualize echo-laden blood in the right ventricle with a typical VSD. M-mode echocardiography may show septal discontinuity when traversing the ventricular septum from the apex of the heart to the aortic root (septal dropout). Moderate to large VSDs show left atrial and left ventricular enlargement, right ventricular enlargement, and pulmonary artery dilation. The left atrial—to—aortic root ratio is increased. Aortic valve prolapse and aortic regurgitation may also be detected because of loss of support of the aortic root from the VSD. Myocardial dysfunction and subsequent CHF may occur with a large VSD. Continuous wave Doppler echocardiography can be used to noninvasively assess the hemodynamic significance of the shunt (see Fig. 30-5, *B*). A peak shunt flow velocity of greater than or equal to 4 m/sec indicates a restrictive VSD with normal or near normal right ventricular pressures. Nuclear angiocardiography can also be used to demonstrate simultaneous opacification of the left and right ventricles. The radiographic presence of cardiomegaly and increased vascularization of the lungs provides only nonspecific evidence of VSD. If polycythemia is found, a complicated VSD should be suspected.

458

459

Fig. 30-5 Two-dimensional echocardiographic image **(A)** and continuous wave Doppler spectral tracing **(B)** of a ventricular septal defect *(arrow)* in a weanling colt. The ventricular septal defect *(VSD)* is located just underneath the septal leaflet of the tricuspid valve and right coronary cusp of the aortic valve. The VSD is best imaged in this left ventricular outflow tract view. There is significant left ventricular enlargement in this colt. The right atrium *(RA)*, right ventricle *(RV)*, left ventricle *(LV)*, left atrium *(LA)*, aortic root *(AR)*, and pulmonary artery *(PA)* are all visible in this view. The spectral tracing shows a peak shunt velocity of slightly under 4 m/sec in systole, with some turbulent flow (spectral broadening) also detected in diastole with a peak flow velocity of approximately 1.3 m/sec.

Cardiac catheterization can be used for qualitative and quantitative assessment of the VSD but has largely been supplanted by echocardiographic diagnosis. Elevated cardiac pressures provide qualitative evidence of a VSD. Right ventricular systolic pressure elevation is most common and may equal left ventricular pressure with a large VSD. Pulmonary artery pressure can be increased as a result of increased blood flow from the left-to-right shunt or increased pulmonary vascular resistance and decreased flow (restrictive pulmonary hypertension). Elevation of left or right ventricular diastolic pressure provides evidence of cardiac failure in the patient with VSD. Oximetric data (oxygen content or oxygen saturation) can be used to locate the shunt and provide some evidence of the size of the defect. A step-up in oxygen content or saturation between the right atrium and the pulmonary artery suggests a moderate or large VSD. Because most VSDs are located high in the right ventricular outflow tract, there may be inadequate mixing of shunted blood in the right ventricle to detect the shunt in this chamber unless the catheter is directed to the outflow tract for sampling. When the oxygen step-up is detected first in the pulmonary artery, a PDA cannot be ruled out. A small shunt may be missed by oximetry as described earlier under oxygen sampling.

Through the use of indicator dilution methods described previously, the shape of the concentration-time or temperature-time curve can be used to demonstrate the left-to-right shunt of a VSD. A comparison of the cardiac output measured in the right ventricle with the cardiac output measured in the pulmonary artery can give an estimation of the percent of pulmonary blood flow coming from shunted blood and therefore an estimation of the size of the defect.[57]

Angiocardiography can be performed in the anesthetized neonate and can definitively demonstrate VSD if there is simultaneous opacification of the left and right ventricles when dye is injected into the left ventricle.

30.4.1.4

Pathophysiology

A small VSD may provide enough resistance to flow that the left-to-right shunt is minimal and the patient remains asymptomatic. Horses can race successfully with small VSDs (≤2.5 cm in diameter with peak shunt velocities ≥4 m/sec), although they are not usually successful as elite racehorses.[32] VSDs produce a left-to-right shunt because the pressure in the left ventricle exceeds the pressure in the right ventricle. A peak shunt velocity of 3 to 4 m/sec indicates an increased right ventricular pressure and a less restrictive VSD; however, the defect is usually compatible with a normal life expectancy. A peak shunt velocity of less than 3 m/sec is indicative of a large shunt that is hemodynamically significant. These animals usually develop CHF by 5 years of age. Occasionally the VSD is so large that the pressure between the two chambers is equalized. The right ventricle, pulmonary circulation, left atrium, and left ventricle must compensate for this volume overload, which generally results in dilation of cardiac chambers and the development of pulmonary hypertension.

Pulmonary vascular resistance can increase because of simultaneous pulmonary disease or left-sided heart failure from chronic volume overload. In addition to volume overload, the right ventricle is subjected to a chronic pressure overload, which may be sufficient to reverse the direction of the shunt (Eisenmenger's complex, more common in cattle than horses). Because of the pressure and volume overload with moderate to large VSDs, patients with this condition run a greater risk of developing CHF.

Considerable turbulence associated with the left-to-right shunts and endocardial damage increase the risk of endocarditis in patients with VSD.[58] Because the VSD usually is located high in the left ventricular outflow tract, structural support of the aortic valve cusps may be lost, and aortic insufficiency may develop.[32] Significant aortic regurgitation adds to the left ventricular volume overload caused by the VSD.

30.4.1.5 Epidemiology

The true incidence of VSD in large animals is unknown, although it is recognized as the most common congenital cardiac defect. In one study, 36 calves had 78 congenital cardiac defects, of which 11 were VSDs.[33]

30.4.1.6 Necropsy Findings

VSD is usually located high in the interventricular septum just ventral to the right or noncoronary cusp of the aortic valve in the left ventricle and underneath the septal leaflet of the tricuspid valve or caudal or ventral to the crista terminalis in the right ventricle. It can be an isolated defect or can be accompanied by other cardiac or organ anomalies. If the defect is moderate or large, there is right ventricular, left atrial, and left ventricular enlargement and pulmonary artery dilation. The lungs may be congested because of increased pulmonary blood flow, and secondary pneumonia is not uncommon. If pulmonary vascular resistance was increased, right ventricular hypertrophy may be present. There may be secondary endocarditis (infrequent in large animals)[58] or endocardial lesions as a result of turbulent blood flow across the defect.

30.4.1.7 Treatment and Prognosis

There is no practical treatment for VSD in large animals. A complete echocardiographic examination is indicated to identify the presence and significance of a VSD. It is important to identify those animals with moderate to large defects, because the prognosis for normal production or function is poor. Horses with large defects (>3.5 cm) and peak shunt velocities through the defect of <3 m/sec should not be broken to ride as they will develop CHF early in life and have a shortened life expectancy. Animals with small defects may remain asymptomatic throughout life. It is important to recognize that small defects, which provide a large resistance to flow, can produce loud murmurs. Because of this, the intensity of the murmur is not a good predictor of the size of the defect.

459

460

Currently there is limited evidence that VSD is inherited in cattle or horses. However, breeding animals with VSD is not advised because of the increased risk of heart failure and other cardiac complications. As a general rule, bull studs do not accept animals with this defect into a breeding program.

30.4.2 Patent Ductus Arteriosus

30.4.2.1 Definition and Etiology

A PDA is the persistent patency of a vessel (normally present in the fetus) that connects the pulmonary arterial system to the aorta. The ductus arteriosus fails to close at birth when breathing begins and placental circulation is removed. Closure of the ductus arteriosus occurs in response to decreasing pulmonary vascular resistance and increased systemic vascular resistance.

A PDA can occur as a single defect (rare in large animals) or with other cardiac anomalies. In large animals the most common other defects reported with PDA are tetralogy and pentalogy of Fallot and pseudotruncus arteriosus.

30.4.2.2

Clinical Signs and Differential Diagnosis

The clinical signs of PDA depend on the length and diameter of the ductus arteriosus, the direction of the shunted blood, and the presence of other cardiac defects. A PDA should be suspected when a continuous, high-pitched murmur, frequently referred to as a “machinery murmur” because of its alternating intensity, is auscultated. The murmur may be heard on the left and right sides of the thorax but is usually loudest in the left third or fourth intercostal space at the level of the shoulder. The intensity of the murmur increases with increased heart rate, exercise, or excitement. The arterial pulses are usually bounding because of the runoff of blood from the systemic to the pulmonary circulation. Occasionally the PDA is manifested by a holosystolic murmur[59] because the diastolic component is barely audible, except at the left heart base. Large PDAs can exist without producing a murmur. In the animal with increased pulmonary vascular resistance and reversal of the shunt, there may be cyanosis of the caudal parts of the body if the PDA enters the aorta caudal to the brachiocephalic trunk. Stunting of growth may also occur.

Other causes of a continuous murmur in large animals are extremely rare; however, the detection of a continuous machinery murmur should lead the veterinary clinician to suspect a complex congenital cardiac defect that includes a PDA, rather than an isolated defect. In older horses an aorticocardiac fistula should be suspected, particularly if the machinery murmur is of recent onset and is loudest on the right side of the chest. A systolic and diastolic murmur can be present in young animals with a large VSD causing aortic insufficiency. A similar murmur is possible with vegetative endocarditis of one of the atrioventricular or semilunar valves, producing insufficiency and stenosis of the affected valve. These latter conditions should not have the machinery murmur characteristic of the PDA. A loud systolic ejection murmur, which is confused with a PDA, frequently can be heard at the left heart base of foals shortly after closure of the PDA. This murmur may persist for 2 to 3 months.[34]

30.4.2.3

Clinical Pathology

No characteristic clinicopathologic changes are associated with a PDA. Radiography may show enlargement of the cardiac silhouette and pulmonary overcirculation in an uncomplicated PDA. Pulmonary venous congestion, interstitial pulmonary edema, and alveolar edema are evidence of a large PDA with left-sided heart failure. These signs are not specific for PDA and can be present with any congenital heart defect that results in a left-to-right shunt. No consistent electrocardiographic pattern has been identified with PDA. Echocardiographic evidence of a PDA is provided by the detection of an enlarged left atrium and left ventricle with a pattern of left ventricular volume overload and increased values for the ratio of the left atrial to aortic root dimension.[31,59–61] Direct visualization of the ductus arteriosus is difficult with echocardiography but is most successful when performed from the left cardiac window. A PDA arising from the pulmonary artery has been imaged echocardiographically in an 11-month-old Friesian-Holstein heifer.[35] High-velocity turbulent flow throughout the cardiac cycle in the pulmonary artery and ductus arteriosus is detected with pulsed wave, continuous wave, or color flow Doppler echocardiography.[60]

Cardiac angiocardiography and nuclear angiocardiography using a selective aortic angiogram provide definitive evidence of a PDA. Oximetric data show a step-up in oxygen content or saturation in the pulmonary artery that is proportional to the size of the shunt. Indicator dilution methods also provide evidence of a left-to-right shunt occurring in the pulmonary artery in cases of an uncomplicated PDA. Pulmonary arterial and right ventricular pressures may be increased with a large PDA.

30.4.2.4 Pathophysiology

Normally the ductus arteriosus narrows near term and constricts rapidly after birth in response to lowered pulmonary vascular resistance, increased systemic vascular resistance, increased blood volume, and increased left ventricular pressure when breathing begins and the placental circulation is removed. If the ductus arteriosus is large or the resistance to flow across the ductus is minimal, there is a significant left-to-right shunt, which produces a large left ventricular volume overload. The left ventricular response may be failure or, with time, dilation (primarily) and hypertrophy. Pulmonary hypertension and congestion result. The right ventricle can be affected by the pulmonary pressure load, and right ventricular hypertrophy can also develop. If the pulmonary resistance equals or exceeds the systemic vascular resistance, a right-to-left shunt occurs.

30.4.2.5 Epidemiology

Normal foals may have a PDA for a few days after birth, but closure of the ductus arteriosus is expected by 96 hours of age.[59] Normal ruminants rarely have a PDA after birth, and if one is present it is considered abnormal. Functional closure may precede anatomic closure of the PDA. This defect is uncommon in older animals. Currently there is no evidence to suggest that this is an inherited defect in horses or cattle.

30.4.2.6 Necropsy Findings

The ductus arteriosus can be of variable length and diameter but is patent between the aorta and the pulmonary artery. The PDA often enters the aorta caudal to the origin of the brachiocephalic trunk. Changes in the left and right ventricles and lung and pulmonary vasculature are variable and depend on the size of the shunt. When the PDA is large, there may be cardiomegaly with left atrial and left ventricular dilation, right ventricular hypertrophy, pulmonary congestion, and edema.

30.4.2.7 Treatment and Prognosis

460

461

There is insufficient evidence on which to base a prognosis for animals with PDA. The condition can be corrected surgically in neonates, but future performance has not been documented. Animals with small defects may remain asymptomatic throughout life. The prognosis is poor if the defect is large, because the risk for left (primarily) and right ventricular failure is increased. Pharmacologic closure of the PDA using inhibitors of prostaglandin synthesis has been successful in humans but is not without risk of complications and recurrence. The efficacy of prostaglandin inhibitors has not been evaluated in large animals.

30.4.3 Tetralogy and Pentalogy of Fallot

30.4.3.1 Definition and Etiology

Tetralogy and pentalogy of Fallot are characterized by biventricular origin (overriding) of the aorta, VSD, right ventricular hypertrophy, and obstruction of pulmonary arterial flow. When there is an associated ASD, the anomaly is referred to as *pentalogy of Fallot*. The defect is caused by abnormal development of the conal septum in the embryonic heart, which leads to narrowing of the right ventricular infundibulum (pulmonic stenosis), an inability of the conal septum to participate in closure of the interventricular foramen (VSD), and

overriding of the aorta. Right ventricular hypertrophy develops as a result of the pulmonary outflow obstruction.

30.4.3.2

Clinical Signs and Differential Diagnosis

Tetralogy of Fallot is one of the more common congenital cardiac defects that cause cyanosis in large animals. Resting cyanosis is rare in horses, although it may be detectable after exercise. Cyanosis of the oral and nasal mucosa, the tongue, the vaginal mucous membranes, and occasionally the nose and skin of light-colored animals is noticed when more than 5 g/dL of hemoglobin are reduced (unoxygenated). Exercise intolerance is often marked and is characterized in most cases by dyspnea or collapse. Frequently the owner complains of slow growth or small size. A loud pansystolic murmur, which is associated with a palpable thrill, is loudest in the left third to fourth intercostal space. The murmur may be a crescendo-decrescendo murmur of pulmonic stenosis or the harsh, plateau-shaped murmur of a VSD; one of these usually predominates. A harsh band-shaped pansystolic murmur is also auscultated in the tricuspid valve area but is usually one or two grades softer than the pulmonic stenosis murmur. Excitement of the animal may result in auscultation of a gallop rhythm or an early systolic ejection click. A continuous machinery murmur can be auscultated in some patients, associated with continuous shunting through the PDA.

Tetralogy and pentalogy of Fallot must be distinguished from other causes of cyanosis in young animals. Respiratory distress syndrome of neonates can be distinguished by the presence of tachypnea, dyspnea, and abnormal lung sounds in the absence of a cardiac murmur. Cyanosis caused by central nervous system disease has other neurologic manifestations. Cyanosis from congenital cardiac disease may be caused by a right-to-left shunt or by heart failure with pulmonary edema. Cyanosis resulting from heart failure or respiratory disease improves with oxygen administration, whereas the patient with a right-to-left cardiac shunt fails to improve. Right-to-left cardiac shunting does or can occur with tetralogy and pentalogy of Fallot, reverse PDA or VSD, tricuspid valve or right ventricular atresia, left ventricular hypoplasia, persistent truncus arteriosus, pseudotruncus arteriosus, and other complex congenital cardiac disease, all of which may occur with cyanosis and a cardiac murmur. A complete echocardiographic examination using a segmental approach to cardiac anatomy is needed to accurately diagnose the correct congenital cardiac malformation and has widely supplanted other methods of diagnosing complex congenital cardiac disease in large animals. Radiography and cardiac catheterization provide supplemental information that may be helpful in distinguishing among the causes of right-to-left cardiac shunting.

30.4.3.3

Clinical Pathology

Increased packed cell volume (PCV), red blood cell count, and hemoglobin concentration (polycythemia) may be present in some animals with tetralogy and pentalogy of Fallot.[37] However, polycythemia is uncommon in foals with cyanotic congenital cardiac disease and is usually less than 45% in most calves. Electrocardiographic changes are usually nonspecific, but a right-axis deviation may be detected.[37] Radiographs of the lungs may show decreased vascularity. The four components of tetralogy of Fallot are easily visualized echocardiographically. The VSD and overriding aorta usually are clearly visible with two-dimensional echocardiography. The malalignment VSD is usually large and located just below the right cusp of the aortic valve, separated from the pulmonic valve by the crista supraventricularis. The aortic root is usually large and overrides the septal defect. Echocardiography shows increased thickness of the right ventricular wall, ventricular septal hypertrophy, paradoxic septal motion, and similar left and right ventricular internal dimensions. Narrowing of the right ventricular outflow tract, pulmonic stenosis, or a hypoplastic pulmonary artery (most common) may be imaged as the cause of the right ventricular outflow tract

obstruction. Pulsed wave and color flow Doppler echocardiography can be used to further characterize the abnormalities of blood flow associated with tetralogy of Fallot, in particular the severity of the right ventricular outflow tract obstruction. Contrast echocardiography also nicely demonstrates the path of blood flow with a peripheral venous injection. Contrast echoes are imaged entering the right ventricle from the right atrium, then simultaneous opacification of the pulmonary artery, left ventricle, and aorta occurs.

Cardiac catheterization can be used to demonstrate equalization of ventricular pressures and a pressure gradient between the right ventricle and pulmonary artery. Oximetry should demonstrate decreased oxygen content in the left ventricle compared with the pulmonary vein. Angiocardiography demonstrates simultaneous filling of the right ventricle, left ventricle, and overriding aorta with decreased pulmonary artery filling and increased right ventricular trabeculation (hypertrophy).

30.4.3.4 Pathophysiology

VSD is usually large, resulting in equalization of pressures in the two ventricles and the aorta. The degree of shunting is controlled by the resistance across the stenotic right ventricular outflow tract compared with the resistance across the aortic valve. If the right ventricular outflow tract is severely obstructed, the clinical signs of cyanosis are more marked. Excitement, drugs, or increased myocardial contractility from any cause decreases right ventricular volume and worsens clinical signs. Right ventricular failure usually is not a consequence of the pressure overload because of equalization of the ventricular pressures.

30.4.3.5 Epidemiology

The prevalence of tetralogy and pentalogy of Fallot in large animals has not been documented, but these defects seem to be more common in calves than in foals. There is no evidence that these disorders are inherited.

30.4.3.6 Necropsy Findings

461

Examination of the heart reveals a rounded apex caused by right ventricular enlargement. A high, usually large 462
VSD, an overriding aorta that straddles the VSD and the left and right ventricle, right ventricular hypertrophy, and septal hypertrophy are present. There is usually right ventricular infundibular narrowing and a hypoplastic pulmonary artery, although there may be valvular pulmonic stenosis with a poststenotic dilation. The right and left atria may be enlarged.

30.4.3.7 Treatment and Prognosis

There is no practical treatment for tetralogy and pentalogy of Fallot in large animals. When cyanosis or exercise intolerance is present or growth is stunted (the latter two are common findings in affected animals), the prognosis for long-term survival, production, or performance is poor. Affected foals should not be used for performance or broken to ride if they live long enough. As with many congenital cardiac diseases, the intensity of the murmur is not a good predictor of the severity of the condition, and further diagnostic tests are indicated.

30.4.4 Other Congenital Cardiac Defects

30.4.4.1 ATRIAL SEPTAL DEFECT

ASD is a connection between the left and right atria at the septal level. The most common type of defect is the ostium secundum defect, of which patent foramen ovale is seen most frequently. Patent foramen ovale is relatively common in calves and is caused by the failure of the septum primum, the valve of the foramen ovale, to become adherent to the crista dividends after birth, when changes in left and right atrial pressures produce functional closure of the foramen ovale. Patent foramen ovale is frequently associated with PDA in calves.[33]

Animals frequently with an ASD are asymptomatic, but a holosystolic, crescendo-decrescendo murmur may be heard at the left heart base. The shunt is usually left to right, and the murmur is the result of increased volume being ejected across the pulmonic valve. If the defect is large, right atrial, right ventricular, and left atrial dilation may be present. Differential diagnostic considerations are a functional murmur, pulmonic stenosis, VSD, or PDA. A definitive diagnosis can be made by two-dimensional echocardiography in which an enlarged right atrium, right ventricle, and left atrium are imaged. Pulsed wave Doppler, color flow, or contrast echocardiography can be used to demonstrate the shunt through the ASD.

30.4.4.2 PULMONIC VALVE STENOSIS

Pulmonic valve stenosis is uncommon as a single defect but has been reported in a foal with VSD and as one of multiple defects in calves and foals.[33,47] Clinical signs of cardiac murmur, cyanosis, and polycythemia are variable and depend largely on the other cardiac defects present. Characterization of the severity of the pulmonic stenosis and other associated cardiac defects can be performed with a complete echocardiographic examination.

30.4.4.3 TRICUSPID VALVE ATRESIA

Tricuspid valve atresia has been reported in foals[38,42–44] in conjunction with other cardiac defects. The abnormalities associated with tricuspid atresia include patent foramen ovale, VSD, small right ventricle, large left ventricle, and large mitral valve orifice. The foals showed cyanosis and a crescendo-decrescendo or band-shaped holosystolic or pansystolic murmur audible over the left and right heart base. Tachycardia, tachypnea, and weak peripheral pulses also were present. Polycythemia was commonly reported. Echocardiographic diagnosis of tricuspid atresia in foals has been reported.[38,43] A thick echo in the region of the tricuspid valve that does not separate in diastole (absent tricuspid valve), an ASD (usually patent foramen ovale), a VSD, a small right ventricle, a large left ventricle, and a large mitral valve orifice are the echocardiographic findings in tricuspid atresia. Blood flow (right to left) through the patent foramen ovale into the left atrium and left ventricle followed by simultaneous opacification of the aorta and right ventricle is detected with contrast echocardiography. Necropsy showed tricuspid atresia, along with ASD, VSD, small right ventricle, and large left ventricle. Pulmonic valve stenosis and dextropositioning of the aorta have also been reported.

30.4.4.4

MITRAL VALVE DYSPLASIA

Mitral valve dysplasia is an early developmental anomaly that has been reported in the horse.[45] The affected foal had a grade 4-5/6 holosystolic decrescendo-type murmur loudest in the mitral to aortic valve area. The mitral valve leaflets appeared thickened, bright, and irregularly nodular echocardiographically. A cleft was imaged in the midportion of the free wall leaflet with small papillary muscles and shortened, unevenly thickened chordae tendineae.[45]

30.4.4.5

VENTRICULAR HYPOPLASIA

Ventricular hypoplasia has been reported in foals and calves.[33,52] The defect may be present with other cardiac defects and is usually associated with early death. The defect was present in three closely related Holstein calves, suggesting possible genetic factors.[33]

30.4.4.6

TRUNCUS OR PSEUDOTRUNCUS ARTERIOSUS

Persistent truncus arteriosus refers to the condition in which one arterial vessel leaves the heart above a VSD. The coronary and pulmonary arteries and aorta arise from this vessel. Persistent truncus arteriosus has been diagnosed in foals and calves.[39] Subclassifications of this condition have been applied to humans, depending on the origin of the pulmonary trunk or arteries. Pseudotruncus arteriosus has also been described in foals and a calf and is characterized by the presence of a remnant of an atretic pulmonary trunk.[38,62] With pseudotruncus arteriosus, the pulmonary blood supply comes from bronchial arteries or a PDA. Clinical manifestations of these conditions include tachycardia, exercise intolerance, and a cardiac murmur. The murmur may be a continuous machinery murmur if a PDA is also present, holosystolic and crescendo-decrescendo and loudest at the left heart base, or the coarse murmur of the VSD may be auscultated, although the relative pulmonic stenosis component is absent. Cyanosis, dyspnea, or syncope may be seen with exercise or excitement. CHF and stunted growth may be noticed. Polycythemia was detected in a calf with a pseudotruncus arteriosus.[62] The presence of cyanosis with the cardiac murmur helps differentiate this condition from a simple VSD or PDA. Definitive diagnosis may be made by echocardiography, angiocardiography, or nuclear angiocardiography.

30.4.4.7

AORTIC ANOMALIES

Dextropositioning or transposition of the aorta are the most common aortic anomalies of foals and calves and are seen most frequently with other defects. Other aortic anomalies of foals and calves are persistence of the right aortic arch and double aortic arch, which may cause esophageal compression. The clinical presentation is one of esophageal obstruction. Interruption of the aortic arch in two foals with VSD, ASD, and PDA has been reported.[49] The foals showed weakness, lethargy, cyanosis, and tachycardia. The murmur was pansystolic and plateau-shaped, with the PMI on the right side of the thorax. Radiology showed cardiomegaly and increased vascularization of the lungs. Cardiac catheterization showed left ventricular failure. Bicuspid and quadricuspid cusps of the aortic and pulmonic valves occur in large animals and usually result in both stenosis and valvular insufficiency. An aneurysm of the sinus of Valsalva was detected in a 3-year-old thoroughbred gelding as an incidental finding.[63] Occasionally a diastolic murmur may be associated with aortic insufficiency in horses with sinus of Valsalva aneurysms.[63,64] These sinus of Valsalva aneurysms usually rupture later in life, and the

horse develops acute distress, colic, and uniform ventricular tachycardia. A continuous machinery murmur is usually present on the right side of the thorax, associated with the presence of an aorticocardiac fistula.

30.4.4.8 EISENMENGER'S COMPLEX

Eisenmenger's complex has been described in a stunted, 24-month-old Holstein heifer that had a loud, crescendo-decrescendo, pansystolic murmur heard best over the pulmonic valve.[41] The heifer had a prominent gallop rhythm from a loud fourth heart sound and exercise intolerance without cyanosis. Polycythemia was present, however. Cardiac catheterization showed increased pressures in the right atria, right ventricle, and pulmonary artery, with normal left-sided pressures. The echocardiogram was characterized by a VSD, overriding aorta, and dilation of the pulmonary trunk, a feature that distinguished this from tetralogy of Fallot. Left ventricular function was decreased, and at necropsy the heart was enlarged and rounded with a dilated pulmonary trunk and small aorta. The right ventricle was dilated and hypertrophied, whereas the left atria and ventricle were only mildly dilated.

30.4.4.9 ECTOPIA CORDIS CERVICALIS

Ectopia cordis cervicalis is a relatively common defect of cattle.[33,48] Although this defect usually results in the heart being in the cervical region, a few animals may have the heart in the pectoral region (14%) or the abdomen (3%).[48] Various defects are associated with ectopia cordis cervicalis, including defects of the heart, great vessels, neck (torticollis), ribs, and sternebrae. The heart is usually contained within the pericardium under the muscles of the skin in the ventral cervical area, with the double apex of the heart pointing craniodorsally. The ligaments of the pericardium are most frequently attached to the mandibles and the parotid fascia cranially, the cervical fascia laterally, and the first rib or manubrium caudally. The lung may lack the cardiac notch and often protrudes to the base of the heart. Although the prognosis for a productive life is poor, some calves lived until approximately 1 year of age.

30.4.4.10 MISCELLANEOUS CARDIAC DEFECTS

Other cardiac defects can occur, but the significance of the lesion is questioned or the defect has been recorded infrequently. Complete atrioventricular canal defect has been reported in a foal.[51] Anomalous coronary artery development has been reported at postmortem examination, but the lesion was not necessarily the cause of death in a calf.[65] Anomalous origin of the coronary artery has been thought to be the cause of death in horses.[66] Congenital hematomas of the atrioventricular valves also have been noted, but the significance is unknown.[33] Endocardial fibroelastosis, an anomalous development of the endocardium associated with left ventricular hypertrophy, is usually a severe defect resulting in death of the animal. The frequency of this defect in large animals is not established.

30.4.4.11 VALVULAR HEART DISEASE

30.4.4.11.1 Definition and Etiology

In adult animals, disorders of the tricuspid, pulmonic, mitral, or aortic valves are usually acquired and most commonly result in insufficiency of the affected valve. These disorders may be the result of degenerative changes, infection (bacterial or viral endocarditis or myocarditis), inflammation (valvulitis), trauma, or

unknown causes (cardiomyopathy). They are usually manifested by a cardiac murmur, most frequently of valvular regurgitation, with the PMI at the location of the affected valve or in the direction of the regurgitant blood flow. The mitral and aortic valves are the most common location of degenerative valve disease in horses.[67] Predisposing causes such as microembolism or infarction have not been identified in large animals. Chronic active infection such as foot abscesses, rumenitis, reticular abscess, or other septic process may lead to sustained or recurrent bacteremia, predisposing the animal to the development of bacterial endocarditis, particularly in cattle, or a nonvegetative valvulitis, probably more common in horses. Experimentally, valvular vegetative endocarditis can be induced by intravenous administration of bacteria without preliminary damage to a valve.[68] Rupture of a valve leaflet or chordae tendineae can cause valvular heart disease, as can dilation of a cardiac chamber from any cause or rupture of the aortic root or of a sinus of Valsalva aneurysm.[69–71] In rare cases neoplasia, primarily lymphosarcoma of cattle, can cause valvular heart disease. Congenital valvular heart disease in adult animals is rare. The most common bacterial isolates from equine and bovine endocarditis cases are streptococci and *Pasturella* or *Actinobacillus* species and *Arcanobacterium (Actinomyces) pyogenes* in horses and cattle, respectively, although a wide variety of organisms has been isolated from large animals with endocarditis.[72,73,75–79]

30.4.4.11.2

Clinical Signs and Differential Diagnosis

Most animals with valvular heart disease have no clinical signs but have a cardiac murmur that is detected during a routine examination. The clinical signs vary depending on the severity of the lesion and its rate of development. Murmurs of valvular heart disease are frequently holosystolic (Fig. 30-6), pansystolic, or holodiastolic (Fig. 30-7). They radiate from the PMI in the direction of the abnormal blood flow; are coarse and band-shaped, crescendo or honking (if systolic), or decrescendo and blowing or musical (if diastolic); and are usually moderate to loud in intensity (≥grade 3/6) but may be softer if holodiastolic. All of these characteristics help distinguish these murmurs from functional or innocent murmurs, which generally occur early or late in systole or diastole but can be holosystolic; are soft and blowing or crescendo-decrescendo in quality; are localized to a small area; do not radiate; and are soft to moderate in intensity (≤3/6). The intensity of the murmur is not a reliable indicator of the severity of the lesion, except in horses with tricuspid regurgitation, in which the longer, louder murmurs are associated with a larger jet of tricuspid regurgitation.[80] In cattle, in particular, severely involved valves (usually in cattle with endocarditis) commonly have faint or no audible murmurs.

Fig. 30-6 Phonocardiogram obtained from a horse with a ruptured mitral valve chorda tendineae. A loud, plateau-shaped holosystolic murmur *(SM)*, which is variable in intensity, occurs when the free wall leaflet of the mitral valve is prolapsing into the left atrium.

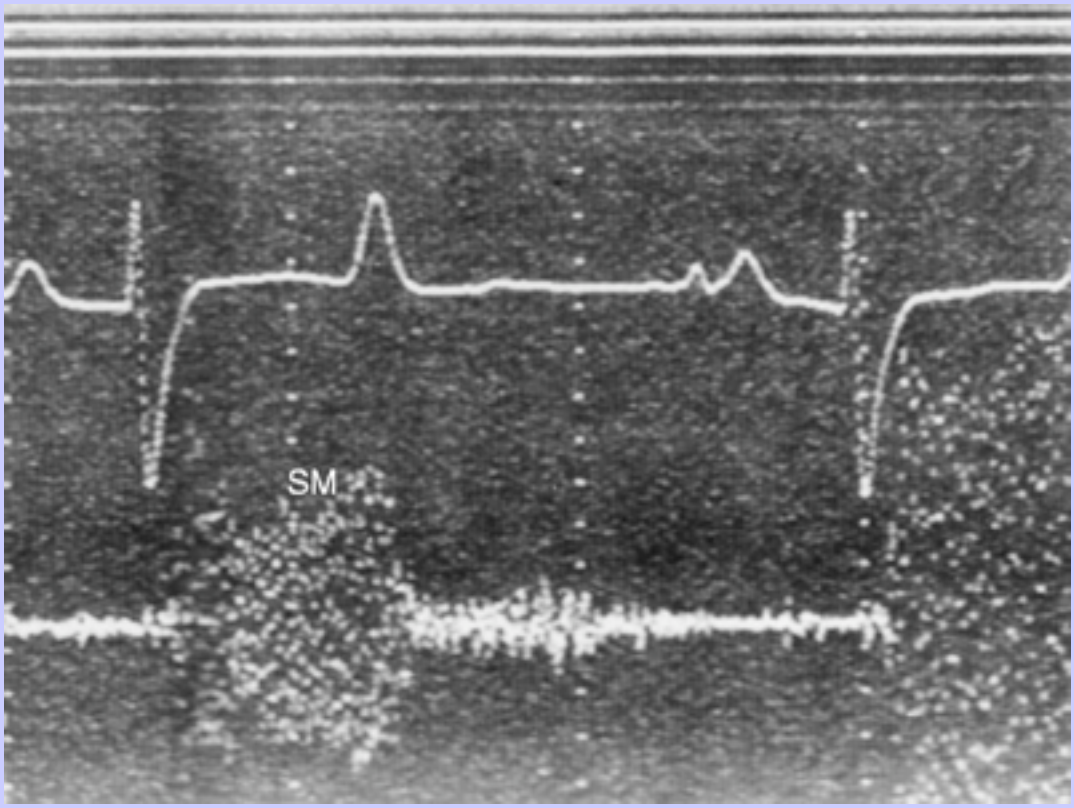

Fig. 30-7 Phonocardiogram and M-mode echocardiogram obtained from a horse with a holodiastolic murmur *(DM)* caused by aortic valve regurgitation. The M-mode echocardiogram shows diastolic flutter *(arrows)* of the septal mitral valve leaflet, characteristic of aortic valve insufficiency.

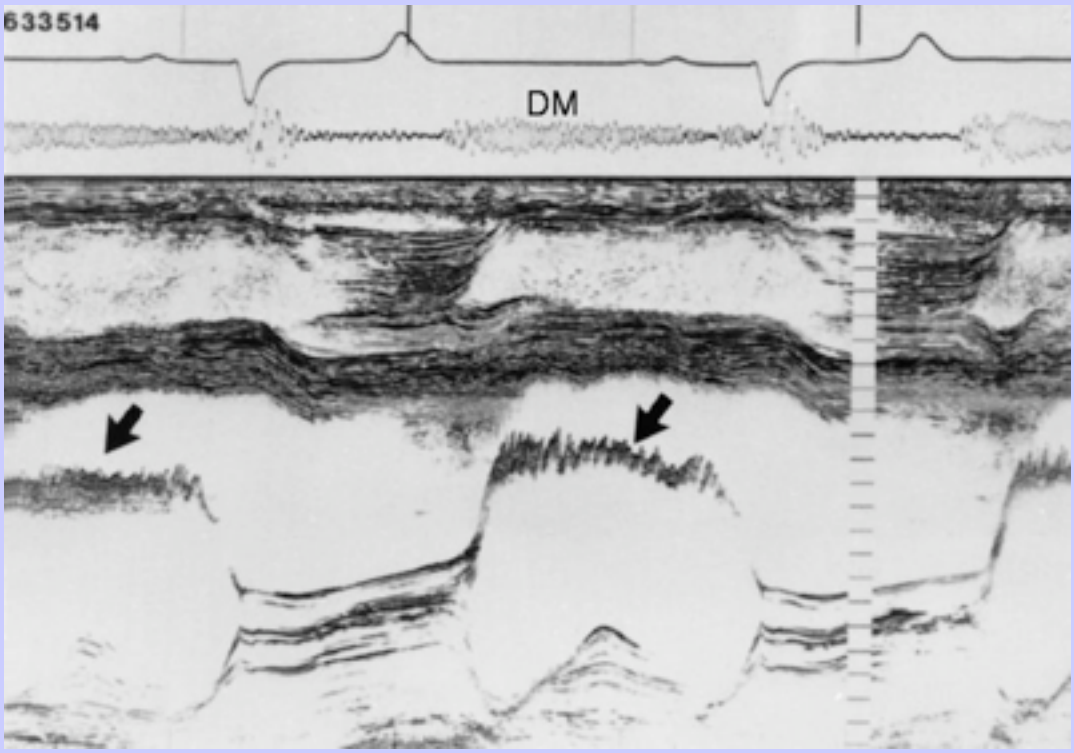

The location of the PMI of the murmur is helpful in distinguishing which valve is involved, although more than one valve can be affected in the same animal. The PMI for lesions of the mitral valve frequently is at the left apex of the heart, although murmurs of mitral regurgitation usually radiate dorsally and toward the left heart base and aortic valve area. Therefore loud systolic murmurs with the PMI in the aortic or mitral valve area in horses are usually mitral regurgitation murmurs. Disorders of the tricuspid valve commonly have the PMI on the right side of the thorax (third to fourth intercostal spaces [horses] or second to third intercostal spaces [cattle]). Infrequently, the murmur may also be heard on the left side of the thorax cranial to the pulmonic valve location in the second intercostal space. Aortic and pulmonic valve lesions produce murmurs with the PMI at the left heart base in the third or fourth intercostal space. Acquired valvular lesions of the mitral and tricuspid valves produce primarily systolic murmurs.[72,73,75,80–84] Diastolic tricuspid flow murmurs have been reported, however, and may be associated with right-sided mural or valvular masses in horses[85] or may be physiologic, associated with normal blood flow across the atrioventricular valves.[86,87] Lesions of the aortic and pulmonic valves may produce diastolic murmurs, systolic murmurs, or both.[72,88–90] However, diastolic murmurs of regurgitation are most common in large animals. Aortic regurgitation associated with degenerative valve disease is most common in horses, whereas

pulmonic regurgitation associated with bacterial endocarditis is more common in cattle. Aortic valve lesions in horses have primarily holodiastolic, decrescendo, musical murmurs (see Fig. 30-7) but can also be decrescendo, soft, and blowing. Aortic regurgitation murmurs are accompanied by a water-hammer or bounding arterial pulse if the aortic regurgitation is associated with a significant left ventricular volume overload.[72,91] The musical quality of the murmur (harmonic) indicates that some part of the aortic valve is vibrating during diastole. The arterial pulse quality becomes more bounding as the aortic regurgitation becomes more severe, and is a good clinical indicator of the degree of left ventricular volume overload. Ventricular premature beats and atrial fibrillation may also be detected in horses with significant aortic regurgitation.

Besides the cardiac murmur, animals with valvular heart disease may have exercise intolerance, weight loss, or signs of CHF evidenced by tachycardia, coughing, respiratory distress, jugular venous distention, subcutaneous edema, and ascites (uncommon in large animals). In adult cattle, mammary vein distention is another sign of CHF.[73] Cardiac enlargement may be noted as an increased area of auscultation and/or percussion or caudal dislocation of the apical impulse of the heart. Atrial fibrillation may be present. This development is usually an indicator of atrial enlargement in animals with valvular heart disease. If tricuspid valve regurgitation is present, there may be abnormal systolic jugular venous pulsations. If mitral regurgitation is present there may be tachycardia, tachypnea, poor recovery to resting respiratory rate after exercise, coughing, and frothy pulmonary edema. Lung sounds may be harsh at rest and on deep inspiration may include rare crackles or moist bubbly sounds. Most horses with pulmonary edema have only harsh breath sounds that are detected at rest and on deep inspiration.

One of the clinical signs of bacterial endocarditis is a cardiac murmur, the PMI and timing of which depend on the valve or valves affected. Other signs may include tachycardia, arrhythmias, auscultation of prominent heart sounds, tachypnea, coughing, recurring fever, anorexia, weight loss, or signs of CHF. Evidence of disseminated sepsis such as pneumonia, hematuria, or pyuria is usually present. Shifting leg lameness and swollen joints or tendon sheaths are common but usually have an immune-mediated cause, although a horse with bacterial endocarditis and septic tenosynovitis has been reported.[76] Mastitis and decreased milk production are common in cattle. The presence of weight loss, fever, and signs of recurring sepsis help distinguish bacterial endocarditis from other forms of acquired valvular disease.

The clinical signs of a major mitral valve chordal rupture (major chorda tendineae) or its characteristic murmur distinguish this disease from other mitral valve diseases. The murmur is usually a widely radiating murmur of mitral valve regurgitation (see Fig. 30-6) with a distinctive honking quality (again the honking quality is consistent with vibration of the mitral valve chorda tendineae or leaflet with blood flow in systole). However, the honking quality may be absent and replaced by a band-shaped pansystolic murmur. There may be evidence of acute hemodynamic collapse. Acute onset of respiratory distress with coughing and expectorating foamy pulmonary edema fluid (this fluid is also detected at the external nares) is a relatively consistent feature with rupture of a major chorda tendineae. Signs of right-sided heart failure (jugular venous distention, subcutaneous edema, and ascites) may develop rapidly. Atrial arrhythmias, most frequently atrial fibrillation, often develop secondary to atrial enlargement. Supraventricular arrhythmias have also been reported in foals with a ruptured mitral chorda tendineae.[83] The acute onset of respiratory distress, along with a honking systolic murmur, distinguishes mitral valve chordal rupture from other causes of mitral regurgitation. The honking systolic murmur of a ruptured mitral valve chorda tendineae can also be heard in the absence of any clinical signs in horses with a minor chordal rupture. The murmur of mitral valve prolapse is also a distinctive murmur and should be suspected in horses whenever a mid- to late-crescendo systolic murmur is auscultated with the PMI over the mitral valve area.[92] A similar murmur is

frequently auscultated in horses with tricuspid valve prolapse. Murmurs of mitral or tricuspid valve prolapse can be detected in horses with all degrees of valvular insufficiency. Most frequently, however, only small amounts of valvular regurgitation are associated with valvular prolapse. An increased prevalence of mitral and tricuspid regurgitation has been reported in young horses in training.[93]

30.4.4.11.3

Clinical Pathology

464

465

Diagnosis of valvular disease is best performed with a complete echocardiographic examination including M-mode, two-dimensional, and Doppler echocardiography. Two-dimensional echocardiography is superior to M-mode for detection of valvular abnormalities (Figs. 30-8 and 30-9), measurement of valvular masses (Fig. 30-9, *B*), and the global assessment of ventricular function, but chamber enlargement, high-frequency vibrations of the valve leaflets, and shortening fraction (an indication of ventricular systolic function) can be determined by both. Pulsed wave, continuous wave, and color flow Doppler echocardiography can be used to semiquantitate the severity of valvular regurgitation.[92–97] The size of the regurgitant jet detected with pulsed wave or color flow echocardiography is one indicator of the severity of the valvular insufficiency.[98] The duration of the mitral regurgitation jet is also important in assessing severity. Clinically insignificant jets of regurgitation are detected only just behind the valve when it is closed. Valvular insufficiency is mild when the jet occupies one third or less of the receiving chamber, moderate when the jet occupies greater than one third but less than two thirds of the receiving chamber, and severe when the jet occupies greater than two thirds of the receiving chamber.

Fig. 30-8 Two-dimensional echocardiographic image obtained from the left parasternal window of a ruptured mitral chorda tendineae *(arrow)* in the left atrium of a gelding with mitral regurgitation and a honking pansystolic murmur.

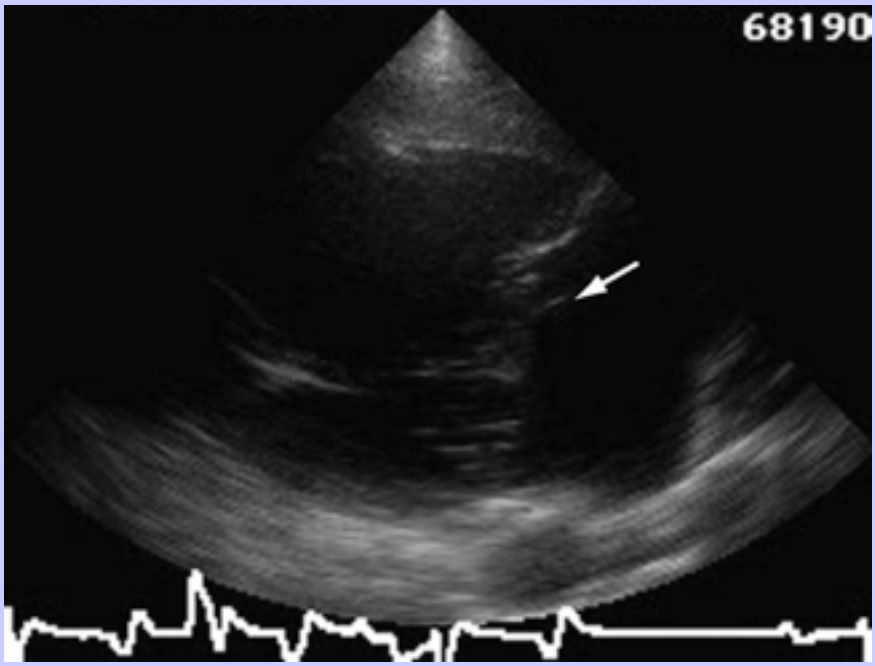

Fig. 30-9 Echocardiograms of a bacterial endocarditis lesion on the aortic valve of a horse. The lesion can be seen on the aortic valve M-mode **(A)** as a thick echoic band *(arrow)* and is measured in the two-dimensional echocardiographic image of the left parasternal long axis view **(B)**.

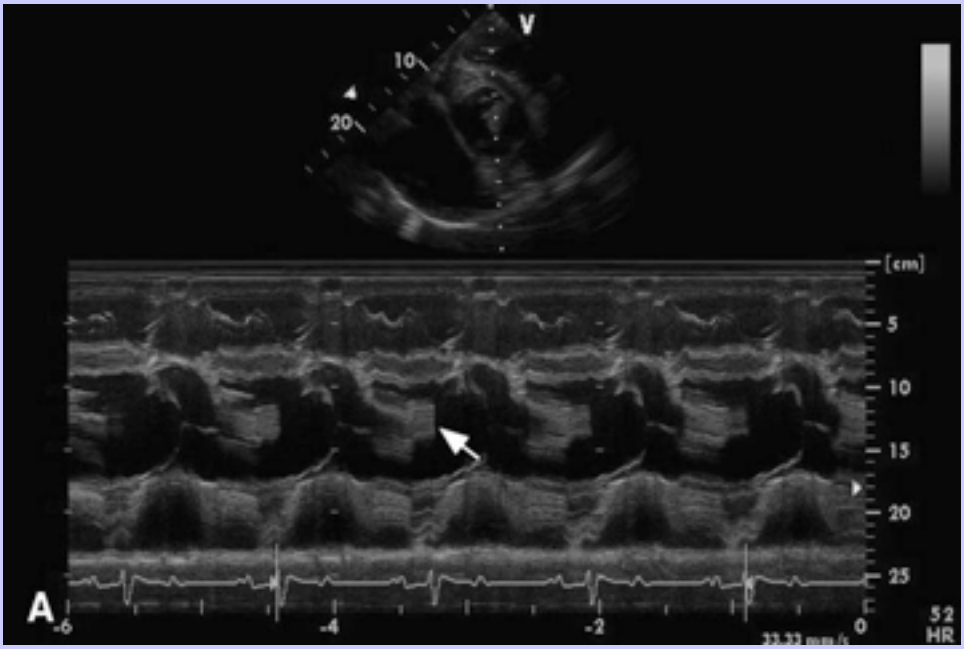
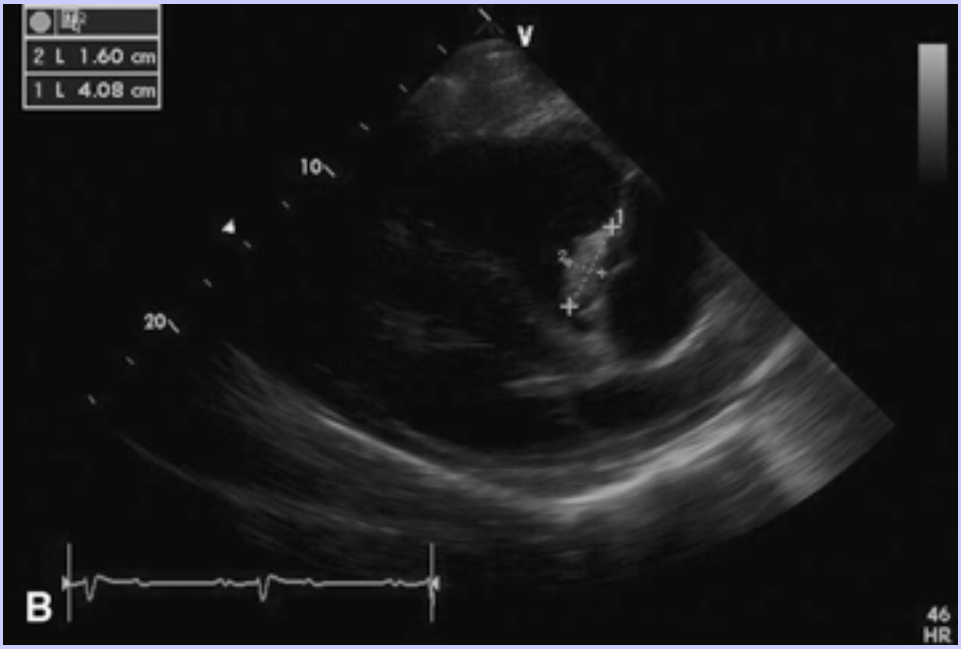


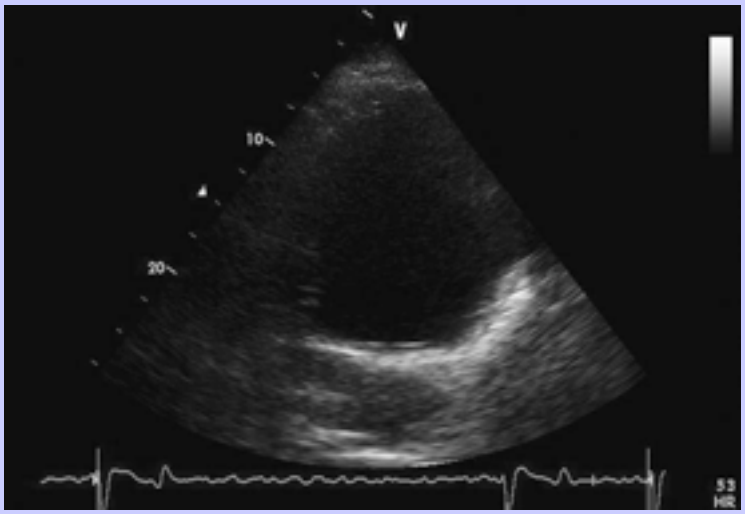


Echocardiographic signs of mitral regurgitation are increased left atrial (Fig. 30-10; see also Fig. 30-3) and left ventricular dimensions and a left-sided volume overload. The cause of the valvular regurgitation can often be determined. Endocarditis (see Fig. 30-9), ruptured mitral valve chordae tendineae (see Fig. 30-8), a flail valve leaflet, valvular prolapse, or thickening of the valve leaflet are readily imaged echocardiographically.[99] The regurgitant jet detected with pulsed wave or color flow Doppler echocardiography usually originates from the site of the valvular abnormalities detected with two-dimensional echocardiography. In some animals, the lesion responsible for the valvular insufficiency is not visualized with two-dimensional echocardiography but the regurgitant orifice is detected with pulsed wave or color flow Doppler echocardiography.[95–97,100] Left ventricular function may be normal (if the mitral regurgitation is mild) or the FS may be increased (if there is a significant left ventricular volume overload associated with moderate to severe mitral regurgitation), unless there is concomitant myocardial disease. A ruptured mitral valve chorda is diagnosed by finding a mobile linear echo everting into the left atrium or a flail leaflet that may prolapse into the left atrium during systole (see Fig. 30-8), systolic and chaotic diastolic mitral valve flutter, rapid mitral valve opening with increased excursion of the affected leaflet, and lack of coaptation of the mitral valve in systole. The asynchronous movement of any portion of the valve leaflet during any phase of the cardiac cycle indicates the presence of a flail valve leaflet.[81,99] A larger than normal pulmonary artery (larger than the aortic root) is compatible with severe pulmonary hypertension and left-sided heart failure. A smaller than normal aortic root is detected echocardiographically in horses in low-output left-sided heart failure.[83,98,99]

Tricuspid regurgitation may produce echocardiographic evidence of right atrial and right ventricular enlargement with paradoxic septal motion. Frequently the cause of tricuspid valve regurgitation in cattle is bacterial endocarditis, and the incompetent valve can be visualized. In cattle, neoplasia of the right atrium, tricuspid valve, or right ventricle can usually be visualized when present.[101] Tricuspid regurgitation is common in horses with no obvious valvular lesion.[87,93,102]

465
466

Fig. 30-10 Left parasternal echocardiographic image of the left atrium and mitral valve from a horse with left atrial enlargement (15.55 cm).



Aortic valve regurgitation is diagnosed echocardiographically by observing left ventricular dilation, increased aortic root diameter (Fig. 30-11), increased left ventricular FS (if the aortic regurgitation is moderate to severe and left ventricular function is normal), diastolic fluttering of the septal mitral valve leaflet (Fig. 30-12; see also Fig. 30-7), or, less frequently, by observing high-frequency vibrations of the interventricular septum or aortic valve in diastole.[89,91,96,98] Rarely, premature closure of the mitral valve is detected. Thickening of the left cusp of the aortic valve is frequently detected echocardiographically, but prolapse, fenestration, and tears of the aortic cusps also occur.

Acquired pulmonic valve lesions are uncommon in large animals and when present are usually associated with bacterial endocarditis.[83,90,103] Diagnosis is established by finding the mass associated with the pulmonic valve. Severe pulmonic regurgitation associated with pulmonic valve rupture has been reported in one horse.[104] Pulmonic regurgitation is most common in horses with pulmonary hypertension and CHF but is rarely detected clinically.

Fig. 30-11 Two-dimensional echocardiographic image of an enlarged aortic root (9.57 cm) obtained from an aged gelding with moderate aortic regurgitation that has been present for several years.

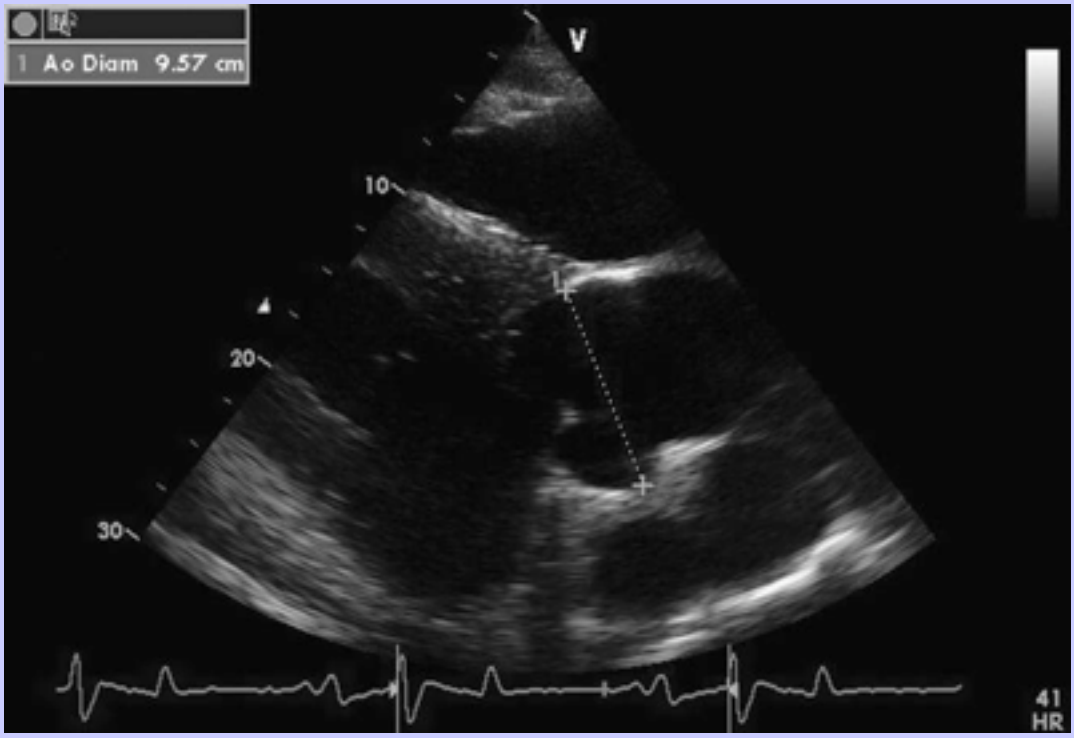


Fig. 30-12 M-mode echocardiogram obtained from a stallion with moderate chronic aortic regurgitation. Notice the high-frequency vibrations *(arrow)* on the septal leaflet of the mitral valve.

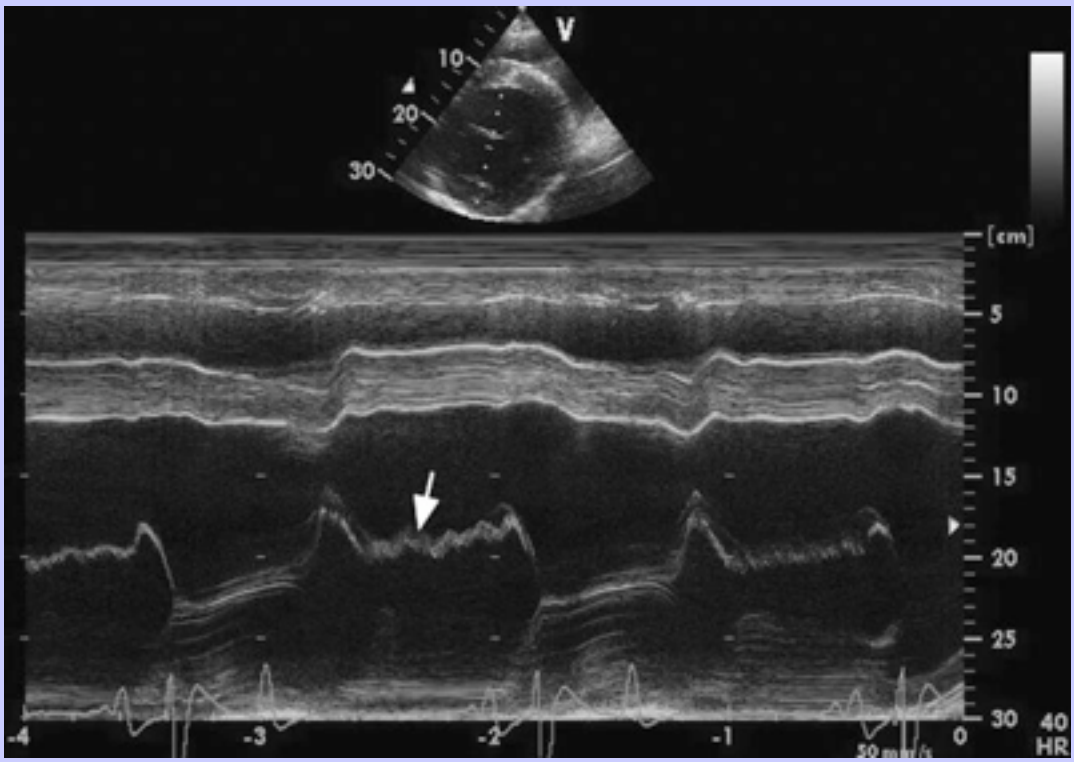

Lesions of bacterial endocarditis (see Fig. 30-9) may have a shaggy, ragged, or cystic appearance on two-dimensional echocardiography.* Occasionally the only abnormality noticed is valve thickening with ventricular hyperkinesis and enlargement of the chambers on the side of the affected valve. Acoustic reverberation and production of microbubbles have also been associated with valvular bacterial endocarditis.[83,86] Other laboratory evidence of bacterial endocarditis includes anemia, neutrophilia (a left shift may be present), an increased serum globulin concentration, and hyperfibrinogenemia. Liver enzymes are frequently mildly elevated, and a urinalysis sometimes shows hematuria or pyuria. Positive blood cultures taken during febrile episodes confirm the diagnosis when associated with the above findings. However, many times the culture results are negative in large animals with bacterial endocarditis. Other laboratory evidence of disseminated sepsis includes neutrophilic response in peritoneal, tracheal wash, or joint fluid. Ventricular arrhythmias are frequently detected electrocardiographically in individuals with mitral or aortic valve endocarditis. Radiographic or sonographic evidence of disseminated pneumonia also may be found with bacterial endocarditis, usually in large animals with a right-sided lesion.

Other laboratory evidence of valvular heart disease is nonspecific. The ECG is not reliable for detecting chamber enlargement associated with valvular incompetence. The ECG is valuable for documentation of cardiac arrhythmias occurring secondary to chamber enlargement or the underlying myocardial disease.

Radiographic findings of cardiac enlargement, increased pulmonary vascular pattern, or pulmonary edema are also nonspecific. Cardiac catheterization can be performed, and pressure measurements help determine the degree of cardiac dysfunction. Nuclear angiocardiography shows cardiac enlargement or prolonged washout of contrast material. Time-activity curves can be helpful in accurately documenting ventricular dysfunction and the valvular regurgitant fraction.[106]

30.4.4.11.4

Pathophysiology

Acquired valvular heart disease that is slow in onset or gradually progressive may be asymptomatic at first, but cardiac changes occur that eventually may lead to CHF. Valvular incompetence from endocarditis, degenerative changes, chordal rupture, or other causes results in volume overload of the recipient chamber. Initially the output of the chamber is increased to maintain forward output, but the increased end-diastolic volume of the recipient chamber leads to compensatory dilation and a mild elevation in end-diastolic pressure. Compensatory hypertrophy may also result. In the later stages of valvular regurgitation, contractile function of the volume-overloaded chamber may diminish, leading to further elevation of end-diastolic pressure and decreased compliance. In the case of severe aortic and mitral regurgitation, this causes elevation of left atrial pressure and eventually pulmonary venous hypertension. Pulmonary artery wedge pressure is higher at rest and during exercise in horses with moderate mitral regurgitation.[107] With severe tricuspid regurgitation, right atrial or central venous pressure increases. Increased myocardial oxygen consumption is a natural sequela, and biventricular failure can ensue.

If valvular heart disease is acute in onset, as with major chordal rupture of the mitral valve, the regurgitation and volume overload are imposed on the left atrium, which cannot dilate and adapt acutely to the increased diastolic filling. The sudden hemodynamic change leads to pulmonary venous hypertension and acute pulmonary edema. However, most horses with mitral regurgitation do not have acute fulminant pulmonary edema. Instead, chronic pulmonary hypertension leading to subtle respiratory signs associated with interstitial pulmonary edema and the subsequent development of right-sided CHF are common in horses with severe mitral regurgitation.[99] In one study 12 of 14 horses with CHF had jugular distentions or pulsations, 10 had abnormal lung sounds (crackles), and nine had a cough.[108]

466

467

Bacterial endocarditis of the mitral or tricuspid valve may lead to rupture of the chordae tendineae. Mitral chordal rupture has been reported in adult horses and foals with bacterial endocarditis, leading to acute left-sided CHF.[83] In addition to the hemodynamic load placed on the heart from an incompetent valve, bacterial endocarditis also results in disseminated sepsis. The vegetations are made up of layers of fibrin, blood cells, necrotic tissue, and bacteria and are relatively resistant to short-term antimicrobial therapy. The disseminated sepsis may be the cause of death or the reason for culling of the animal. Myocardial necrosis of a papillary muscle was associated with mitral chordal rupture in one foal.[83]

30.4.4.11.5

Epidemiology

Acquired valvular heart disease is common in large animals, involving 356 of 1557 horses (22.9%) in one abattoir survey.[67] Endocarditis, one form of valvular heart disease, was reported in 4% of cattle in another study.[109] Bacterial endocarditis most commonly affects the tricuspid valve in cattle but has been reported on the pulmonic, mitral, and aortic valves as well.[73,89,90,101] Most cases of tricuspid valve bacterial

endocarditis have been reported in horses with septic jugular vein thrombophlebitis.[72,75,110] Tricuspid valve endocarditis has also been reported in a horse with a VSD.[85] Aortic and mitral valve endocarditis are most common in horses, occurring with nearly equal frequency.[74,75] In the largest survey of acquired valvular heart disease in horses, the aortic valve was affected most commonly with degenerative valve changes, followed by the mitral valve, tricuspid valve, and, uncommonly, the pulmonic valve.[67] Not all valvular lesions are associated with incompetency of the valve. Degenerative valvular changes, particularly changes involving the aortic valve, are seen more commonly in older horses.

30.4.4.11.6

Necropsy Findings

Acquired valvular disease is associated with finding nodular thickening, fibrous bands, valve fenestrations, rupture of mitral valve chordae tendineae, fibrinous masses typical of endocarditis, and combinations of these lesions on postmortem examination. There may be associated or secondary changes varying from enlargement of a chamber or vessel to hematomas, degeneration, inflammation, and fibrosis. Enlargement (primarily dilation) of the chamber receiving the regurgitant flow, in addition to enlargement (primarily dilation) of the chamber or vessel from which the regurgitant flow arises, is commonly detected. Jet lesions, usually found in the receiving chamber, are associated with the high-velocity turbulent regurgitant blood flow.

Subcutaneous edema; increased pericardial, pleural, or peritoneal fluid; and congestion and mottling of the liver may be present and indicate CHF. Ascites associated with CHF is uncommon in large animals, particularly in horses. A primary source of chronic or active infection, along with evidence of bacterial embolization, may be seen in cattle with endocarditis but is rare in horses.

30.4.4.11.7

Treatment and Prognosis

The treatment and prognosis of acquired valvular heart disease depend on the cause, onset, duration, and severity of the lesion. In general, the prognosis is guarded to poor when evidence of valvular incompetence includes tachycardia, exercise intolerance, signs of CHF, or echocardiographic evidence of severe chamber enlargement. Degenerative valve disease may be asymptomatic except for a cardiac murmur, or it may be mild; but it generally is slowly progressive and therefore historically has been given a guarded prognosis. A more accurate prognosis for horses with murmurs can now be obtained from a complete echocardiographic examination, including Doppler echocardiography. The valve affected, the lesions detected on the valve leaflets, the degree of chamber enlargement and volume overload detected, the echocardiographic assessment of myocardial function, and the severity of the regurgitation determined with Doppler echocardiography, coupled with the animal's age and intended use, can be used to formulate a prognosis.[96,98] Valvular regurgitation associated with no detectable abnormalities, valvular prolapse, and mild valvular thickening usually has a fair to good prognosis if the amount of valvular regurgitation is small. Individuals with ruptured chordae tendineae, flail valve leaflets, and marked valvular thickening usually have moderate to severe regurgitation, which is likely to progress more rapidly and usually warrants a guarded to poor prognosis. Mitral regurgitation is the most likely valvular insufficiency to be associated with clinical signs of cardiovascular disease, whereas primary aortic regurgitation and tricuspid regurgitation infrequently result in the development of CHF or the death of the animal, except in horses with severe aortic regurgitation. Bacterial endocarditis has a guarded to grave prognosis, even with long-term antibiotic therapy, and frequently results in sudden death of the animal, although bacteriologic cures have been reported.

Despite the guarded long-term prognosis, palliative therapy can be applied for most forms of acquired valvular heart disease. Bacterial endocarditis is treated with long-term administration, ideally intravenously (IV), of bacteriocidal antimicrobials, the choice of which is based on blood culture and sensitivity results. Continuous intravenous infusion of antimicrobials is the ideal initial treatment, when feasible. In cattle and horses, initial therapy is directed at the likelihood of a gram-positive infection. Combination antibiotic therapy consisting of a penicillin and an aminoglycoside can be used for gram-negative organisms. Using rifampin at a dose of 5 mg/kg twice daily orally (PO) in combination with another antibiotic with appropriate spectrum has improved the short-term outlook for large animals with bacterial endocarditis. Aspirin (100 mg/kg/day, ruminants; 17 mg/kg every other day, horses) and low-dose heparin (30 U/kg subcutaneously [SC] twice daily, ruminants and horses) may be used in patients with valvular endocarditis in an attempt to prevent platelet adhesion and increased size of the valvular mass. Early diagnosis and aggressive treatment with the appropriate antimicrobials for a prolonged period are important for successful treatment of bacterial endocarditis. The long-term outcome for successfully treated cases is still poor because the scarring that results as the endocarditis lesion heals may lead to severe valvular regurgitation and the death of the animal, particularly with left-sided bacterial endocarditis lesions.[75,76,78,98,111] Compliance and economics are also major drawbacks in treating endocarditis.

The hemodynamic consequences of valvular heart disease (volume overload or CHF) may be improved by using diuretics. Furosemide has been used most commonly at a dose of 0.5 to 1 mg/kg as needed. With the low bioavailability of oral furosemide, intravenous administration is preferred to obtain the maximal diuretic effect.[112] Digoxin can be used to improve contractility when CHF has occurred. Conditions such as aortic valve or mitral valve regurgitation may show little or no long-term improvement, although many individuals improve for 2 to 6 months before the CHF becomes refractory to treatment. The administration of a maintenance dose of digoxin at 2.2 µg/kg IV twice daily or 11 µg/kg PO twice daily has resulted in therapeutic plasma digoxin concentrations and clinical improvement in horses with CHF with no significant adverse effects.[113] Loading doses are rarely used, because of problems with digoxin toxicity.[114] An intravenous loading dose of 12 to 14 µg/kg can be used in horses but must be divided into three administrations, followed by a maintenance dose of 6 to 7 µg/kg daily.[115] Digoxin can also be administered PO to horses at a dose of 34 to 70 µg/kg for loading and 17 to 35 µg/kg for maintenance.[115] Digoxin is administered IV to cattle at a loading dose of 22 µg/kg followed by a maintenance dosage of 11 µg/kg three times daily or, preferably, at an infusion rate of 0.86 µg/kg/hr.[116] The clinical impression is that horses, as do other species, benefit from the use of vasodilators. Clinical and echocardiographic improvement has been seen in several horses with moderate mitral or aortic regurgitation treated with angiotensin-converting enzyme (ACE) inhibitors. Quinapril at 120 mg/horse/day resulted in an increase in stroke volume and cardiac output that was statistically significant after 8 weeks of treatment in horses with mitral regurgitation.[117] Clinical and echocardiographic improvement has been seen in horses with CHF. Clinical improvement has been seen with hydralazine at 0.05 to 1.5 mg/kg PO twice daily. The ACE inhibitor enalapril has also appeared to be effective in horses with moderate to severe mitral or aortic regurgitation and in horses with CHF, at a dose of 0.5 mg/kg PO twice daily. Ramipril was beneficial in the treatment of one horse with CHF at 50 µg/kg daily PO.[118] Until recently the expense of these drugs limited the usefulness of enalapril and the other ACE inhibitors. However, a generic form of enalapril maleate is now available, making this treatment more affordable for most owners. Although the short-term outlook may be improved with use of cardiovascular drugs, the prognosis is guarded for long-term survival or production.

30.4.4.11.8 Prevention and Control

Many causes of acquired valvular heart disease cannot be controlled. Appropriate therapy for chronic active infections and careful attention to asepsis with intravenous medication and other invasive procedures may help prevent endocarditis and, possibly, nonvegetative valvulitis. Effective parasite control measures may eliminate some predisposing causes of valvular heart disease such as trauma to heart valves, microembolism, or infarction in horses.

30.4.5 BRISKET DISEASE: COR PULMONALE AND PULMONARY HYPERTENSION

30.4.5.1 Definition and Etiology

Cor pulmonale is a term used to refer to the effect of lung dysfunction on the heart and is therefore a secondary form of heart disease. Regardless of the cause, the underlying feature is pulmonary hypertension that leads to right ventricular hypertrophy, dilation, or failure. The primary cause of the disease (also called *high-mountain disease* or *high-altitude disease* in cattle) is hypoxic vasoconstriction from high-altitude dwelling. The disease is worsened by the ingestion of locoweed (*Oxytropis* and *Astragalus* species).[119,120] Chronic pulmonary disease such as bronchopneumonia or lungworm infection in cattle also can result in cor pulmonale.[121] In the horse, right-sided heart dysfunction (e.g., decreased cardiac output, increased right ventricular end-diastolic pressure, increased right atrial or central venous pressure, jugular venous distention, or subcutaneous edema) associated with chronic pulmonary disease is rare but may be more common than previously recognized. However, right-sided heart dysfunction associated with pulmonary hypertension and left-sided heart dysfunction is a common cause of CHF.

30.4.5.2 Clinical Signs and Differential Diagnosis

Frequently the primary presenting clinical sign of brisket disease is subcutaneous edema of the brisket, the ventral thorax, the submandibular area, and occasionally the limbs. Jugular venous distention or pulsations may be present. Dyspnea and tachypnea frequently are exhibited. Tachycardia is present, and a gallop rhythm may be auscultated. Splitting of the second heart sound (S_2) is a variable finding. Pulmonary hypertension may accentuate the separation of the aortic and pulmonic valve closures, producing audible splitting of S_2 that is most noticeable during inspiration. In some horses with moderate or severe recurrent airway obstruction (RAO) and increased vascular impedance; however, pulmonic valve closure occurs early, and only a single S_2 is audible.[122]

A cardiac murmur may be auscultated, caused either by tricuspid insufficiency or a pulmonic valve ejection murmur. The murmur of tricuspid insufficiency, which is secondary to right ventricular dilation, is regurgitant or plateau-shaped with the PMI over the right thorax or, less frequently, the left second intercostal space. The pulmonic valve ejection murmur, found less commonly, is audible as a crescendo-decrescendo murmur at the left heart base.[123] Pleural or pericardial effusion is not common with cor pulmonale.[124] In horses with RAO leading to cor pulmonale, tachypnea, labored breathing, coughing, and exercise intolerance are common complaints. Wheezes are usually auscultated bilaterally in the thorax of affected horses.

These clinical signs are not specific for brisket disease (cor pulmonale) and largely reflect right-sided heart failure. Other considerations when signs of right-sided heart failure are present should be bacterial

endocarditis or tricuspid insufficiency from any cause, cardiomyopathy, cardiac lymphosarcoma or other thoracic neoplasms, pericarditis, left-sided heart failure, pleuritis or pleural effusion, and congenital pulmonic valve stenosis (rare). With pericarditis, heart sounds may be muffled, or the characteristic “washing machine murmur” may be audible. Left-sided heart failure is frequently accompanied by pleural effusion, pulmonary edema, and weak peripheral pulses. In horses, however, expectoration of pulmonary edema fluid occurs only with sudden onset of severe left-sided heart failure. In horses with chronic left-sided heart failure, tachypnea, coughing, poor recovery after exercise, and harsh lung sounds may be all that is detected.

30.4.5.3

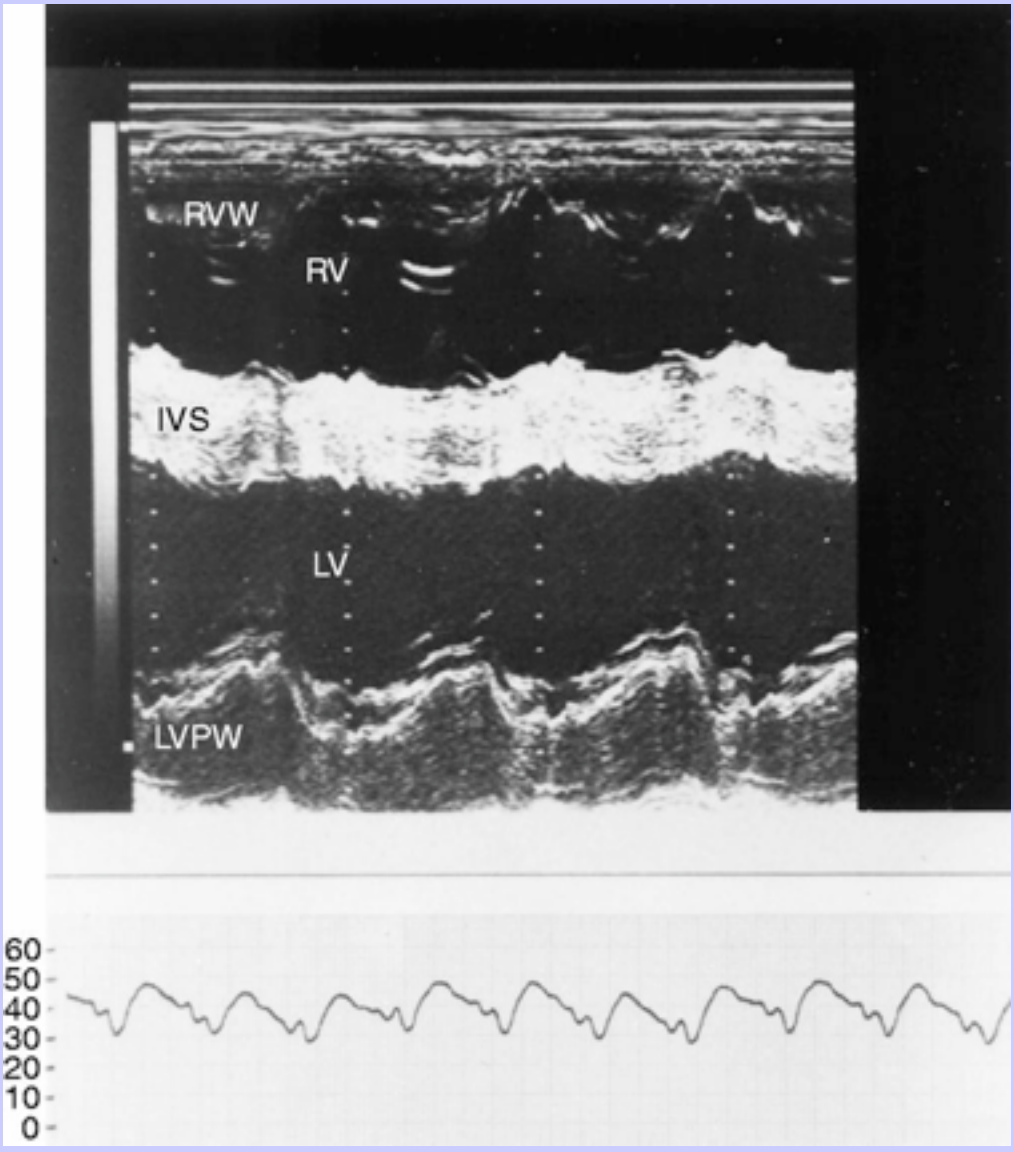
Clinical Pathology

A complete blood count may reveal a neutrophilia in cases of cor pulmonale caused by primary lung disease. Radiography of the thorax reveals primary pulmonary disease such as bronchopneumonia, bronchiectasis, or chronic bronchitis in cattle that have developed this disease at low altitudes. Radiographic findings in horses with RAO usually reveal an interstitial pattern. Arterial blood gases demonstrate the presence of hypoxia and may also show hypercapnia. Transtracheal wash fluid cytology and bacterial culture may provide evidence of the cause of the primary lung disease. Fecal sedimentation helps rule out parasitic bronchitis or pneumonia. Electrocardiographic findings are not specific. An echocardiogram may provide further evidence of pulmonary hypertension and right-sided heart dysfunction by showing right ventricular hypertrophy and dilation, increased septal thickness, and abnormal septal motion (Fig. 30-13).[125,126] Dilation of the pulmonary artery is also detected with two-dimensional echocardiography and is a sensitive indicator of pulmonary hypertension or increased flow through the pulmonary artery. A dilated pulmonary artery has been reported in horses with cor pulmonale and in horses with acute pulmonary obstruction from RAO.[126,127] Cardiac catheterization reveals elevated pressure in the pulmonary artery, right ventricle, and right atrium. Elevation of right ventricular end-diastolic pressure is a sign of right ventricular failure.

468

469

Fig. 30-13 M-mode echocardiogram and pulmonary artery pressure curve obtained from a cow with pulmonary hypertension and cor pulmonale. The echocardiogram shows mild thickening of the right ventricular wall *(RVW)* and interventricular septum *(IVS)*, dilation of the right ventricle *(RV)*, and abnormal septal motion. *LV*, Left ventricle; *LVPW*, left ventricular free wall. The pulmonary artery pressure curve demonstrates elevated systolic and diastolic pressures. (Pulmonary artery pressure curve in millimeters of mercury [mm Hg].)



30.4.5.4

Pathophysiology

Pulmonary arteriolar constriction is the response to hypoxia from high-altitude dwelling or pulmonary disease. The response to hypoxia varies, depending on the amount of smooth muscle in the pulmonary arteries. In cattle, increased pulmonary vascular resistance and pulmonary hypertension frequently develop. Chronic pulmonary artery hypertension causes a pressure overload on the right ventricle, which responds to the increased work load with hypertrophy, dilation, or failure, depending on the speed with which the condition develops. The disease is progressive, and at some stage the right ventricular myocardium is unable to compensate, dilates, and fails. With failure come the typical signs of jugular venous distention and development of subcutaneous edema. Chronic right-sided heart failure may result in diastolic dysfunction of the left ventricle.

30.4.5.5

Epidemiology

The disease is more common in cattle than in other animal species, especially when cattle are kept at altitudes over 6000 feet, in which cases the incidence has been estimated at 0.5% to 2%.[128] Mainly calves are affected, and some herds with a higher prevalence are thought to have a genetic predisposition to develop pulmonary arterial constriction when subjected to hypoxia at high altitude. Ingestion of locoweed (*Oxytropis* and *Astragalus* species) also predisposes cattle to right-sided heart failure at high altitudes by causing toxic myocardial damage.[119]

30.4.5.6

Necropsy Findings

There is evidence of right-sided heart failure such as subcutaneous edema in the submandibular area, brisket, and ventral abdomen. Findings include dilation and hypertrophy of the right ventricle, congestion of the liver, and ascites. The lung may have changes of pneumonia, bronchitis, bronchiectasis, or emphysema. Lesions of locoweed toxicity may be found in other organs in cattle.[119] Lesions of chronic interstitial pulmonary disease are found in horses with RAO.

30.4.5.7

Treatment and Prognosis

Removing the animal from high altitude, treating the primary lung disease, and administering oxygen may help eliminate the hypoxia and thus the pulmonary artery hypertension. Cor pulmonale from high altitude is potentially reversible when the animal is returned to a lower altitude. The heart failure can be treated with digoxin and diuretics. Beneficial effects of vasodilator therapy have not been documented. Once heart failure signs have developed, the prognosis is guarded even with appropriate treatment. Removing the horse from the environment inducing RAO is critical to the treatment of the horse with cor pulmonale. A more detailed discussion of the treatment and management of horses with RAO can be found in Chapter 31.

30.4.5.8

Prevention and Control

The selection of breeding stock with low or normal pulmonary arterial pressures at altitudes above 5000 feet (mean pulmonary artery pressure less than 35 mm Hg) helps to eliminate the predisposing genetic susceptibility to the effects of hypoxia of high altitude.[128] The disease can also be controlled by removing susceptible animals from high altitude and preventing locoweed ingestion. Herd health practices such as

avoiding crowding and poor ventilation and using appropriate vaccinations to reduce the incidence of pulmonary disease help to reduce the incidence of other causes of cor pulmonale.

30.4.6 MYOCARDIAL DISEASE: MYOCARDITIS AND CARDIOMYOPATHY

30.4.6.1 Definition and Etiology

Myocarditis is an inflammation in the myocardium caused by bacterial, viral, or parasitic organisms or thromboembolic disease caused by these organisms. In large animals, recognized bacterial causes include *Staphylococcus aureus, Streptococcus equi, Clostridium chauvoei,* and *Mycobacterium* species. Myocarditis also can occur after bacteremia, septicemia, pericarditis, or endocarditis, regardless of the causative agent. Known viral causes of myocarditis include foot-and-mouth disease, equine infectious anemia, equine viral arteritis, equine influenza, and African horse sickness. Parasitic causes of myocarditis may include strongylosis[129] or onchocerciasis in horses, and toxoplasmosis, cysticercosis, or sarcocystic infection in ruminants.[130,131] Currently it is thought that infection with the spirochete *Borrelia burgdorferi* may be a cause of myocarditis in domestic animals, as it is in human beings.[132] Cardiomyopathy is a subacute or chronic disease of the ventricular myocardium that occurs without anatomic valvular disease, congenital malformations of the heart or vessels, or pulmonary disease. In large animals, dilated cardiomyopathy is the only cardiomyopathy of known significance. Dilated cardiomyopathy is associated with ventricular dilation, increased ventricular mass, and decreased systolic function. Although the cause is frequently undetermined,[133–135] several conditions have been related to or identified with cardiomyopathy. The most common cause of cardiomyopathy in horses is probably myocarditis, although the inciting insult is usually difficult to identify. 469
An inherited cardiomyopathy, which is thought to be linked to the red Holstein gene, has been found in 470
Holstein-Friesian cattle in Canada, Japan, Australia, the Netherlands, and Switzerland.[136–139] There is also a cardiomyopathy associated with a curly hair coat in polled Herefords.[140] Cardiomyopathy has been associated with ingestion of monensin, lasalocid, salinomycin, gossypol, *Cassia occidentalis,* and *Phalaris* species. Vitamin E and selenium deficiency, copper deficiency, excessive molybdenum, or high sulfates (secondary copper deficiency) may cause cardiomyopathy.[141–150] Myocardial infiltration by neoplasia such as lymphosarcoma or fibrosarcoma also may cause cardiomyopathy. A fibrofatty infiltration of the right ventricle and interventricular septum that appears to be similar to arrhythmogenic right ventricular dysplasia has been reported in horses.[151]

30.4.6.2 Clinical Signs and Differential Diagnosis

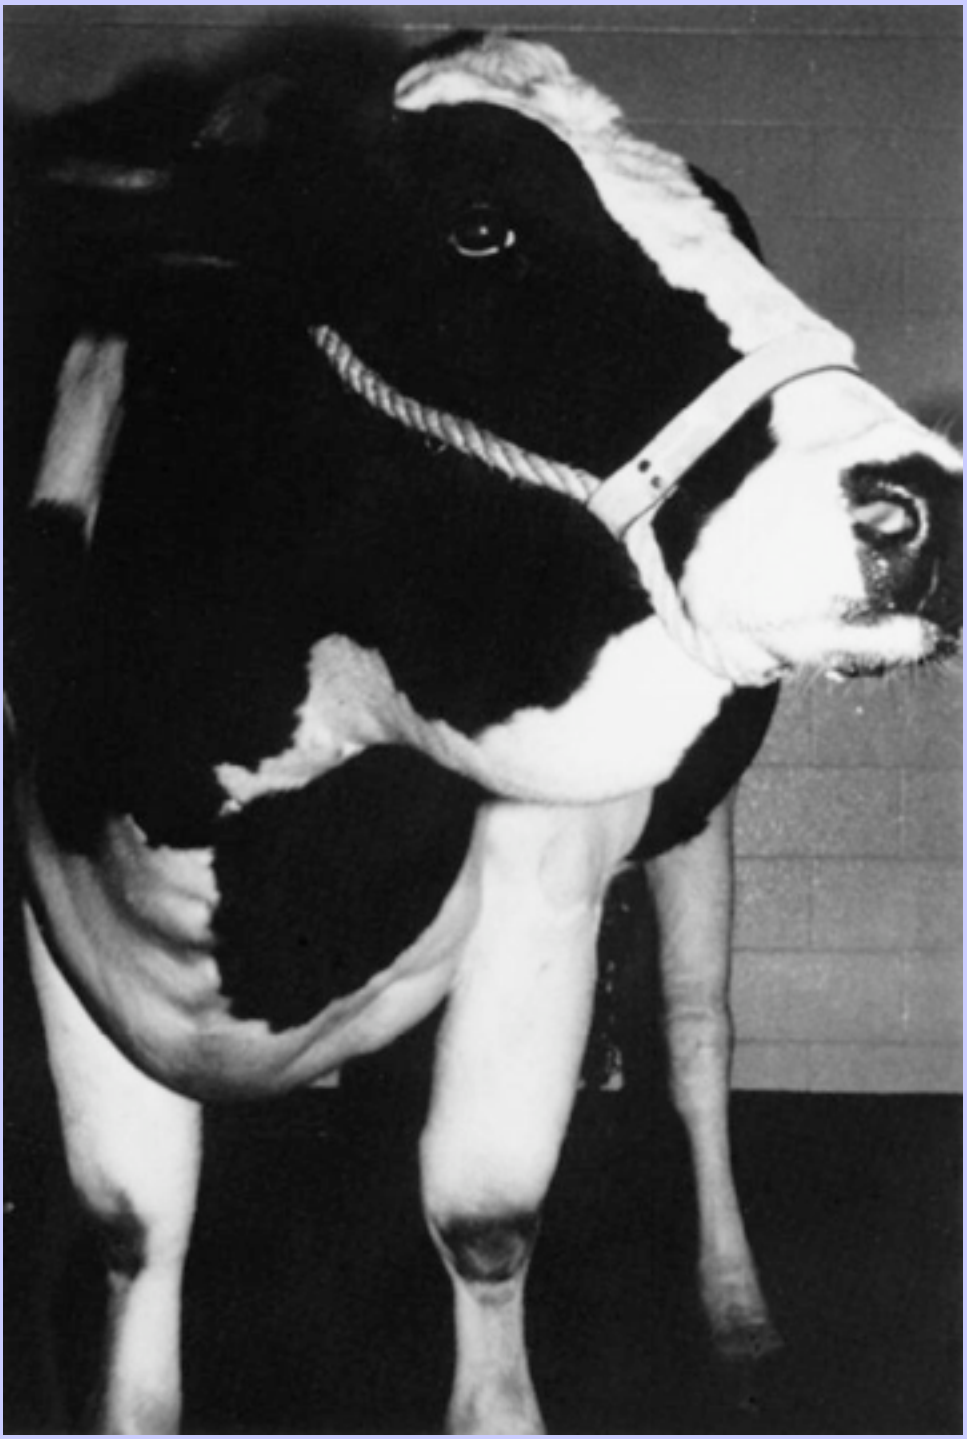
The manifestations of myocarditis are highly variable, depending on the extent of the disease, location of the inflammation within the myocardium, and associated systemic illness. Myocarditis can easily be missed because of the lack of specific cardiac signs or the predominance of signs related to the organ system with primary involvement (e.g., strangles in horses or mastitis in cattle). Animals with myocarditis are often febrile or have a recent history of fever and may have tachycardia. The elevated heart rate may be caused by sinus tachycardia or other paroxysmal or sustained supraventricular or ventricular arrhythmias, because cardiac arrhythmias are common. Premature beats are also commonly detected in large animals with myocarditis and may be present in animals with a normal or increased heart rate. Occasionally, acute myocarditis is associated with auscultation of a pronounced gallop rhythm or a cardiac murmur of either tricuspid or mitral valve insufficiency. Jugular venous distention, other signs of CHF such as peripheral edema, and signs of circulatory collapse may be present. Horses may show evidence of myalgia, reluctance to move, or exercise intolerance.

With these signs it may be difficult to distinguish myocarditis from colic, respiratory disease, lameness, or septicemia. If signs are more clearly cardiac (e.g., murmur, arrhythmia, jugular venous pulsations), the practitioner should rule out endocarditis, cardiomyopathy, cardiac neoplasia, and CHF from another cause.

The clinical signs associated with dilated cardiomyopathy can also be variable but are usually more clearly associated with heart disease. Most animals have signs of cardiac failure such as peripheral edema and jugular venous distention or pulsations (Fig. 30-14). Auscultation frequently reveals tachycardia, gallop rhythm, muffled heart sounds, or a cardiac arrhythmia. Cardiac murmurs of tricuspid or mitral valve insufficiency are usually present secondary to the ventricular dilation. The breath sounds are increased, tachypnea is present, and, frequently, percussion of the thorax reveals signs of pleural or pericardial fluid. Occasionally, respiratory distress is evident with hyperpnea, dyspnea, coughing, and the presence of a bloody froth at the nostril. Nonspecific signs of cardiomyopathy such as exercise intolerance, syncope, diarrhea, or anorexia may also be present. In cattle, decreased milk production and abomasal displacement have been associated with dilated cardiomyopathy.[136] Palpable liver enlargement has also been reported in cattle with cardiomyopathy.[137] Most affected cows develop clinical signs within 3 months of calving.[137]

Sudden death can be a feature of myocarditis or dilated cardiomyopathy, and it frequently follows stress or exercise. Recumbency, collapse, and sudden death are common presenting signs in animals with ionophore toxicosis.[141–147,149] In many animals with inherited cardiomyopathy, death occurs within 6 months of age.[138,140] In Holstein-Friesian cattle with suspected inherited cardiomyopathy, heart failure and death may not occur until cattle are 2 to 4 years old.[136,137] Other acquired causes of cardiomyopathy can occur at any age.

Fig. 30-14 Holstein cow with cardiomyopathy showing signs of CHF (submandibular and brisket edema, jugular venous distention, and pulsations).



When animals show clinical signs of dilated cardiomyopathy, many differential diagnoses should be considered. If the animal is young, other congenital heart defects, cor pulmonale, and nutritional myodegeneration should be considered. In adults, bacterial endocarditis, cardiac neoplasia, thoracic abscess, pericarditis, pleuritis, and diaphragmatic hernia may also have similar clinical manifestations. Although the cause of dilated cardiomyopathy may be difficult to determine, nutritional (vitamin E, selenium, or copper deficiency), toxic (monensin, gossypol, salinomycin, lasalocid, *Cassia* species, or *Phalaris*), infectious (viral, bacterial, or parasitic) or drug-induced causes should be investigated.

30.4.6.3

Clinical Pathology

Depending on the cause of the myocardial disease, the clinicopathologic findings may vary. Routine complete blood count may be normal, or a neutrophilic leukocytosis may be present. No consistent changes are expected in the serum chemistry profile, but serum albumin concentration may be slightly decreased and serum urea nitrogen, creatinine, γ-glutamyltranspeptidase (GGT), sorbitol dehydrogenase (SDH), and bilirubin concentrations may be increased because of congestive liver disease when signs of CHF are present. Serum concentrations of creatine kinase (CK) and lactic dehydrogenase (LDH) may be elevated, but hepatic and skeletal muscle contribution to these elevations cannot be ruled out. A better indication of myocardial disease may be the elevation of cardiac troponin I (cTnI) or the myocardial isoenzymes of CK (myocardial bound [MB]) and LDH (LDH_1). Large elevations of the myocardial isoenzymes of CK and LDH were detected in one outbreak of monensin toxicosis[144] and have been detected in other horses with myocardial necrosis of unknown etiology. Marked elevations of cTnI have also been reported in a horse with multiform ventricular tachycardia and myocardial necrosis of unknown cause.[152] and in a horse with ventricular tachycardia and aortic septal rupture.[153] Elevations of cTnI were detected in a recent herd exposure to lethal concentrations of monensin. Mild elevations of cTnI were also reported in two Belgian horses with atypical acute monensin toxicosis.[150] Analysis of pericardial or pleural fluid reveals a transudate with low protein concentration (less than 2.5 g/dL) and cellularity (white blood cell [WBC] count less than 2500/μL), with the predominant cell type being mononuclear cells, unless the myocarditis is an extension of pericarditis. Serum should be tested for serologic evidence of bovine leukosis (BLV) infection in adult cattle, α-tocopherol, glutathione peroxidase, and copper concentrations. Whole blood selenium levels should be determined. In infectious myocarditis or inherited cardiomyopathy, the results of these tests will most likely be normal. A negative BLV test result essentially eliminates lymphosarcoma as a cause of the myocardial disease; a positive test result does not confirm a causal relationship. In horses, serum should be tested for serologic evidence of a variety of equine viruses, particularly influenza, equine viral arteritis, and herpes virus. Hemoglobinuria, if present, suggests consideration of monensin, gossypol, or nutritional myodegeneration as the cause of myocardial disease. Arterial blood oxygen tension may be reduced below 80 mm Hg in animals with myocardial disease.

470
471

An ECG may demonstrate sinus tachycardia or other cardiac arrhythmias; the frequency and severity of these arrhythmias are best demonstrated with continuous electrocardiographic monitoring. There may be some evidence of conduction abnormalities in the base-apex lead, but these findings are not specific for myocardial disease. Echocardiography may be normal in animals with myocarditis, or the abnormalities detected may be caused by the arrhythmias present. A small left ventricular internal diameter, thickened left ventricular free wall and interventricular septum, small aortic root diameter, and decreased FS may be detected in animals with sustained ventricular tachycardia and decreased cardiac output (Fig. 30-15). More frequently, however, there is increased ventricular chamber size, decreased thickness of the interventricular septum and left ventricular free wall, and decreased myocardial function (decreased FS, decreased EF, and myocardial dyskinesis), especially in more severe cases of myocarditis and in animals with dilated cardiomyopathy (Fig.

30-16). In humans with myocarditis there may be evidence of abnormal left ventricular wall motion, paradoxic motion of the interventricular septum, or an echo-free pericardial space.[154] Additional echocardiographic features of dilated cardiomyopathy are increased end-systolic and end-diastolic dimensions of the left and right ventricles (see Fig. 30-16), increased left atrial size, and an increased left atrial to aortic root dimension ratio. There may be abnormal mitral valve closure (increased EF slope) and increased separation of the septal mitral valve leaflet and the interventricular septum. A decreased aortic root diameter may be detected, along with a shortened ET, in animals with low-output left-sided heart failure. An enlarged pulmonary artery indicative of pulmonary hypertension (Fig. 30-17) may also be present.

Cardiac catheterization may reveal elevated intracardiac pressures (right atrial, right ventricular, pulmonary artery, pulmonary capillary wedge, and left ventricular end-diastolic) in animals with dilated cardiomyopathy. 471
Humans with acute infectious myocarditis may show hypotension and a narrow pulse pressure. Nuclear 472
angiocardiography may be used to show decreased EF[155] in animals with myocardial disease.

Fig. 30-15 M-mode echocardiogram of the left ventricle *(LV)* obtained from a mare with sustained uniform ventricular tachycardia. Note the small end-diastolic and end-systolic dimensions of the left ventricle and the little variation between systole and diastole in this dimension. *RV*, Right ventricle.

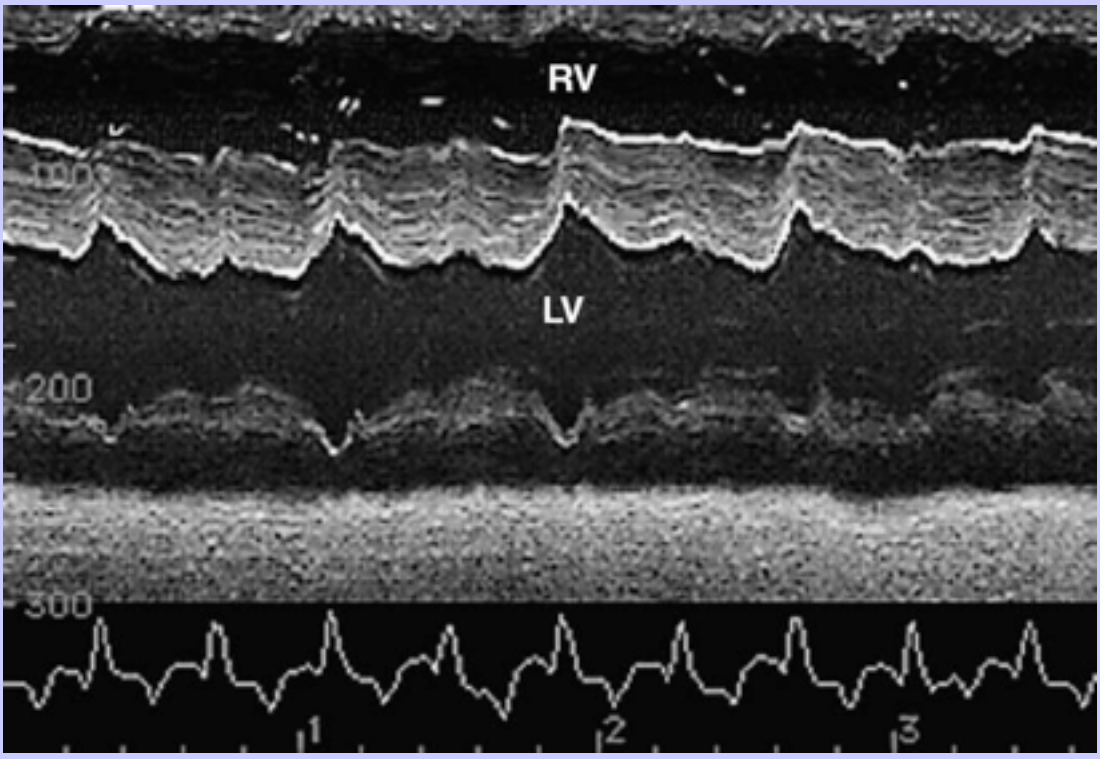


Fig. 30-16 M-mode echocardiogram of the left ventricle obtained from a mare with cardiomyopathy and severe left ventricular dysfunction. Note the large end-diastolic dimension of her left ventricle *(LV)*, the thin interventricular septum and left ventricular free wall, and the poor left ventricular contractility. The fractional shortening in this mare varied from 2% to 8%. *RV*, Right ventricle.

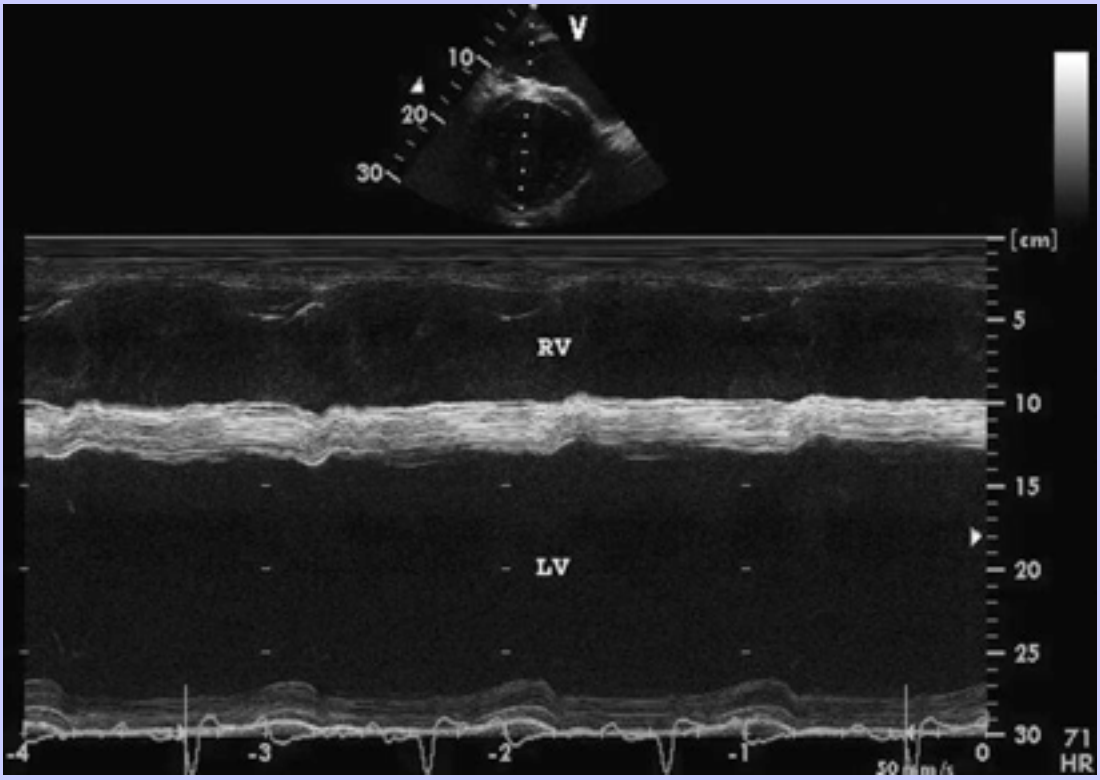

Fig. 30-17 Two-dimensional echocardiogram of the aorta *(AR)* and main pulmonary artery *(PA)* obtained from a foal with cardiomyopathy and severe mitral and tricuspid regurgitation. The pulmonary artery is larger than the aorta, indicative of pulmonary hypertension and impending left-sided CHF. The aorta measured 3.54 cm at its origin.

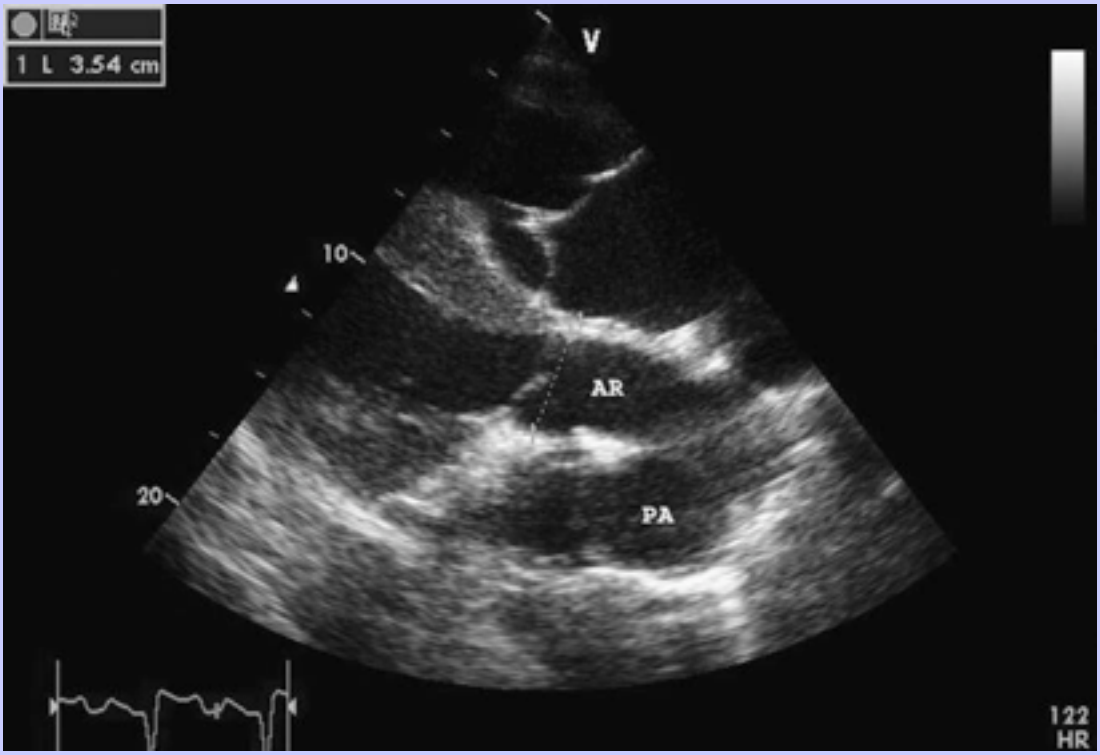


30.4.6.4

Pathophysiology

The pathophysiologic changes associated with myocardial disease depend on the specific nature and extent of the disease. Acute myocarditis or angiopathic myocardial lesions[129] may go on to develop into idiopathic dilated cardiomyopathy. It is speculated that changes in cellular metabolism occur with either acute myocarditis or dilated cardiomyopathy, resulting in ECG abnormalities and reduced myocardial performance (reduced cardiac output). In an attempt to compensate for reduced cardiac output, circulating fluid volume is increased by activation of the renin-angiotensin-aldosterone system, and arterial resistance is increased. These compensatory mechanisms frequently lead to only minor improvement in the cardiac output of the failing heart, and the increase in ventricular preload (venous return) and afterload (arterial resistance) may cause pulmonary edema and a further reduction in cardiac contractility. Ventricular dilation, further reduction in cardiac output, and signs of heart failure occur.

30.4.6.5

Epidemiology

The prevalence of acute myocarditis is difficult to estimate, because frequently the disease goes undiagnosed, is mild, or is masked by disease in another organ system or the animal recovers spontaneously. Similarly, it is difficult to assess the clinical significance of postmortem findings of myocardial inflammation and fibrosis. The morbidity of myocarditis in large animals probably is underestimated because it is rarely the cause of mortality and is associated with viral, bacterial, and parasitic infections that manifest themselves without specific signs of cardiovascular disease.

Inherited cardiomyopathy has been reported in cattle in Japan, Australia, the Netherlands, Canada, and Switzerland, with the incidence in inbred populations reaching 3% to 5%.[137] A familial form of dilated cardiomyopathy has also been reported in cattle in Sweden, Denmark, Australia, and the United Kingdom.[137] These cattle may be genetically linked by the presence of the red gene in Holstein-Friesian cattle.[136] Although in some cattle inherited cardiomyopathy resulted in death by 6 months of age,[138,140] other cattle failed to show clinical signs until 2 to 6 years of age.[134–135,137,139] No sex predilection is recognized in inherited cardiomyopathy of cattle.

The morbidity and mortality from cardiomyopathy stemming from other causes in cattle and horses is not known. From the number of clinical reports, inherited cardiomyopathy seems to be more prevalent in cattle than in horses. Idiopathic dilated cardiomyopathy or cardiomyopathy secondary to viral or bacterial infections may be more common in horses and is a common cause for the acute onset of CHF in horses of racing age.

30.4.6.6

Necropsy Findings

There may be no gross lesions associated with myocarditis. Depending on the relationship between death and the occurrence of myocarditis, microscopic examination of the myocardium may show no inflammatory cells but increased fibrous tissue in the interstitium, or there may be foci of inflammatory cells (typically mononuclear cells), variation in the cross-sectional area of the cardiac myocyte, degeneration of adjacent myocardial fibers, myocardial necrosis, and fibrosis. Focal interstitial nephritis and fibrosis were reported in eight of nine Holstein-Friesian cattle in Scotland with dilated cardiomyopathy.[137] Often the inciting cause of myocardial necrosis in horses is unknown.[152] Samples of gastric or ruminal contents should be obtained and submitted for analysis of ionophores if ionophore toxicosis is suspected. Feed samples should also be obtained and submitted for ionophore analysis in these cases.

The lesions of cardiomyopathy are recognized more easily grossly as enlargement of the heart, which may be rounded to globose. Biatrial, biventricular, and pulmonary artery dilation is usually present. Patchy or uniform streaks of myocardial pallor may be detected. In rare cases, one of the chambers or major vessels (usually pulmonary artery) may rupture. Generalized edema is frequently found as ascites (uncommon in horses), pericardial or pleural effusion, and edema of the mesentery and subcutaneous tissues. There may be evidence of vascular congestion of the liver, lungs, and spleen. The kidneys may be pale and swollen and have an irregular, granular, pitted surface.

Microscopically the lesions of cardiomyopathy are characterized as myocardial vacuolation and degeneration with necrosis and fibrosis. Calcification may be associated with these lesions. Occasionally there is increased vascularization with proliferative regeneration of myofibers. In some cases, no histopathologic abnormalities are found.

30.4.6.7

Treatment and Prognosis

The treatment of myocarditis includes treatment of the underlying causative agent if it is recognized and control of the complications such as arrhythmias, CHF, or shock. Thromboembolism is rarely a complication recognized in animals. Prompt administration of vitamin E may be beneficial to the survivors in cases of ionophore toxicosis. Performance animals should be rested. Corticosteroids may be beneficial in animals with severe toxemia, complicated arrhythmias, or intractable heart failure, but their use in early cases of myocarditis or in infections suspected of having a viral cause is controversial because viral recrudescence may occur. However, in many cases the corticosteroids appear to have a beneficial effect. Prognosis is good if there are no signs of heart failure and if cardiac arrhythmias are managed successfully. Prognosis is guarded to poor if signs of CHF are present.

Therapeutic strategies currently used for treatment of dilated cardiomyopathy include positive inotropic agents (digoxin), diuretics, vasodilators, rest, and in some cases removal of pleural or abdominal fluid. The advantages of vasodilators (venodilators to relieve pulmonary edema and arterial dilators to reduce preload and afterload and improve contractility) in the treatment of cardiomyopathy are recognized in humans and small animals,[156] but these drugs have not been widely used in large animals because of the lack of pharmacokinetic studies and clinical trials.

Digoxin is the positive inotropic agent used almost exclusively in large animals but is contraindicated in animals with acute monensin toxicosis. A priming or loading dose can be used in horses with acute severe CHF, followed with a maintenance dose, or, more frequently, the horse is started on a maintenance dose from the onset of therapy. In horses the drug can be administered PO or parenterally. In cattle, low bioavailability limits its use to the intravenous route of administration.[157] Guidelines for the use of digoxin are given in Box 30-1.[158–160] In general, maintenance dosages are used because of the lowered risk of adverse reactions. A peak and trough serum digoxin concentration should be obtained 3 to 5 days after digoxin therapy is begun, and the dosage should then be adjusted accordingly. Ideally the peak and trough digoxin concentration should be 1 to 2 ng/mL.

472

473

30.4.6.7.1

Box 30-1 Guidelines for Digoxin Therapy in Horses and Cattle

HORSES	CATTLE
Priming dose IV: 12 to14 µg/kg	Priming dose IV: 22 µg/kg
Priming dose PO: 34 (elixir)to 70 (powdered tablets in suspension) µg/kg	Maintenance dosage IV: Infusion of 0.86 µg/kg/hr or give 11 µg/kg three times daily
Maintenance dosage IV: 2.2 µg/kg every 12 hours (most commonly used) or 6 to 7 µg/kg/24 hr	
Maintenance dosage PO: 11 µg/kg every 12 hours (most commonly used)	
or 17 (elixir) to 35 (powdered tablets in suspension) µg/kg/24 hr	

IV, Intravenous; *PO,* by mouth.

Dehydration, acid-base imbalance, and electrolyte abnormalities should be corrected before digoxin therapy. The dose of digoxin should be decreased in animals with elevated creatinine or blood urea nitrogen (BUN) until these values return to normal. In horses the intravenous loading dose of digoxin should be administered slowly or divided and given at a rate of one third of the loading dose hourly until completion.[158] Alternatively, therapy can be initiated with the maintenance dose. Close monitoring of body weight, appetite, electrolyte concentrations, creatinine or BUN concentration, and cardiac rhythm is essential during therapy. Therapeutic drug monitoring with digoxin plasma concentrations can be helpful during initial therapy, when the volume of distribution of the drug and the patient's body weight may be in a state of flux. Samples for determination of peak serum digoxin concentrations should be obtained 1 to 2 hours after digoxin administration and should not exceed 2.5 ng/mL.[160,161]

The diuretic used most commonly in large animals is furosemide. It is administered parenterally at the rate of 0.5 to 1 mg/kg twice daily or as needed to control edema. Oral absorption of furosemide is poor or variable in horses.[162] A continuous rate infusion of furosemide is recommended in horses when rapid profound diuresis is needed.[163] The half-life and diuretic effect of bumetanide, a sulfonamide diuretic, are shorter than those of furosemide in horses.[164] Electrolyte concentrations and water consumption should be monitored closely in patients receiving diuretics.

The vasodilators used most frequently in horses include hydralazine and enalapril, an ACE inhibitor. Both have resulted in clinical improvement in animals treated for CHF. Hydralazine is administered PO at a dose of 0.5 to 1.5 mg/kg twice daily. Enalapril has been used at a dose of 0.5 mg/kg PO twice daily in the management of horses with moderate to severe mitral or aortic regurgitation and in the treatment of horses with CHF. However, after a single 0.5-mg/kg oral dose of enalapril, neither enalapril or enalaprilat were detectable in the serum.[165] Ramipril was reported to result in clinical and echocardiographic improvement of a horse with CHF.[166] Quinipril at a dosage of 120 mg/horse/day has also been shown to increase stroke volume and cardiac output in horses with mitral regurgitation after 8 weeks of therapy.[167]

Control of cardiac arrhythmias should be attempted in animals that are hemodynamically unstable or threatened with the development of worsening arrhythmias. Quinidine is usually the drug of choice for control of atrial and ventricular arrhythmias in cattle and is one of the drugs of choice in horses. Procainamide, lidocaine and propafenone have also been successful in the treatment of ventricular arrhythmias in horses (Table 30-3). Although administration is limited to the intravenous route in cattle, oral or intravenous administration in horses results in adequate plasma concentrations to control arrhythmias. Quinidine is administered IV by infusion or by divided bolus injections as shown in Box 30-2.

When quinidine is used IV, concurrent intravenous administration of a balanced electrolyte solution at the rate of 3 to 4 mL/kg/hr is desirable to maintain blood pressure in animals with a severely compromised cardiovascular status.

Prognosis for animals with dilated cardiomyopathy is poor. Echocardiography is useful in determining the severity of the myocardial dysfunction and in formulating a prognosis. The results of the initial echocardiographic examination were the best prognostic indicator of survival in a recent outbreak of monensin toxicosis.[144] Recovery of animals with cardiomyopathy is unusual, constant therapy is required for maintenance of animals with CHF, and sudden death can occur at any time. Some animals may have significant myocardial dysfunction without CHF and are “cardiac cripples,” comfortable at pasture but not safe to use for performance. These animals may later develop CHF.

Table 30-3 Drug Therapy for Ventricular Tachycardia

Drug	Usual Dose
Bretylium tosylate	0.5 mg/kg IV for life-threatening ventricular tachycardia or ventricular fibrillation
Dexamethasone	0.05–0.22 mg/kg, IV or IM
Furosemide	1-2 mg/kg as needed for pulmonary edema
Lidocaine	Equine: 0.1-0.25 mg/kg as a bolus; repeat up to total of 0.5 mg/kg in 10–15 min
	Bovine: 0.5 mg/kg, slowly IV; can repeat in 15 min
Magnesium SO_4	IV infusion at 1 g/min, to effect, up to a maximum of 25 g
Procainamide	1 mg/kg/min, IV to a maximum of 20 mg/kg
Propafenone	2 mg/kg PO tid
	0.5-1 mg/kg in 5% dextrose slowly IV over 5-8 min for refractory sustained ventricular tachycardia (not available in United States)
Propranolol	0.03 mg/kg, IV
Quinidine gluconate (IV)	1-10 mg/kg, IV; total dose in 0.25- to 0.5-mg/kg boluses 5-10 min apart

IM, Intramuscular; *IV,* intravenous; *PO,* by mouth; *tid,* three times per day.

30.4.6.7.2

Box 30-2 Quinidine Administration in Horses and Cattle

HORSES	CATTLE
IV: 1.5 to 2 mg/kg every 10–20 min until conversion or desired effect but not to exceed a total dose of 12 mg/kg	IV: 48 mg/kg infused IV over a 4-hr period
PO: 22 mg/kg (1 g/100 lb of body weight) q2h until conversion or desired effect; not to exceed a total dose of 132 mg/kg q2h; if quinidine plasma concentrations cannot be obtained promptly, a total dose of 88 mg/kg q2h should not be exceeded	

IV, Intravenous; *PO,* by mouth.

30.4.6.8

Prevention and Control

Maintenance of a good vaccination program may limit the bacterial and viral causes of myocarditis. Parasite control may also reduce myocardial injury that predisposes to myocarditis or cardiomyopathy in horses. Toxic myocardial diseases are prevented by proper mixing of feeds containing monensin, salinomycin, or lasalocid

in feed mills in which horse feed is not made, by not shipping bulk horse feed in trucks in which medicated ionophore-containing feed has been transported, and by preventing horses from ingesting these medicated feeds. Gossypol toxicity can be prevented by feeding no cottonseed meal or cottonseed meal with low gossypol content, especially when feeding preruminants.[168] Feeding of cottonseed meal can be limited by providing more forage or additional protein sources in the diet of ruminants so that ingestion of gossypol is limited to concentrations of 1 to 2 g/kg or less of feed for adult cattle and 0.5 to 1 g/kg or less of feed for immature cattle.[169] Nutritional myocardial disease can be prevented by adequate feeding of vitamin E, selenium, and copper with supplementation as required. Inherited cardiomyopathy is controlled by avoiding breeding of known or suspected carriers of the polled Hereford and Holstein-Friesian breeds.

30.4.7 PERICARDITIS

30.4.7.1 Definition and Etiology

Pericarditis is inflammation of the pericardium that results in the accumulation of fluid or exudate between the visceral and parietal pericardium. Pericarditis in large animals can be caused by trauma from penetration of ingested foreign objects or external wounds, hematogenous spread (septicemia) of infection, extension of infection from the lung or pleura, viral infections such as equine viral arteritis or equine influenza, and neoplasia. Idiopathic pericarditis, characterized by an aseptic inflammatory exudate, is not uncommon in horses and has recently been reported in cattle.[170–176] Autoimmune, hereditary, and metabolic causes of pericarditis have not been documented in large animals.

30.4.7.2 Clinical Signs and Differential Diagnosis

The clinical presentation of pericarditis can vary, depending on the volume and rate of development of the pericardial effusion and the cause. Nonspecific clinical signs—fever, anorexia, depression, or weight loss—may be the chief complaints, but, more frequently, peripheral edema, jugular venous distention and pulsations, tachypnea, or dyspnea is the presenting clinical sign. Cattle may exhibit pain by an abnormal stance characterized by abducted elbows, a spontaneous or induced expiratory grunt, reluctance to move, or preference to stand with the forequarters elevated. Horses may show signs of colic or syncopal episodes.

The most consistent findings on auscultation are tachycardia, muffling of heart sounds, and absence of lung sounds in the ventral thorax. Dorsally the lung sounds are louder than normal. These findings are in contrast to pleuritis, an important diagnostic ruleout for pericarditis, in which the lung sounds are muffled ventrally but the heart sounds are not and radiation of the heart sounds occurs over a wider area than normal.[177] In cattle, splashing sounds frequently are audible in the cardiac auscultation area, a sound some refer to as a “washing machine murmur.” This is attributed to the accumulation of gas and fluid in the pericardium and is indicative of the presence of gas-forming (anaerobic) organisms and a grave prognosis. In cattle this murmur distinguishes pericarditis from cardiac neoplasia or other causes of CHF. The splashing sounds are absent in horses, and muffled heart sounds are the rule, but pericardial friction rubs may be auscultated, especially after pericardial fluid accumulation has been relieved.[172] A gallop rhythm may be auscultated in either horses or cattle.

Mucous membranes may be congested and have a prolonged capillary refill time. Jugular venous distention and pulsations usually are present. Arterial pulses are weak. The latter findings may help distinguish pericarditis from primary pleuritis. Percussion of the thorax reveals ventral dullness, and pleural effusion is

frequently present in horses with pericarditis. A concurrent pleuropneumonia or septic pleuritis is present in some horses.[174,178–181] Ascites is infrequently detected in horses with pericarditis, but concurrent peritonitis has been reported.[182]

30.4.7.3

Clinical Pathology

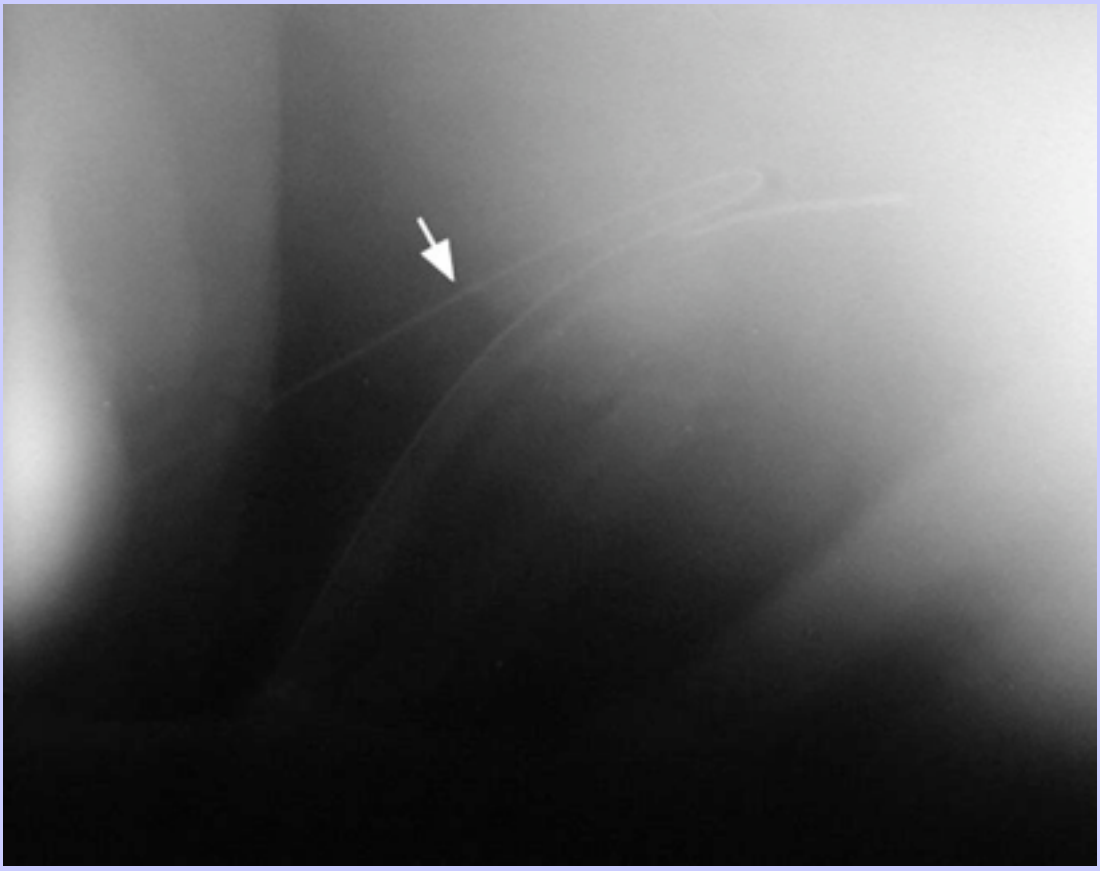
The changes shown in a complete blood count are not specific and depend on the cause of the pericarditis. There may be hemoconcentration if the animal is dehydrated or toxemic, or there may be a mild anemia associated with chronic infectious pericarditis. The WBC count may be normal or increased. There may be an absolute neutrophilia or a lymphopenia. Frequently the fibrinogen concentration is elevated. The serum chemistries are usually normal except for albumin concentration, which may be low[171–172] and accompanied by an elevation in globulin concentration. Liver enzyme, bilirubin, serum urea nitrogen, and creatinine concentrations are frequently mildly elevated, consistent with the development of CHF. Laboratory evidence of dehydration (increased PCV, total protein, serum urea nitrogen, and creatinine concentrations) may be exaggerated when diuretics have been administered previously. Although total serum LDH concentration may be elevated, more specific information may come from finding an increase in the cTnI or the myocardial isoenzymes CK and LDH. An elevated cTnI was reported in one cow with hemorrhagic pericarditis.[175] Electrolyte concentrations are frequently normal, but serum calcium and potassium concentrations may be low because of anorexia. Decreased sodium and chloride concentrations have been reported in horses with pericarditis.[172] No consistent abnormalities in arterial or venous blood gas concentrations have been reported in large animals with pericarditis.

Radiography is not a sensitive diagnostic test for pericarditis in horses, although an enlarged rounded cardiac silhouette is detected with large pericardial effusions. In cattle, traumatic pericarditis frequently results in fluid and gas accumulation in the pericardium that is detectable radiographically and is relatively specific for this disease. A metallic foreign body is usually detected radiographically in the cranial reticulum or caudal thorax in cattle with traumatic pericarditis (Fig. 30-18). Radiographic changes may not be detected in early or uncomplicated pericarditis and, if fluid accumulation is large and there is concurrent pleural effusion, are indistinguishable from those associated with pleuritis. An enlarged, rounded cardiac silhouette is not specific for pericarditis and can be seen with other causes of generalized cardiomegaly. An obscured cardiac silhouette, vena cava, and diaphragm with dorsal displacement of the trachea may be seen with pericarditis or pleuritis. The lungs, which may be aerated only dorsally, frequently have interstitial infiltrates.

474

475

Fig. 30-18 Lateral radiograph of the caudal thorax and cranial reticulum showing a wire *(arrow)* in a cow with traumatic reticuloperitonitis.

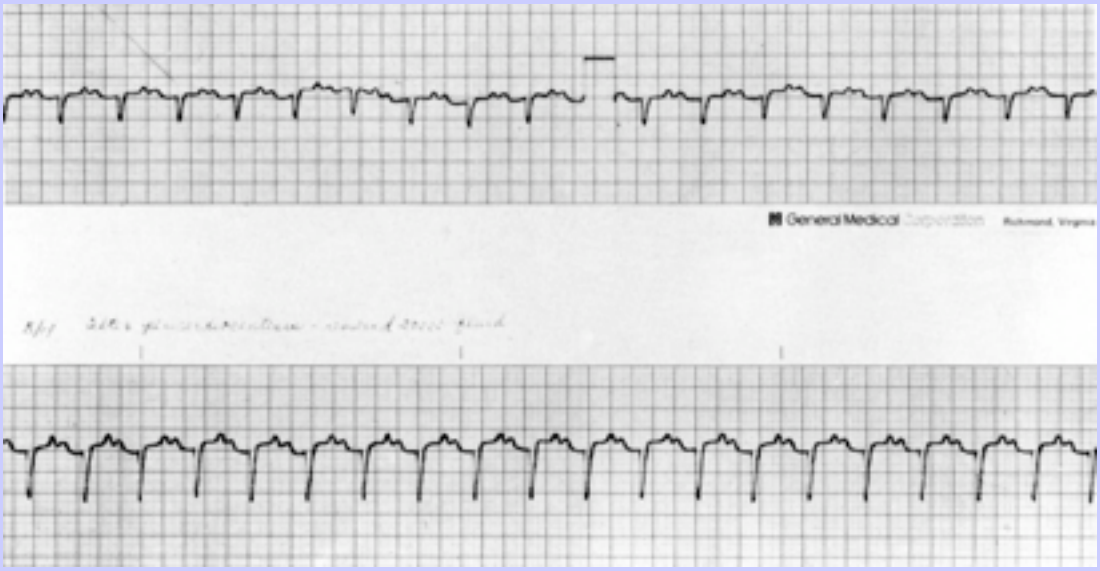


The ECG changes most commonly associated with pericarditis in large animals are decreased amplitude of the QRS complexes (less than 1.5 mV in the base-apex lead)[172,173,182] (Fig. 30-19), electrical alternans (altered configuration of the P, QRS, or T complexes on a regular basis), and ST-segment elevation or slurring.[171,172,178,182,183] A right-axis deviation in the standard limb leads may be apparent.[171,183] Cardiac arrhythmias (usually atrial or ventricular premature beats) may be detected in affected animals, suggesting a concurrent myocarditis (Fig. 30-20). In some animals, no ECG changes are evident.[184]

Echocardiography reveals findings specific for pericarditis and is used to confirm the diagnosis noninvasively. An echo-free space between the visceral and parietal pericardium is evident (Fig. 30-21) and apparent even with a minimum amount of fluid accumulation.[177,178] Frequently, hypoechoic to echoic strands that correspond to fibrin are imaged in the pericardial space with a hypoechoic to echoic layer covering the epicardial surface of the heart in large animals with pericarditis. The pericardial effusion is often anechoic to hypoechoic, but more echoic pericardial fluid is occasionally seen, consistent with a more exudative fluid. Bright hyperechoic pinpoint echoes representing free gas are often imaged in cattle with pericarditis. Gas in the pericardial sac of cattle with splashy heart sounds may limit the ability to obtain an echocardiographic

evaluation of all cardiac structures. The visualization of intrapericardial gas is a sensitive indicator of anaerobic pericarditis. Pericardial effusion is differentiated from pleural effusion by finding the echo-free space surrounding the right ventricle and left ventricular free wall, but pericardial effusion is rarely imaged behind the left atrium.[185,186] Right ventricular diastolic collapse and right atrial collapse are common findings with large pericardial effusions and are an indication of the development of cardiac tamponade and hemodynamically significant pericardial effusion.[173] Other echocardiographic findings consistent with pericarditis are decreased left ventricular chamber dimension, decreased left ventricular free wall motion, and decreased parietal pericardial motion.[173,174,178,187] Increased (see Fig. 30-21) or paradoxic motion (cranial motion beginning before the QRS complex) of the interventricular septum may be apparent.[186,187]

Fig. 30-19 Base-apex lead ECG taken from a cow before *(upper strip)* and after *(lower strip)* removal of 2 L of pericardial fluid. The markedly decreased amplitude (0.6 mV) of the QRS complexes is improved (1.2 mV) after pericardiocentesis.



The site for pericardiocentesis should be selected echocardiographically. Pericardial fluid is obtained most commonly from the left fifth intercostal space 2.5 to 10 cm dorsal to the olecranon, above the level of the lateral thoracic vein, the safest site for pericardiocentesis. When there is a large volume of pericardial effusion, pericardiocentesis can be productive from the right at approximately the same location. If at all possible, a pericardial catheter (large-bore Argyle tube) should be inserted into the pericardial space at the time the initial pericardiocentesis is performed to enable repeated drainage and lavage of the pericardial sac (Fig. 30-22). Fluid analysis and bacterial and viral culture results depend on the cause. In cattle with traumatic pericarditis, fluid analysis usually reveals elevated protein concentration (>3.5 g/dL) and an elevated WBC count (>2500/μL), composed primarily of neutrophils. The fluid is urine colored to slightly blood tinged and foamy, and it has a foul odor. A mixed population of gram-positive and gram-negative aerobic and anaerobic bacteria (gastrointestinal flora) usually are present. Protozoa may be found in unusual circumstances. Hemorrhagic effusion has been reported in several cows with idiopathic pericarditis that responded favorably to pericardial

drainage (usually with lavage) along with systemic antimicrobial therapy.[175] In horses, protein concentration of the pericardial fluid is elevated (≥2.5 g/dL) and the WBC count is normal or elevated with a population predominantly of neutrophils, although red blood cells, lymphocytes, eosinophils, mesothelial cells, and histiocytes have been observed.[171–173,178,182] Bacterial (aerobic and anaerobic) cultures and viral cultures may be negative. *Actinobacillus* organisms were frequently isolated from mares with pericarditis in association with the mare reproductive loss syndrome.[188] Paired serum may support a viral cause. Analysis of pleural and peritoneal fluid (when present) usually reveals fluid characterized as a modified transudate or that is mildly inflammatory.

Fig. 30-20 ECG (rhythm strip) obtained from a horse with pericarditis and junctional tachycardia. Note the P wave at the same place in the QT interval.

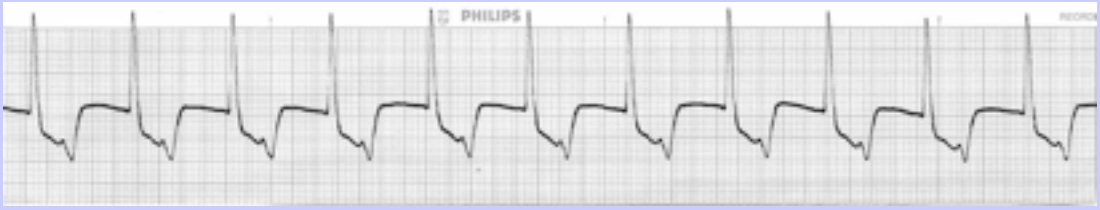


Fig. 30-21 M-mode echocardiogram obtained from a cow with traumatic pericarditis. There is a separation between the visceral and parietal pericardium cranial to the right ventricle *(RV)* and caudal to the left ventricle. The cranial pericardial effusion *(PE)* is echogenic, suggesting that fibrin or debris is present. The left ventricular *(LV)* dimension is reduced, and there is marked cranial motion of the interventricular septum *(IVS)* just before the QRS complex.

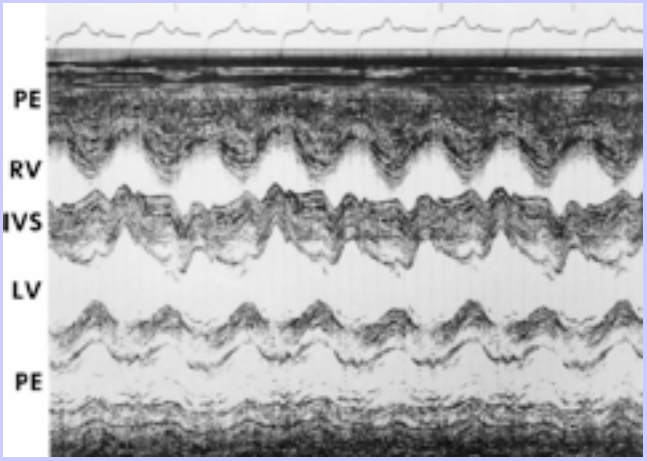

Fig. 30-22 Insertion of a pericardial chest tube into the left fifth intercostal space for drainage and lavage of the pericardial space. Note that the left foreleg is being pulled forward, the clinician is inserting the large-bore Argyle chest tube into the left fifth intercostal space above the lateral thoracic vein, and the cow is wearing a radiotelemetry ECG system underneath the surcingle.

Cardiac catheterization demonstrates an elevation in central venous or right atrial pressure, and the atrial and ventricular pressure curve may be abnormal in appearance. Right atrial, right ventricular, and pulmonary artery end-diastolic pressures may equilibrate.[183] In combination these findings are relatively specific for pericarditis.

30.4.7.4

Pathophysiology

The accumulation of fluid in the pericardium occurs as a result of inflammation. The rate of fluid accumulation and the degree to which the pericardial pressure increases determine the pathophysiologic consequences. Generally pericarditis results in decreased distensibility (increased ventricular end-diastolic pressure) of the heart, which impairs the ability of the heart to fill during diastole. The elevation in end-diastolic pressure and impairment of ventricular filling elevate atrial pressure and reduce venous flow or venous return to the heart and diastolic perfusion of the myocardium. The result is a depression of ventricular contractility, stroke volume, and consequently cardiac output. In addition, arterial pressure and renal blood

flow are decreased. Initially, compensatory mechanisms consisting of vasoconstriction, increased heart rate, and sodium retention (increased vascular volume) may maintain cardiac output. Failure to maintain cardiac output results in circulatory collapse.

Pericarditis can be classified as primarily effusive, constrictive, or a combination of both.[183] The hemodynamic consequences of effusive pericarditis are primarily caused by the physical presence of pericardial fluid, whereas constrictive pericarditis is classified as such because the reduction in ventricular compliance is caused by fibrinous or fibrotic involvement of the pericardium and epicardium. Removal of pericardial fluid results in improved cardiac performance in effusive pericarditis but is of limited usefulness in constrictive pericarditis.

30.4.7.5

Epidemiology

Pericarditis is uncommon in horses; when it does occur, it is most frequently idiopathic and can occur in a horse of any age. History of a recent respiratory tract infection is not uncommon. Exposure of horses to Eastern tent caterpillars was the greatest risk factor for the development of fibrinous pericarditis during the epidemic of mare reproductive loss syndrome.[189] Traumatic pericarditis has been reported in horses but is rare.[190] Traumatic pericarditis is not uncommon in cattle, but it occurs in less than 10% of cattle with traumatic reticuloperitonitis.[191] Most cattle are affected in late gestation or at parturition. Idiopathic pericarditis is rare in cattle.

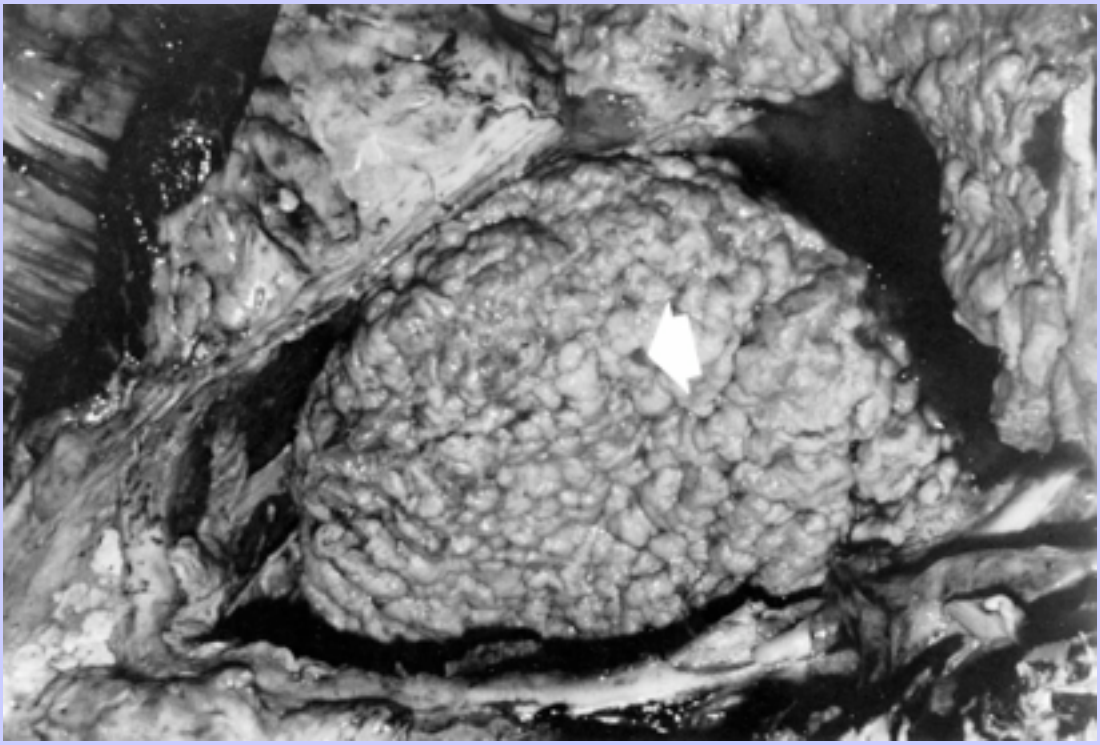
30.4.7.6

Necropsy Findings

476
477

Gross postmortem examination shows distention of the pericardial sac with serosanguineous or urine-colored fluid that is foamy and may be malodorous (cattle). There may be organization of fibrinous exudate and fibrosis that is also evident on the epicardium (Fig. 30-23) and may infiltrate the myocardium. Pleural effusion may be present. Other signs of CHF such as pulmonary congestion, pulmonary edema, and chronic passive congestion of the liver may be present. If the cause is traumatic, the offending object may be well contained in a fibrous tract located between the reticulum and the pericardium.

Fig. 30-23 Postmortem photograph of a cow with constrictive pericarditis. The pericardium is opened and reflected, revealing the epicardium *(arrow)* covered in fibrinopurulent exudate.



Histopathologic examination reveals pericardial, epicardial, and occasionally myocardial fibrosis and inflammation with neutrophilic, lymphocytic, eosinophilic, or plasma cell infiltrates. Bacteria may be visible. The liver may show diffuse, centrilobular necrosis, fatty change, dilation and congestion of sinusoids, and perivenous fibrosis.

30.4.7.7

Treatment and Prognosis

Treatment of traumatic pericarditis in cattle is unrewarding and usually is addressed toward salvage or short-term survival to calving. Repeated pericardial drainage by means of pericardiocentesis or a fifth rib resection, lavage, or pericardiectomy may be useful for short-term survival, but the prognosis for return to normal function is poor, because CHF results from involvement not only of the pericardium but also of the epicardium and myocardium (see Fig. 30-23). Thoracotomy by a split-rib technique followed by pericardiectomy has been effective in treating some cattle with traumatic, restrictive pericarditis.[192]

Treatment of pericarditis not caused by trauma has been successful in horses, but the initial prognosis should be guarded. Aggressive treatment of horses with moderate to large pericardial effusions should include the placement of a large-bore indwelling chest tube into the pericardial sac under echocardiographic guidance and drainage and lavage of the pericardial sac, with local infusion of antibiotics, in addition to the initial broad spectrum antimicrobial therapy. Obtaining a sample for cytology and culture and sensitivity testing via a

pericardiocentesis should be postponed until an indwelling catheter can be safely inserted because it is difficult to insert the catheter once the pericardiocentesis has been performed. The pericardial drainage and lavage, performed once or twice daily as needed, has been very effective in treating idiopathic or septic pericarditis in horses.[173,174,178,182] The indwelling tube should remain in situ until the fluid recovered at the time of drainage is consistently less than or equal to the volume instilled in the pericardial sac with antimicrobials 12 to 24 hours earlier. The ECG should be monitored, because occasionally cardiac arrhythmias occur during the therapeutic procedure or during a routine pericardiocentesis. All horses with pericarditis should initially be treated for septic pericarditis with systemic broad-spectrum bacteriocidal antimicrobial drugs. The antimicrobial choice should be based on the most likely causative agents and modified as needed by the results of culture and sensitivity testing. Fibrinous pericarditis has been successfully treated in horses with broad-spectrum bacteriocidal antimicrobials when the amount of pericardial fluid detected echocardiographically was too small to safely obtain a sample for cytology and culture and sensitivity testing. Treatment of idiopathic pericarditis with corticosteroids should be initiated only after the results of the cytology and culture and sensitivity testing demonstrate no evidence of sepsis. Pericardiotomy or preferably pericardiectomy is the treatment of choice if signs of restrictive (constrictive) pericarditis are present. The surgical procedure is prolonged, expensive, and of considerable risk. A partial pericardiectomy was performed in one horse with constrictive pericarditis but was only transiently successful.[179]

In traumatic pericarditis the antibiotic selected must be capable of covering gram-positive and gram-negative aerobic and anaerobic bacteria. Nonsteroidal antiinflammatory drugs have been deemed useful as adjunctive therapy, as have corticosteroids if bacterial culture of the fluid is negative and if no evidence of sepsis is detected cytologically.

Although diuretics are effective in eliminating the severity of peripheral edema, they further reduce venous return and preload in animals with pericarditis. The result is further compromise of cardiac output and worsening of heart failure.

30.4.7.8 Prevention and Control

477

Traumatic pericarditis in cattle can be prevented by routine administration of magnets to heifers at the time of 478 pregnancy diagnosis. At each subsequent pregnancy diagnosis, the cattle should be checked for the presence of the magnet in the reticulum. It is not beneficial to have more than one magnet present at one time.

Some types of infectious pericarditis in horses may be controlled by routine vaccination against the common respiratory pathogens.

30.4.8 CARDIAC TUMORS

30.4.8.1 Definition and Etiology

The heart may be the primary site of neoplastic disease, or it may be involved secondarily by tumors from adjacent structures such as the lungs, pleura, lymph nodes, or diaphragm. Cardiac neoplasia is uncommon in large animals. The most common primary cardiac tumor is lymphosarcoma. Mesotheliomas, fibrosarcoma, adenocarcinomas, and other carcinomas, especially squamous cell carcinomas in horses, may involve structures adjacent to the heart and may extend to the heart or heart base, producing signs of heart disease.[193,194] An infiltrative cardiac lipoma has been reported in a horse, but no signs of cardiac disease were attributed to it.[195] A metastatic anaplastic pulmonary carcinoma that did cause signs of CHF in a horse has

been reported.[194] Disseminated hemangiosarcoma with myocardial involvement was thought to be responsible for ventricular arrhythmias in one horse.[196] Primary pericardial hemangiosarcomas also have been reported in a horse.[197]

30.4.8.2

Clinical Signs and Differential Diagnosis

The clinical signs of cardiac neoplasia are not specific and depend on the cardiac site involved and on the other sites of tumor manifestation. Nonspecific signs of neoplasia are common and include anorexia, depression, weight loss, and fever. These signs can be produced by any site of chronic disease; and in large animals pneumonia, peritonitis, enteritis, and liver and kidney disease are considered differential diagnoses, among others. If the tumor involves the pericardium, signs of pericarditis or pericardial effusion such as tachycardia, pain, jugular venous distention, peripheral edema, and weak arterial pulses may be seen. Myocardial involvement of the neoplasia, as is most common with lymphosarcoma, may result in cardiac signs that include tachycardia, cardiac arrhythmias, and cardiac murmur (atrioventricular valve insufficiency) or signs of CHF such as peripheral edema, ascites, and diarrhea. Clinical signs attributable to tumor involvement of the endocardium (e.g., obliteration of a cardiac chamber, valvular obstruction or damage, embolic showering) are rare in large animals.

Tumor involvement of other organ systems and tissues can be manifested by lymphadenopathy, peripheral edema, diarrhea, melena, rectal palpation of abdominal masses, dysphagia, tachypnea, or pleural effusion.

30.4.8.3

Clinical Pathology

Cardiac tumors present no consistent clinicopathologic feature. The complete blood count from horses or cattle with lymphosarcoma may reveal neoplastic lymphocytes. The absence of leukemic changes does not rule out lymphosarcoma. Cattle with lymphosarcoma may test positive for fecal occult blood. A serum chemistry profile may reveal nonspecific changes such as hypoalbuminemia, hyperglobulinemia, or elevated liver enzyme concentrations, depending on the other organ systems affected by the tumor or the animal's debilitation. Diagnosis of the cardiac tumor is based on histopathology of tumor tissue. Tumor cells may be found in pericardial or pleural fluid or adjacent lymph nodes. Serologic evidence (agar gel immunodiffusion or radioimmunoassay) of BLV infection does not confirm a diagnosis of lymphosarcoma, but a negative test result virtually rules out the adult or enzootic form of lymphosarcoma in cattle. No evidence of BLV infection will be found in cattle or horses with the thymic form of lymphosarcoma.

If electrocardiographic evidence of cardiac tumors is present, it is nonspecific. Cardiac tumors may produce cardiac arrhythmias; reduce amplitude of the QRS complexes; or alter the normal appearance of the P, QRS, and T complexes. Two-dimensional echocardiography or an ultrasound examination of the lungs or pleura may show evidence of the cardiac tumor by providing direct evidence of abnormal echogenic masses involving the heart or surrounding tissue, abnormal fluid accumulation, or myocardial functional changes. The ultrasound findings can determine if there are any masses that can be safely biopsied to confirm the diagnosis.

Radiographs may provide evidence of cardiac tumors by showing abnormal soft-tissue densities in the thorax that obscure the cardiac silhouette or the ventral lung borders.

30.4.8.4

Pathophysiology

The most common cause of cardiac tumors in cattle, lymphosarcoma, has a predilection for the right atrial myocardium. Right ventricular myocardial involvement is not uncommon; left atrial or left ventricular involvement is rarer. Involvement of the right side of the heart may result in little or no evidence of heart disease. More commonly the myocardial involvement results in dilation of the chamber involved. As a consequence, the tricuspid valve ring may be dilated, and tricuspid valve insufficiency occurs. Either because of chamber enlargement or infiltration of the myocardial conduction system, cardiac arrhythmias may develop. Myocardial function may be impaired, so that signs of right-sided heart failure become apparent, including tachycardia, peripheral edema, jugular venous distention or pulsations, pericardial or pleural effusion, hepatic congestion, and ascites.

30.4.8.5

Epidemiology

Cardiac tumors are rare in large animals. The most common cause in cattle is lymphosarcoma. Although more than 50% of cattle in some parts of the United States are infected with BLV, less than 1% develop lymphosarcoma.[198,199] In herds with more than 50% of cattle infected with BLV, the incidence of lymphosarcoma may be higher. Cardiac involvement is common in cattle with the adult or enzootic form of BLV, a disease that occurs most commonly in cattle over 4 years old. Thymic lymphosarcoma, which is not associated with BLV infection, also involves the heart but is much less common, occurring in cattle under 30 months of age.

Lymphosarcoma, mesothelioma, and squamous cell carcinoma probably are the most common causes of neoplastic involvement of the equine heart, but the prevalence is not documented.

30.4.8.6

Necropsy Findings

Necropsy findings depend on the type of cardiac tumor. Direct involvement of the myocardium with lymphosarcoma is associated with finding diffuse infiltration by a pale, tan, homogenous tissue that frequently causes enlargement of the cardiac chamber. Involvement of the right atrium (Fig. 30-24) is the most common manifestation of adult enzootic BLV, but any area of the myocardium and pericardium may be involved. Intracavitary extension of the tumor may be evident (see Fig. 30-24). Histologic evaluation of the tumor shows diffuse infiltrates of lymphoblastic cells that obliterate the normal architecture of the myocardium.

Other tumors such as fibrosarcoma, squamous cell carcinoma, pulmonary carcinoma, thymic lymphosarcoma, and mesothelioma (Fig. 30-25) may involve the heart by extension or metastasis from other sites in the thorax.

Fig. 30-24 Postmortem photograph of a cow with lymphosarcoma demonstrating right atrial myocardial infiltration by a tumor and extension of the tumor into the atrial lumen.

Fig. 30-25 Postmortem photograph of a horse with pericardial mesothelioma. Notice the huge heart base tumor mass, along with several smaller masses.

30.4.8.7

Treatment and Prognosis

No definitive treatment exists for neoplasias involving the heart, and the prognosis for survival is poor. Death can be expected within 6 months with most cardiac tumors. Lymphosarcoma of the heart in cattle has a grave prognosis and is usually associated with death within a few months. Short-term improvement has been achieved in cattle with lymphosarcoma treated with a combination of corticosteroids, l-asparaginase, and cytotoxin. Thorascopic pericardiotomy has been used as a palliative treatment in a cow with pericardial lymphoma.[200]

30.4.8.8

Prevention and Control

The prevention and control of BLV can be accomplished by isolation of BLV-positive and BLV-negative animals; use of individual or sterilized supplies such as needles, rectal examination sleeves, tattooing, dehorning, and ear-tagging equipment on each animal; rigorous attention to a vector control program; and feeding colostrum from serologically negative cows only.[199,201] Frequent testing (at least every 6 months) and isolation of serologically positive animals over 6 months of age should be performed.

Prevention and control of other cardiac tumors is not possible.

30.4.9 VASCULAR DISEASE: ANEURYSMS, THROMBOSIS, EMBOLISM

30.4.9.1 Definition and Etiology

Aneurysms, which are vascular dilations, develop from weakening of the medial elastic coat of blood vessels. The medial weakness may be primary or caused by a progression of an intimal atherosclerotic lesion that has enlarged from hemorrhage, calcification, ulceration, and thrombus formation. The specific causes of aneurysms in large animals are unknown, but trauma (internal or external), sepsis, parasite migration, degenerative vascular disease, atherosclerosis, or aging changes (dilation, elongation, and loss of elasticity of blood vessels) may play a role.[202–204] Congenital aneurysms of the sinus of Valsalva have been reported in horses.[205–209] Hypertension can accelerate the degeneration of the wall.

Thrombosis is the formation of a clot that obstructs blood flow in the circulatory system. The causes of thrombosis are numerous and include trauma, venous stasis, and catheterization for administering medication or fluids. Needle penetration, indwelling catheters, thrombogenic solutions, or bacterial contamination can cause thrombosis associated with catheterization. Secondary thrombosis can result from perivascular inflammation caused by cellulitis, lymphangitis, or other sources of bacterial invasion around the blood vessel. Mural thrombi, which occur in cardiac chambers dilated from valvular regurgitation or chronic atrial fibrillation in humans and which are associated with low-flow states, also may occur in large animals, although they have been rarely diagnosed antemortem. Thrombosis usually occurs when intimal disease is present, but it may occur in arteries with no intimal disease when a hypercoagulable state exists such as with dehydration, endotoxemia, anemia, hypotension, stress, or stasis.[210,211] This type of thrombosis is frequently a complication of acute infectious disease (particularly acute toxic enteritis or colitis), neoplasia, or any chronic debilitating disease.

479

480

An embolism is foreign material carried in the bloodstream. Emboli frequently arise from an arterial or venous thrombus, but unusual emboli include catheters and other foreign bodies inadvertently introduced into the circulatory system. In large animals, emboli occur most commonly in bacterial endocarditis, thrombophlebitis, omphalophlebitis, and parasitic arteritis. Emboli may also originate from detachment of mural thrombi in other forms of cardiac disease such as chronic atrial fibrillation and valvular heart disease. Aortoiliac thromboembolism has been reported as a complication of valvular endocarditis in a calf and mural endocarditis in a cow.[212–213]

30.4.9.2 Clinical Signs and Differential Diagnosis

Sites of thrombosis associated with thrombophlebitis are likely to have pain, swelling, redness, and palpable thickening of the involved vein. These signs frequently occur within 12 to 24 hours after catheter removal when the thrombus is associated with catheterization. If there is bilateral jugular venous thrombosis, sudden, marked swelling of the head may occur. If the thrombosis involves the terminal aorta and iliac arteries in horses, the signs are frequently a vague hindlimb lameness, exercise intolerance, or poor performance. These nonspecific signs make it necessary to rule out lameness from other causes, cardiac disease, or respiratory problems. Failure to ejaculate has been reported in breeding stallions with aortoiliac thrombosis.[214] Aortoiliac thrombosis in horses also is characterized by heavy sweating after exercise, except over the hindlimbs, which

are cool. With severe aortoiliac thrombosis the affected limb can be cool to the touch at rest or can be cold with no palpable femoral arterial pulse. Saphenous vein filling is slow or nonexistent in affected horses, and the metatarsal and other peripheral arterial pulses of the hindlimbs are weak. Rectal examination may be normal; or weak, absent, or asymmetric iliac pulses may be palpated. Fremitus of the iliac arteries or terminal part of the aorta may be palpated. The terminal part of the aorta may feel larger or firmer than normal, or an aneurysmal dilation may be detected. Similarly with verminous arteritis of the cranial mesenteric artery, a thickened, dilated cranial mesenteric artery or aorta may be palpated that may be firmer than normal and have a weak pulse, or fremitus may be palpated. In calves with aortic or aortoiliac thrombosis weakness, lameness, knuckling, paresis or paralysis of the hindlimbs, inability to rise, and cold hindlimbs lacking a femoral arterial pulse have been described.[212,215–217]

The signs attributable to embolism and thrombosis may be identical. Embolism usually is manifested by an acute episode of pain or fever, abnormal pulsation in a peripheral vessel, or a change in skin temperature. If there is peripheral vessel showering, superficial veins may be collapsed, and muscular weakness may be present. Embolic showering usually occurs in animals suspected of having or known to have thrombus formation.

Clinical signs associated with an aneurysm depend on the location of the aneurysm and may vary from being asymptomatic, to being a noticeable enlargement or mass associated with a blood vessel, to causing colic, syncope, seizures, or sudden death on rupture. In a peripheral artery a pulsatile, expansile mass may be visualized or palpated. Other considerations for this finding are a false aneurysm and an arteriovenous fistula. A false aneurysm is clinically indistinguishable from a true aneurysm but can be distinguished ultrasonographically. A false aneurysm is caused by a break in the continuity of all three coats of the arterial wall rather than in the tunica media alone. This results in extravascular accumulation of blood in adjacent tissues. Signs attributed to low blood flow such as lameness, colic, or edema may be present with arterial aneurysms. Aneurysms of the cranial mesenteric artery frequently are manifested as chronic episodes of colic. With involvement of major cardiac vessels there may be pain, an auscultable heart murmur, rapid tachycardia, signs of CHF, acute onset of pulmonary edema, or sudden death when the aneurysm ruptures. The latter signs make aneurysms difficult to distinguish from valvular heart disease or cardiomyopathy. One cause of an aorticocardiac fistula in horses is the result of rupture of an aneurysm of the sinus of Valsalva.[205–209]

30.4.9.3

Clinical Pathology

Aneurysms or pseudoaneurysms may be visualized radiographically as soft-tissue density masses continuous with a vessel wall (true aneurysm) or extending outward from a vessel wall (false aneurysm).[203,204] However, the majority of the aneurysms involving the aorta and aortic root are not visible radiographically. Echocardiography is useful in the diagnosis of aneurysms involving the aortic root (Fig. 30-26).[206–209] Angiography can be used in the diagnosis of peripheral vessel swelling or suspected thrombosis but is of little use in diagnosis of aneurysms of major vessels in adult animals. Ultrasonography may be used for the diagnosis of aneurysms or thrombosis of major arteries and peripheral vessels. In aortoiliac thrombosis of horses, ultrasound has been used to determine the origin of the thrombus and the extent of occlusion of the involved arteries (Fig. 30-27).[218] Abdominal ultrasonography of the upper left flank dorsal to the left kidney has been used to diagnose aortoiliac thrombosis in calves.[215] Diagnostic ultrasound has been used to detect thrombi in the caudal vena cava in cattle.[219,220] Although the occluding thrombus is not imaged, the detection of a distended oval or round caudal vena cava, rather than the normal triangular vessel, in the eleventh and twelfth intercostal spaces is consistent with this diagnosis in cattle. Thrombi have been detected

ultrasonographically in the hindlimb in both horses and cattle.[221–224] Jugular vein thrombophlebitis has also been diagnosed ultrasonographically in both horses and cattle (Fig. 30-28).[225,226] Similarly, diagnostic ultrasound has been used to image the cranial mesenteric artery, its branches, and the aorta in horses with verminous arteritis.[227] Aneurysms appear as dilated vascular structures or vascular outpouchings continuous with the vessel wall,[205] whereas a thrombus is apparent as a hypoechoic to echogenic mass within a blood vessel.[226] Cavitation of an occlusive thrombus is suggestive of septic thrombophlebitis (see Fig. 30-28), whereas a nonseptic thrombus usually has a homogeneously hypoechoic to echoic appearance.[226] Complete occlusion of the vessel can be determined ultrasonographically, or flow within an aneurysm or alongside a thrombus determined. Doppler ultrasound provides a more sophisticated method for determining blood flow and vessel patency. Computer-assisted radiographic techniques such as computed tomography and digital subtraction angiography may also be useful but have not yet been widely used in large animals. The latter methods may be limited in usefulness by the size of large animals and the cost of the equipment and procedures.

Fig. 30-26 Two-dimensional echocardiogram of a horse with a ruptured sinus of Valsalva aneurysm. Not the defect in the right side of the aorta at the sinus of Valsalva *(vertical arrow)* extending into the right atrium *(horizontal arrow)*. The right atrium *(RA)*, right ventricle *(RV)*, left ventricle *(LV)*, left atrium *(LA)*, and aorta *(AO)* can be seen in this left ventricular outflow tract view.

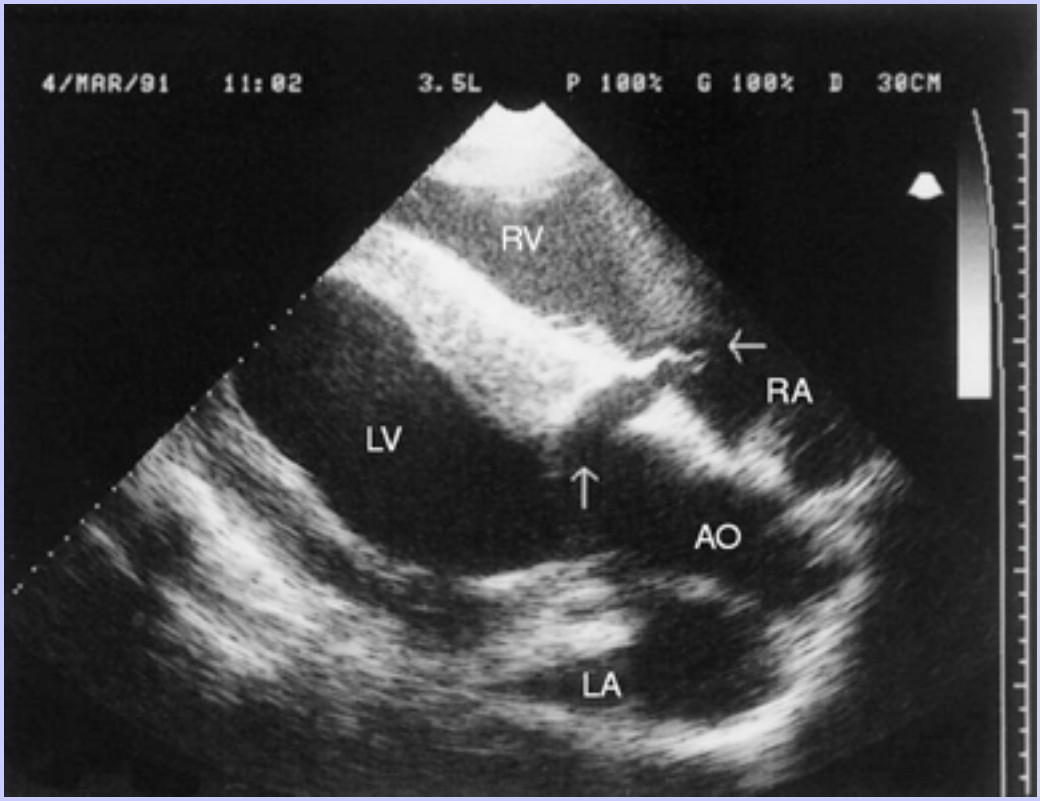

Fig. 30-27 Transverse sonogram of a large somewhat heterogeneous thrombus *(arrow)* in the terminal portion of the aorta extending into the right internal and external iliac arteries.

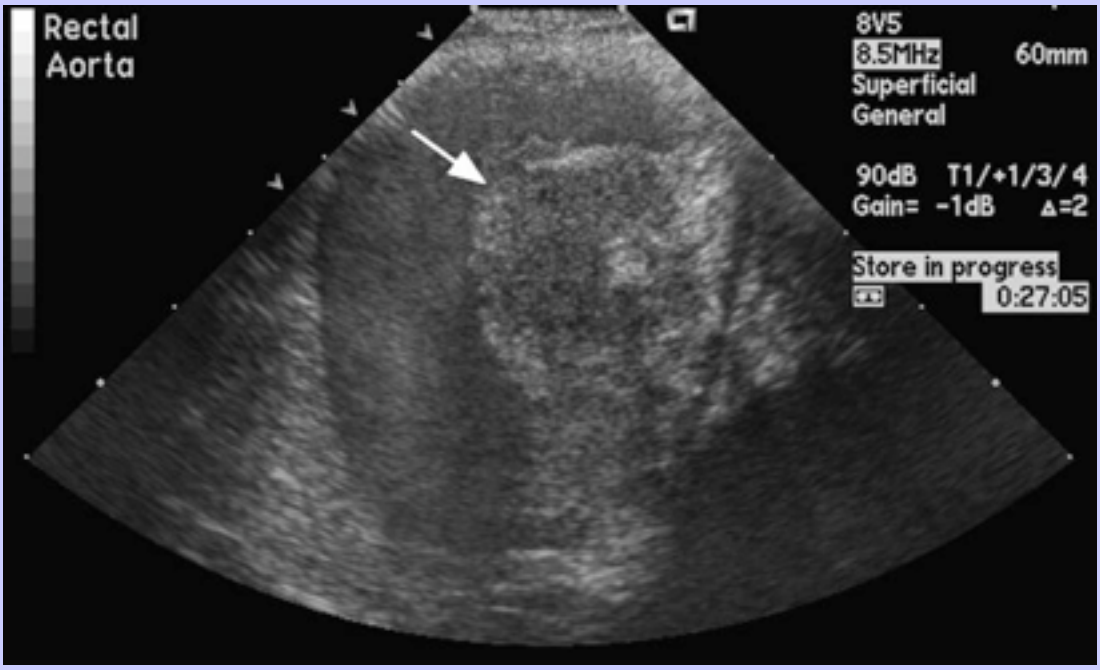
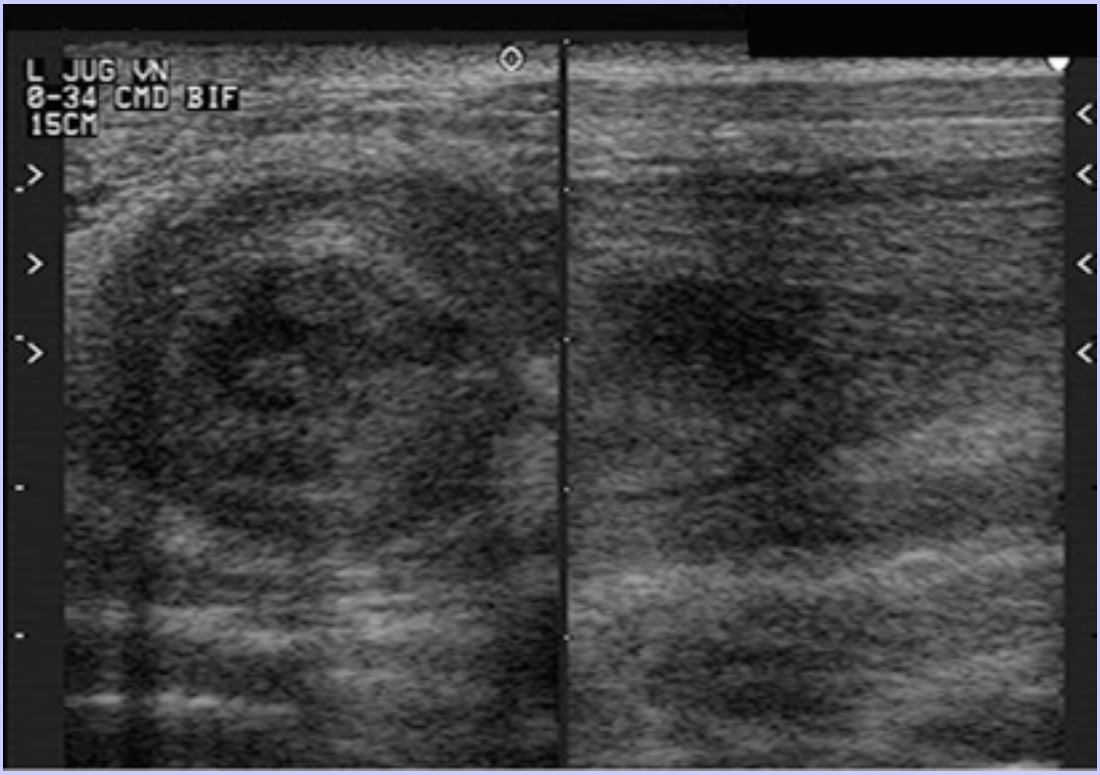


In the case of catheter-associated thrombosis, a positive catheter tip culture (>10^3 colony-forming units), along with a positive blood culture, provides evidence of septic thrombophlebitis.[228] An aseptic ultrasound-guided aspiration of the cavitary lesion within a heterogeneous thrombus can be performed, and the aspirate submitted for culture and sensitivity testing.[226] Septic thrombophlebitis from any cause or embolic showering of septic thrombi may be accompanied by neutrophilic leukocytosis and elevation in fibrinogen concentration.

Fig. 30-28 Sonogram of the left jugular vein from a horse with septic thrombophlebitis. Note the cavitary appearance in the center of the thrombus consistent with infection.



30.4.9.4

Pathophysiology

Irritation of the intimal lining of a blood vessel, stasis of blood flow, or the existence of a hypercoagulable state triggers the clotting cascade and sets the stage for the development of thrombosis. Further injury causes hemorrhage, more thrombosis, ulceration, and calcification. These in turn can compromise the media of the vessel, predisposing to aneurysm formation, and impinge on the lumen of the vessel, causing obstruction to blood flow. Either aneurysm or thrombosis can occlude blood flow to vital structures or organs, resulting in ischemia.

Thrombosis in any sizable vein causes venous hypertension, passive congestion, and subsequent edema and pain of the structure. As the thrombus matures, it adheres to the wall more, but with clot retraction and lysis, recanalization may occur. However, parts of the thrombus may protrude into the moving bloodstream and serve as the source of embolic showering, even during thrombus organization. The most common site for an embolus to lodge has not been established in large animals; the femoral and iliac arteries are common locations in humans. Emboli usually lodge at bifurcations, where the caliber of the artery is suddenly reduced.

The most common outcome of aneurysm of a major vessel is thought to be rupture. Rupture of sinus of Valsalva aneurysms into the right atrium, right ventricle, and interventricular septum has been reported in the

horse.[206–208] Ventricular tachycardia often occurs with rupture of an aortic sinus of Valsalva aneurysm and dissection into the interventricular septum.[207,208] Unruptured aneurysms may have other complications such as thrombosis or embolization of the thrombus. The frequency of rupture or embolic showering from thrombosis is unknown in animals.

30.4.9.5

Epidemiology

The significance of thromboembolism in large animals is poorly defined. Spontaneous thromboembolism is most commonly associated with parasitism in horses, and the aorta and cranial mesenteric arteries are the sites most frequently involved.[229] Aortoiliac thrombosis is also a recognized syndrome diagnosed most frequently in heavily exercised horses. Although parasitism has been associated with aortoiliac thrombosis in horses, other causes of this syndrome are probable but have not been elucidated. Thrombotic disease can occur in any animal having repeated intravenous injections or being catheterized for administration of medication or fluids but is particularly common in horses with acute toxic enteritis or colitis.

Arteriosclerosis is recognized in horses and in cattle. In cattle the lesion is most frequently caused by excessive vitamin D_3 supplementation or by ingestion of calcinogenic plants such as *Solanum malacoxylon, Cestrum diurnum,* or *Trisetum flavescens*.[230] In horses the arteriosclerotic lesions were caused by lesions induced by *Strongylus vulgaris*.[231]

Aneurysms are uncommon in large animals but have been documented as the cause of sudden death in breeding stallions and racing thoroughbred and standardbred horses.[208,231] Aneurysms of the sinus of Valsalva are probably a common cause of aortic rupture in older horses and are probably congenital in horses, as they are in humans.[205–208] Aortic root rupture also occurs with the presence of a preexisting aneurysm and has been associated with medial necrosis of the aorta.

30.4.9.6

Necropsy Findings

Aneurysms are detected grossly as dilations of the involved blood vessel. Aneurysms of the sinus of Valsalva are characterized by an absent tunica media in the wall of the aorta, causing the aneurysmal dilation.[205,208] 481
Rupture of a sinus of Valsalva aneurysm may occur into the right atrium, right ventricle (Fig. 30-29), or 482
interventricular septum, resulting in an aortic cardiac fistula and volume overload.[205–209] Rupture through the tricuspid valve or chordae tendineae may also occur. Subendocardial dissection of blood down the interventricular septum may occur, with subsequent rupture into the left ventricle and of the mitral chordae tendineae also reported. Aneurysms of the major vessels leaving the heart may involve more than one vessel by dissection and hemorrhage. Aneurysms may contain thrombi or parasites, and there may be evidence of embolic showering of thrombi into peripheral vessels or other organ systems, especially the lungs. Histologically there may be necrosis and inflammation at the site of the aneurysm with foci of mineralization.

Thrombosis and arteriosclerotic lesions are recognized as rounded, well-demarcated fibrous plaques frequently located in the thoracic and cranial abdominal aorta (Fig. 30-30). The plaques may contain a central calcified core or parasitic larvae. Microscopically there is a thin layer of fibrin, platelets, and inflammatory cells in early lesions, whereas older lesions have a greater fibrous component. Thrombotic lesions may be associated with proliferation of the underlying aortic intima. In horses, parasitic larvae may be found.

Fig. 30-29 Ruptured sinus of Valsalva aneurysm in a horse with acute onset of colic and right-sided congestive heart failure. The large aneurysm *(arrow)* ruptured through the tricuspid valve, creating an aortic-cardiac fistula.

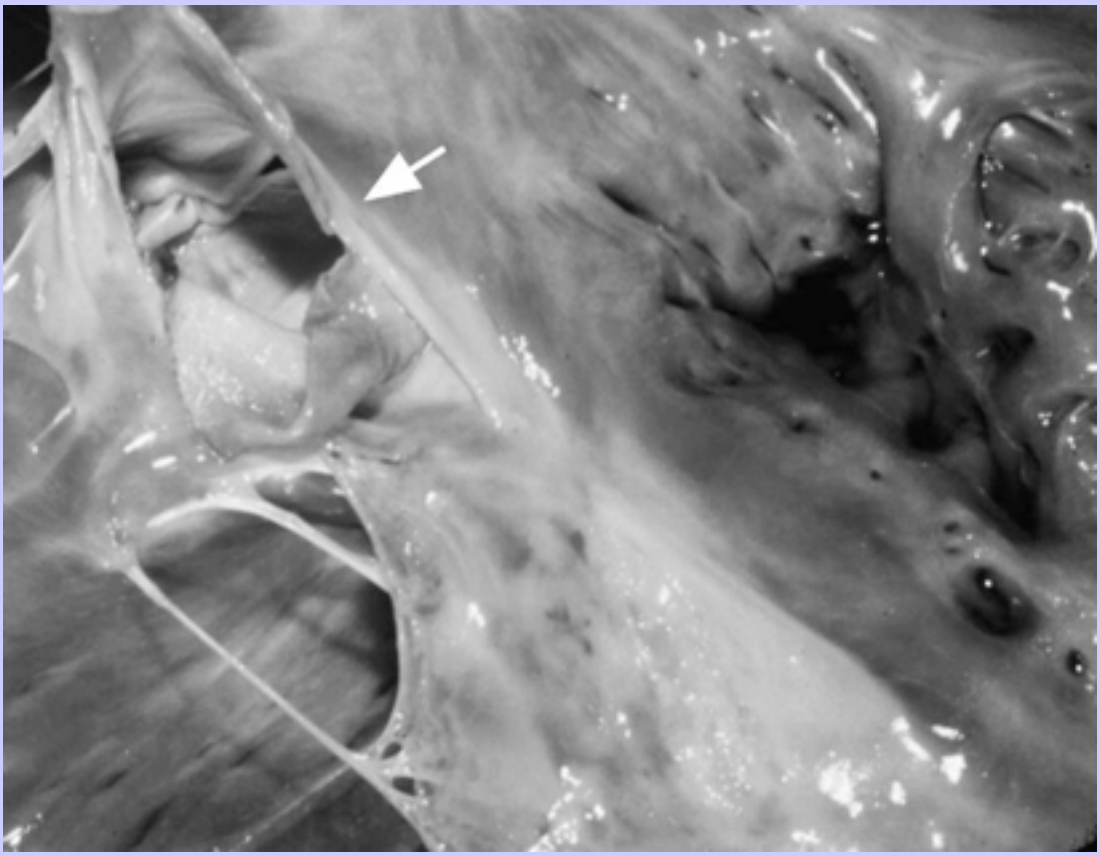


Fig. 30-30 Ascending aorta from a horse that experienced an acute onset of uniform ventricular tachycardia after exercise and died within 3 hours of onset. Notice the irregular calcified surface of the aorta, consistent with atherosclerosis.

30.4.9.7

Treatment and Prognosis

Aneurysms of major vessels carry a guarded to grave prognosis because surgical correction is rarely attempted and spontaneous rupture is thought to be relatively common. Intact aneurysms of the sinus of Valsalva can be detected echocardiographically, and once an aneurysm has been detected, the horse should be removed from all athletic competition because of the risk of rupture.[205]

Treatment of thrombosis consists of removal of the catheter, if present, and resting the affected vessel. Warm compresses or hydrotherapy may be helpful in some animals. Support wraps may be useful to control swelling. The effectiveness of anticoagulant therapy (aspirin at 100 mg/kg once daily PO or heparin at 30 U/kg SC twice daily) or antiinflammatory drugs for dissolving a thrombus is questionable. Anticoagulant therapy may be useful in preventing additional thrombus formation or propagation of the existing thrombus. Ultrasonographic guidance can be used to obtain a sterile aspirate of the cavitated area of the thrombus for culture and sensitivity testing when septic thrombophlebitis is suspected.[226] Broad-spectrum bactericidal antimicrobial therapy should be instituted for suspected septic thrombophlebitis or when a cavitated thrombus is detected ultrasonographically and modified, if necessary, based on the results of culture and sensitivity

testing.[226] Bacterial endocarditis, particularly involving the tricuspid valve, is a potential complication of septic jugular vein thrombophlebitis. With the exception of a jugular venous thrombus, surgical removal of an embolism or thrombus is rarely attempted in large animals. Surgical resection of a jugular vein with septic thrombophlebitis has been performed successfully when the surgeon could ligate the affected vein above and below the thrombus. Although the prognosis for complete resolution of the thrombophlebitis is guarded, especially if the thrombus is infected, many veins do recannulate with complete resolution of the thrombus and without vascular stricture. However, the time course is slow, and persistent local induration and obstruction to blood flow may persist.

30.4.9.8 Prevention and Control

Thrombosis and embolization from intravenous catheters can be prevented by aseptic insertion, stabilization of the catheter, use of topical antiseptics, application of a sterile dressing, daily inspection of the catheter and vein, and replacement of the catheter at another site (preferably in another vein) if phlebitis occurs. Attempts should be made to place long-term catheters in large peripheral or central veins, where contact between the endothelium and catheter is minimized and medications administered are diluted by the large volume of blood flow. Catheters left in place for prolonged periods should be of silicone rubber or polyurethane.[228] Aspirin (100 mg/kg PO once daily, ruminants; 17 mg/kg every other day, horses) and low-dose heparin (30 U/kg SC twice daily, ruminants and horses) therapy should be considered in maintaining a catheter without thrombus formation in septic or endotoxic patients. Horses are much more prone to jugular thrombosis than are ruminants.

Parasite control is important in the control of thromboembolic disease and aneurysm in horses. Aneurysms of the sinus of Valsalva may be detected by routine echocardiographic screening of horses. In cattle, arteriosclerotic lesions are prevented by proper calcium and vitamin D supplementation.

483

30.4.10 ATRIAL FIBRILLATION

30.4.10.1 Definition and Etiology

Atrial fibrillation is a cardiac arrhythmia characterized by a lack of coordinated atrial electrical activity. It is caused by an abnormality of impulse conduction that results from unidirectional conduction block and random reentrant activation of the atria. High resting vagal tone, commonly found in horses, shortens the action potential duration in atrial myocardial cells, making atrial fibrillation more likely to occur. Atrial fibrillation can occur in the presence of atrial enlargement from atrial myocardial disease, atrioventricular valvular regurgitation, ventricular failure (organic atrial fibrillation), myocarditis, endocarditis, autonomic nervous system imbalance, electrolyte or acid-base disturbances, anesthetic drugs or tranquilizer administration, or unknown causes (functional or benign atrial fibrillation).

30.4.10.2 Clinical Signs and Differential Diagnosis

Large animals with atrial fibrillation may be asymptomatic at rest, and atrial fibrillation may be detected as an incidental finding in an otherwise normal horse. Horses that perform in rigorous athletic events usually have a history of exercise intolerance or poor performance. Other complaints may be exercise-induced epistaxis, respiratory disease, weakness, syncope, myopathy, colic, or CHF. Cattle with atrial fibrillation usually have gastrointestinal disease.[232,233] Atrial premature depolarizations have also been reported in cattle with

gastrointestinal disease and may be a prelude to the development of atrial fibrillation.[233] Foot rot, pneumonia, and endocarditis also have been associated with atrial fibrillation in cattle. Anorexia and decreased milk production are common in cattle with atrial fibrillation. Atrial fibrillation and the clinical signs associated with it in horses and in cattle can be paroxysmal. Paroxysmal atrial fibrillation usually lasts no more than 24 to 48 hours before spontaneous conversion to sinus rhythm occurs.[234] Spontaneous conversion usually occurs only in horses with small atria or in cattle with correction of the underlying problem. Transient potassium depletion associated with the administration of furosemide is a common cause of paroxysmal atrial fibrillation in horses. The administration of bicarbonate "milkshakes" has also been implicated in horses with paroxysmal atrial fibrillation.

Animals with atrial fibrillation have an irregularly irregular cardiac rhythm. In horses with atrial fibrillation, there is a high degree of underlying periodicity.[235] The heart sounds vary in intensity, and no fourth heart sound is audible. The heart rate may be slow, normal, or elevated. In cattle with severe abdominal disease, the heart rate usually reflects the severity of the underlying disease. In horses the resting heart rate is usually normal to slightly elevated and is rarely above 50 beats/min, unless there is underlying myocardial or valvular disease. During exercise, horses with atrial fibrillation develop abnormally high heart rates that are usually 40 to 60 beats/min higher than expected for each level of exercise, far exceeding the peak heart rate of 240 beats/min at maximal exercise.[236,237] The arterial pulse varies in intensity. A pulse deficit occurs when two beats occur in rapid succession and is infrequent unless the heart rate is elevated. Cardiac murmurs of grade 3/6 or louder are present in less than 50% of the horses and in even fewer cattle with atrial fibrillation.[238–240] Signs of CHF (peripheral edema, jugular venous distention) may be present in some animals, but they are not caused by the arrhythmia. In these cases the atrial fibrillation occurs secondary to the atrial enlargement that occurs with the underlying valvular or myocardial disease.

The lack of an auscultable fourth heart sound in the presence of an irregular cardiac rhythm with no underlying regularity distinguishes atrial fibrillation from other cardiac arrhythmias. Sinus arrhythmia, which is also an irregular rhythm, has an audible fourth heart sound. Ventricular and atrial ectopic beats usually occur with a relatively regular underlying rhythm. A complicated ventricular rhythm with more than one focus of activation may have characteristics similar to those of atrial fibrillation and must be distinguished from it by an ECG. Atrial tachycardia with varying degrees of atrioventricular block has similar characteristics, and the underlying fourth heart sounds may be missed if the animal is auscultated in a noisy environment.

30.4.10.3

Clinical Pathology

In cattle with atrial fibrillation, acid-base and electrolyte disturbances occur frequently and are most likely attributable to the underlying primary disease. Most cattle with atrial fibrillation have gastrointestinal disease, and the most consistent acid-base disturbance is metabolic alkalosis.[240] Hypocalcemia, hypokalemia, and hypochloremia may also be seen in cattle with atrial fibrillation. Experimental induction of metabolic alkalosis with hypokalemia in cattle has been associated with the development of atrial fibrillation.[241] Most horses with atrial fibrillation have normal electrolytes, although the fractional excretion of potassium may be low, particularly in horses that sweat excessively or are routinely receiving furosemide for exercise-induced pulmonary hemorrhage.

The diagnosis of atrial fibrillation is made by ECG. The arrhythmia is characterized by an irregular R-R interval. The ventricular response rate is low, normal, or high, depending on the presence of heart disease or the severity of the primary disease. The ventricular complexes have normal polarity and amplitude but vary slightly in appearance from beat to beat. Similarly, the QT interval and the appearance of the T wave vary. P

waves are absent, replaced by fine undulations of the baseline called *fibrillation* or *f waves*. In some leads the f waves are barely visible, particularly in cattle (Fig. 30-31).

The echocardiogram is used to determine whether cardiac disease is present. The most significant change associated with the arrhythmia is a mild reduction in shortening fraction (24% to 32%) that occurs, in part, secondary to the loss of the atrial contribution to ventricular filling.[242] Absence of the second (atrial) opening of the mitral valve, corresponding to atrial contractions, is also detected with atrial fibrillation.[243] Conversion to sinus rhythm usually results in these echocardiographic findings returning to normal within several days, if there is no underlying myocardial disease.[242,244] Similar findings were reported in horses with mitral and aortic regurgitation after conversion to normal sinus rhythm.[244] In many large animals with atrial fibrillation, no evidence of heart disease can be detected echocardiographically; these animals are often considered to have "lone" atrial fibrillation. Abnormal echocardiographic dimensions, if detected, indicated that underlying heart disease is present. Measurement of the maximal left atrial dimension in the two-chambered view of the left atrium and left ventricle from the left cardiac window should be performed to determine whether there is left atrial enlargement. This measurement is a more sensitive indicator of left atrial enlargement than the left atrium—to—aortic root ratio. In normal horses the left atrial diameter in this view should be less than or equal to 13.5 cm.

Cardiac catheterization reveals normal cardiac output and blood pressure measurements in most conscious horses with atrial fibrillation, but conversion to normal sinus rhythm may induce a reduction in mean right atrial, pulmonary arterial, and aortic pressures.[245] Similar studies have not been reported in cattle.

483

484

Fig. 30-31 ECGs showing atrial fibrillation in a horse **(A)** and cow **(B).** The irregular QT intervals and absence of P waves are apparent. *Arrows* point to fibrillation waves, which are apparent only in **A.**

30.4.10.4

Pathophysiology

Experimentally rapid stimulation of the atrium can initiate atrial fibrillation, which can be sustained if the animal has a large heart and sufficient vagal tone.[233,246–249] In horses and cattle the normal atria may be large enough to support atrial fibrillation once it is established. In addition, both species have a high vagal tone at rest. This combination of factors may be responsible for the large number of benign or functional cases of

atrial fibrillation in large animals. The ventricular response during atrial fibrillation results from rate-dependant concealment of atrial fibrillation wavelets bombarding the AV node.[235] Cardiac diseases such as endocarditis, atrioventricular valvular regurgitation, and CHF that result in atrial enlargement and rapid stimulation of the atria provide a setting in which atrial fibrillation can develop and can be sustained naturally. Microscopic cardiac pathology might also create the proper setting for the development of conduction block and reentry.

During atrial fibrillation there is no coordinated contraction of the atria; thus ventricular filling is passive. Although this might be expected to reduce cardiac output, there is no evidence that this occurs in resting horses without concurrent mitral or aortic regurgitation.[245] In horses with aortic regurgitation (n = 2) or aortic and mitral regurgitation (n = 3), a decreased cardiac output was detected compared with horses without valvular insufficiencies before conversion.[244] The cardiac output increased significantly in warmblood horses with valvular regurgitation after conversion. During exercise, however, the heart rate of horses with atrial fibrillation exceeds normal limits, often by 40 to 60 beats/min for each level of exercise. This results in a decreased cardiac output and the resultant exercise intolerance that occurs in horses performing high-intensity athletic work.[236] Blood flow to other organs and viscera, although not studied, may be altered in large animals with atrial fibrillation, resulting in reduced gastrointestinal motility, colic, reduced muscle blood flow, and poor milk production.

Atrial pressures are elevated in horses with atrial fibrillation.[245,250] Sustained high pressure is likely to produce dilation of the atria. With progressive dilation, secondary atrioventricular valve regurgitation may occur. During atrial fibrillation blood flow to the atrial myocardium is reduced, and progressive fibrosis can also be a consequence of chronic atrial fibrillation. Sustained atrial fibrillation may result in progressive cardiac disease, although it is usually well tolerated in the horse.

30.4.10.5

Epidemiology

Standardbred, thoroughbred, and draft horses have been reported to have the highest incidence of atrial fibrillation.[237–239] Racehorses have been diagnosed most frequently, but atrial fibrillation has been found in all types of horses.[238,239,244] Horses of all ages are susceptible to atrial fibrillation; however, atrial fibrillation occurs infrequently in ponies, foals, weanlings, and yearlings. Older horses, ponies, foals, weanlings, and yearlings with atrial fibrillation more frequently have underlying heart disease associated with the arrhythmia.

In cattle, atrial fibrillation is diagnosed more frequently in dairy cattle than in beef cattle, but there is no apparent breed predilection.[232,240] It is commonly associated with gastrointestinal disease or abdominal pain in cattle.[232,233,240] Foot rot and pneumonia can also be associated with the development of atrial fibrillation in cattle.

30.4.10.6

Necropsy Findings

Many cattle and horses have “lone” atrial fibrillation without apparent underlying heart disease, so the necropsy findings reflect the primary disease. Microscopic cardiac pathology has been found in horses with atrial fibrillation that consists of focal atrial myocardial fibrosis, microvascular alterations, and cardiac nerve abnormalities.[251–253] Multifocal or large areas of myocardial fibrosis were detected in dairy cows with idiopathic atrial fibrillation.[254] Whether these changes predisposed to the development of atrial fibrillation, were a consequence of atrial fibrillation, or are aging changes has not been established. A minority of horses

and cattle have endocarditis, CHF, or valvular lesions; and the necropsy findings reflect these conditions. In horses with atrial fibrillation, mitral valve disease was the most common valvular lesion.[239] Pharmacologic and transvenous electrical cardioversion are both options for conversion of atrial fibrillation to normal sinus rhythm in horses.[239,255–262]

30.4.10.7

Treatment and Prognosis

Quinidine is the drug of choice to convert atrial fibrillation to normal sinus rhythm in horses and cattle. The drug is a negative inotrope at high dosages, causes systemic hypotension, increases the ventricular response rate, and can produce undesirable side effects and toxicity; thus it must be used with caution. In animals with CHF, quinidine therapy has considerable risk.[239] Because most large animals have little or no underlying cardiac pathology, treatment with quinidine is successful in restoring normal sinus rhythm. Treated animals should be monitored frequently by physical examination, with careful auscultation and ECG recording. Continuous ECG recording using radiotelemetry should be performed throughout treatment, if possible.[258] Animals should have normal acid-base balance and electrolyte concentrations before treatment. They should be adequately hydrated, allowed to drink and eat, or given additional oral fluids (horses) or intravenous fluids (cattle) during therapy. The intravenous administration of quinidine gluconate is successful in converting horses with recent-onset atrial fibrillation to sinus rhythm.[259] Quinidine gluconate is most successful when administered to horses with atrial fibrillation of 2 weeks or less. However, quinidine gluconate had been successful in converting horses with atrial fibrillation of 2 to 4 weeks duration. Horses with longer durations of atrial fibrillation should be treated PO with quinidine sulfate. Quinidine is poorly absorbed after oral administration to cattle and so must be given by intravenous infusion to obtain therapeutic concentrations. Cattle should be given intravenous fluids during quinidine infusion. Quinidine therapy should always be discontinued when conversion to normal sinus rhythm occurs.

484

485

Quinidine sulfate is the preparation most economically used in large animals, although quinidine gluconate has resulted in successful conversion of a cow with atrial fibrillation.[263] Before therapy, a baseline ECG is recorded. Horses are given a dose of 22 mg/kg (1 g/100 lb) of body weight in a suspension of water via nasogastric tube. At 2 hours (time by which blood concentration of quinidine should have peaked), horses are evaluated closely for idiosyncratic or toxic reactions such as nasal edema, cutaneous reactions (urticaria or wheals), laminitis, colic, diarrhea, or ataxia. If no abnormalities are noticed, an ECG is recorded. If conversion to normal sinus rhythm has not occurred and the QRS duration is not greater than 25% of the pretreatment QRS duration, an additional dose is administered. Two hours after each dose administered via nasogastric intubation, an ECG is recorded. If there has been no conversion to normal sinus rhythm, another dose is administered, up to a maximum of four doses. A plasma quinidine concentration should be obtained 1 hour after the fourth dose administered every 2 hours to be sure that the horse will be able to tolerate another dose without experiencing toxicity. If the QRS complex is prolonged by more than 25% of the pretreatment value or if a fast (more than 80 to 100 beats/min) supraventricular arrhythmia, ventricular rhythm, colic, diarrhea, ataxia, nasal edema or laminitis develops, therapy should be discontinued. Although laminitis is a frequently reported complication of quinidine sulfate therapy, the actual incidence of laminitis associated with the administration of quinidine is rare.[258] Nasal mucosal edema, neurologic signs, and prolongation of the QRS duration to greater than 25% of the pretreatment value are all signs of quinidine toxicity that, if detected, should prompt discontinuation of the drug. Colic, associated with high dosages of quinidine, should also prompt discontinuation of treatment (at least for this attempt at conversion). If conversion has not occurred after a total of four to six doses (one every 2 hours) or after a cumulative dose of 88 to 132 mg/kg of quinidine sulfate has been administered, treatment intervals should be prolonged to every 6 hours (half-life of

quinidine).[258] The every-6-hour treatment can be continued until the horse converts or shows toxic or adverse side effects or the owner elects to discontinue treatment. The advantage of this treatment regimen is that steady-state plasma and myocardial concentrations of the drug are achieved. There is less quinidine toxicity, a lower total dose of quinidine sulfate is used, and horses that did not convert after the standard every-2-hour administration may convert with this treatment regimen. Digoxin at 0.011 mg/kg PO twice daily can then be added to the therapeutic regimen if conversion has not occurred in 24 to 48 hours and appears to be helpful in some horses. The concurrent administration of digoxin and quinidine will result in increased plasma digoxin concentration. Therefore, digoxin concentrations should be monitored beginning the second day of combined quinidine and digoxin therapy to prevent digoxin toxicity. If this is not possible, the horse should not receive more than 2 days of combined digoxin and quinidine therapy. Transvenous electrical cardioversion has been very successful in converting horses to normal sinus rhythm and is particularly useful in horses in which adverse or toxic reactions to quinidine prompted discontinuation of antiarrhythmic therapy with the result that conversion to normal sinus rhythm was not achieved.

Quinidine sulfate at a dose of 48 mg/kg is suspended in 4 L of saline or lactated Ringer's solution when cattle are treated for atrial fibrillation. This dose is administered at a rate of 1 L/hr. Intravenous fluids are administered simultaneously in the opposite jugular vein. Cattle should be monitored continuously during the infusion. Cattle frequently become depressed and develop diarrhea during the infusion of quinidine. These signs are side effects, and therapy can be continued. The infusion rate should be slowed if the ventricular response rate exceeds 100 beats/min. If the QRS complex is visibly prolonged or a fast (more than 120 beats/min) supraventricular arrhythmia or ventricular rhythm develops, therapy is temporarily discontinued. Just before conversion, some cattle have blepharospasm and are ataxic. The infusion should be discontinued as soon as conversion occurs. Therapy should be discontinued after the 4 L infusion, even if conversion to normal sinus rhythm has not occurred.

During quinidine therapy the ECG shows predictable changes. The fibrillation waves become coarser and less frequent. The R-R interval becomes more regular as the heart rate increases. Before conversion there may be a rapid regular atrial rate with more than one P wave for each QRS complex (atrial tachycardia with atrioventricular block). At the time of conversion, a single P wave is present for each QRS complex. Frequently a large T_a wave is present and the ST segment is elevated. The ECG should be normal within 12 hours of conversion. A continuous 24-hour ECG is recommended in horses with atrial fibrillation after conversion to determine if frequent atrial premature depolarizations are present. If the continuous ECG is normal during the 24 hours after conversion and myocardial function has returned to normal, the horse can be returned to training. If frequent supraventricular premature extrasystoles are detected, the horse should be rested and treatment with corticosteroids may be considered for a possible myocarditis. The horse should not be returned to work until the atrial premature depolarizations have resolved. Intravenous amiodarone and flecainide have been used to convert horses with atrial fibrillation.[261,262] However, ventricular arrhythmias were common in horses given flecainide, limiting its usefulness as a treatment for atrial fibrillation in horses.[262]

Digoxin is used before quinidine therapy in horses and cattle with fast heart rates. The ventricular response rate should be less than 60 beats/min in horses and 100 beats/min in cattle before quinidine therapy. One or two doses of digoxin are administered before initiation of quinidine therapy in horses with only mild tachycardia. In horses with very labile heart rates or problems with supraventricular tachycardia during a previous conversion, digoxin is administered for up to 5 to 7 days before initiation of quinidine therapy. Digoxin should be administered at a dose of 11 µg/kg twice daily PO to horses. Cattle are given digoxin IV by infusion of 0.86 µg/kg/hr or 11 µg/kg three times daily. The side effects of quinidine treatment such as rapid supraventricular tachycardia may be decreased in animals pretreated with digoxin. Digoxin is also indicated as

a pretreatment in horses with atrial fibrillation and very low FS (<24%), indicative of underlying myocardial disease. Transvenous electrical cardioversion should be considered in horses with high heart rate responses to stimulation or during prior quinidine therapy.

Cattle with primary gastrointestinal disease that is treated successfully frequently convert to normal sinus rhythm spontaneously. Spontaneous conversion usually occurs within 5 days of resolution of the primary problem; therefore treatment is delayed for this period.[240] Cattle that do not convert spontaneously in 5 days, have chronic gastrointestinal problems, or have atrial fibrillation with adverse hemodynamic effects (poor peripheral perfusion, weak arterial pulses, pulse deficit) are selected for quinidine therapy. The prognosis for cattle with atrial fibrillation is good if the primary problem has been resolved and conversion to normal sinus rhythm occurs. Prognosis for cattle with chronic gastrointestinal disease is guarded, but many show improved appetite and milk production when atrial fibrillation is resolved. Unless heart disease is present, few cattle experience a recurrence of atrial fibrillation. A small percentage of cattle fail to respond to quinidine therapy, and their prognosis is guarded to poor because milk production and appetite are intermittently poor and heart disease can be progressive.

Horses with paroxysmal atrial fibrillation have a good prognosis for return to performance, and few have a recurrence of the arrhythmia. Predisposing factors such as transient potassium depletion should be removed, if possible, by discontinuing the furosemide administration or adding oral KCl to the diet. Oral bicarbonate milkshakes should be avoided. Horses with “lone” sustained atrial fibrillation have a good prognosis for conversion to normal sinus rhythm and a return to previous performance level.[238,239] Horses with sustained atrial fibrillation associated with mild to moderate valvular regurgitation and atrial enlargement often have a recurrence of atrial fibrillation but can usually be successfully converted when indicated. Horses with heart rates greater than 60 beats/min or with signs of CHF have a guarded to grave prognosis, and conversion to sinus rhythm is rarely warranted. Treatment of the underlying cardiac disease, if possible, is warranted, and the horse should be treated for CHF with digoxin, diuretics, and vasodilators as needed. Recurrence of atrial fibrillation and side effects of quinidine therapy are more frequent in horses that have had atrial fibrillation for longer than 4 months before treatment.[239] The recurrence rate for horses with atrial fibrillation of greater than 4 months’ duration increases to 60% from 25%. This may be the result of microscopic cardiac lesions that developed with chronic atrial fibrillation.

30.4.11 VENTRICULAR TACHYCARDIA

30.4.11.1 Definition and Etiology

Ventricular tachycardia is a cardiac arrhythmia characterized by a rapid rhythm originating in the ventricle. This rhythm originates below the bundle of His in the specialized conduction system, the surrounding ventricular myocardium, or both.[264] Ventricular tachycardia may be caused by disorders in impulse formation or impulse conduction or a combination of these two mechanisms.[264] Ventricular reentry is an important mechanism in the genesis of sustained ventricular tachycardia, whereas abnormal automaticity is probably responsible for idioventricular rhythms and parasystole. Changes in autonomic tone may also be important in the genesis of ventricular tachycardia. Early afterdepolarizations are thought to be the mechanism responsible for ventricular tachyarrhythmias associated with sympathetic stimulation. Late coupled ventricular complexes or a very premature ventricular depolarization are usually required to initiate ventricular tachycardia. Ventricular tachycardia can occur when there is myocarditis, myocardial necrosis, fibrosis or neoplasia, bacterial endocarditis (especially involving the aortic or mitral valve), autonomic nervous system imbalance,

hypoxia, ischemia, electrolyte or metabolic disturbances, anesthesia, drug administration, sepsis, endotoxemia, toxic myocardial injury, or aortic root rupture; or it may be associated with other, unknown causes.[265–269]

30.4.11.2 Clinical Signs and Differential Diagnosis

The clinical signs detected depend on the ventricular rate, the type of ventricular tachycardia (uniform or multiform), the duration of ventricular tachycardia, and the severity of the underlying cardiac disease.[266] Large animals with ventricular tachycardia may be asymptomatic at rest, if the rhythm is relatively slow and uniform, or may have severe CHF with rapid uniform or multiform ventricular tachycardia.[266] Exercise intolerance is common and may be so severe that the animal has frequent syncope. Other complaints include depression, weakness, colic, respiratory distress, coughing, ventral edema, and pulmonary edema. Acute viral or bacterial respiratory disease with high fever may precede the development of ventricular tachycardia in horses or may occur concurrently with it.[270] Gastrointestinal disease and primary myocardial disease are common in horses with ventricular tachycardia.[265] In cattle, ventricular tachycardia occurs most frequently secondary to sepsis and toxemia. Anorexia and decreased milk production are common in affected cows.

Animals with sustained ventricular tachycardia have a rapid heart rate with a regular (uniform) or irregular (multiform) rhythm.[271–274] Heart rates as high as 300 beats/min have been detected in horses with ventricular tachycardia. Heart sounds vary in intensity, with some very loud booming sounds (“bruit de cannon”). Arterial pulse may be variable or uniform, with normal (slower rate) or weak (rapid rate) intensity pulses. Pulse deficits frequently occur, particularly with rapid or multiform ventricular tachycardia. Jugular pulses are frequently detected in large animals with ventricular tachycardia. The large pulse waves seen in the jugular vein are cannon “a” waves that occur when the right atrium and ventricle contract simultaneously. Cardiac murmurs are not commonly detected. Signs of CHF are usually present when ventricular tachycardia is rapid and sustained but are uncommon in animals with slower or paroxysmal ventricular tachycardia.[271–273] Signs of right-sided CHF (ventral edema, venous distention) usually predominate with sustained uniform ventricular tachycardia and increase in severity the longer the duration and more rapid the rate of the arrhythmia. Signs of left-sided CHF (coughing, expectoration of foamy fluid, respiratory distress) usually predominate with multiform ventricular tachycardia.[270]

The presence of jugular pulses and “bruit de cannon” in an animal with a rapid regular rhythm helps distinguish ventricular tachycardia from sinus or supraventricular tachycardia. Multiform ventricular tachycardia can be difficult to distinguish from atrial fibrillation, because both arrhythmias have an irregular rhythm with heart sounds that vary in intensity. Jugular pulses may also be detected in large animals with atrial fibrillation but are usually less prominent than in animals with ventricular tachycardia. Although large animals with multiform ventricular arrhythmias usually have more severe clinical signs, an ECG is necessary to distinguish these arrhythmias.

486
487

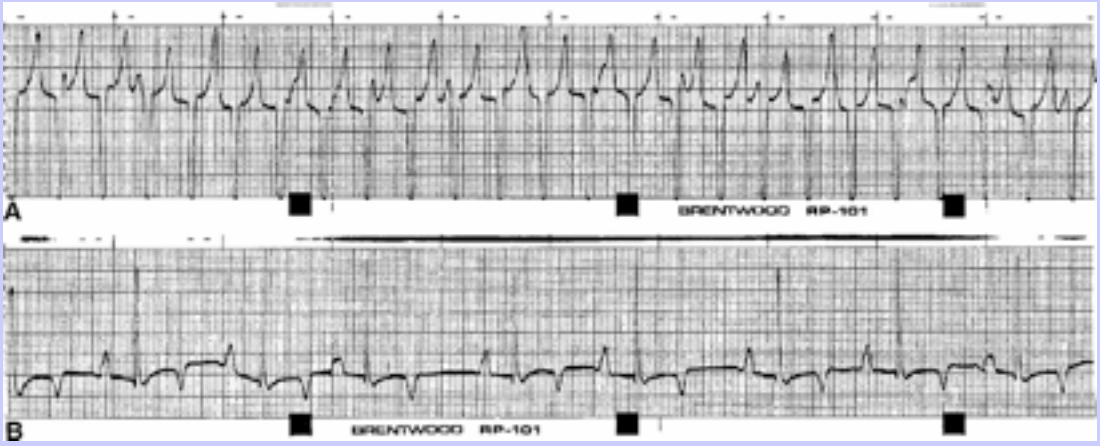
30.4.11.3 Clinical Pathology

Electrolyte, metabolic, or toxic causes of ventricular tachycardia may be present in large animals with primary gastrointestinal disease. Hypomagnesemia and hypokalemia has also been associated with the development of ventricular tachycardia.[274] Serum creatinine and BUN may be elevated in horses and cattle in CHF associated with prerenal azotemia. Serum osmolality, BUN, and creatinine increase and urine osmolality decreases acutely in horses with experimental monensin toxicosis.[270,275] Initial decreases in serum potassium and serum calcium have also been reported in these animals. Marked elevations of cTnI have been seen in horses with

ventricular tachycardia.[276,277] cTnI is a more sensitive indicator of myocardial injury in human beings and appears to have a similar sensitivity in the horse. Cardiac isoenzymes of CK and LDH are often elevated if there is recent myocardial injury associated with the ventricular tachycardia. Elevation of the myocardial fraction of CK (CK-MB) in excess of 5% of the total CK is compatible with myocardial injury in horses.[270,275] A neutrophilic leukocytosis and hyperfibrinogenemia may be detected in animals with an infectious myocarditis or bacterial endocarditis or may be elevated associated with the primary underlying disease. In most large animals with ventricular tachycardia, however, the hematology is normal.

The diagnosis of ventricular tachycardia is made from the ECG. A series of four or more ventricular premature depolarizations is diagnostic of ventricular tachycardia.[265,278] The electrocardiographic appearance of the ventricular premature depolarizations may be widened and bizarre, or the QRS duration and appearance of the QRS and T may be near normal, especially in horses (Fig. 30-32).[265,266] Although the duration of QRS complexes that are ventricular in origin is usually within the normal range reported for horses, it is usually longer than the QRS duration of the horse's normal sinus beats.[265] The major direction of the QRS complex is usually oriented opposite to that of the T wave. The R-R intervals may be regular or irregular. The morphology of the QRS complexes may be similar (uniform) or may vary widely (multiform). Atrioventricular dissociation is usually present, with an atrial rate slower than the ventricular rate. Fusion beats and capture beats may be detected (Fig. 30-33). Ventricular tachycardia can be sustained or paroxysmal.

Fig. 30-32 Lead II ECG obtained from a horse with sustained uniform ventricular tachycardia and CHF before **(A)** and after **(B)** conversion to sinus rhythm. Note the abnormal QRS and T configuration and slower atrial rate during the sustained ventricular tachycardia.



The echocardiogram is used to determine whether cardiac disease is present. The echocardiogram is usually abnormal in large animals with primary myocardial disease and normal in large animals with secondary ventricular tachycardia, except for the changes associated with the ventricular tachycardia itself. Abnormal echocardiographic findings that may be detected in large animals with primary myocardial disease include myocardial dyskinesis, hypokinesis, and akinesis; abnormal myocardial echogenicity; decreased FS, ET, and EF; loss of the normal systolic and diastolic undulations of the aortic root; and detection of spontaneous

contrast, small aortic root, and large pulmonary artery (see Fig. 30-15). Occasionally the echocardiographic abnormalities created by ventricular tachycardia may be difficult to distinguish from those of primary myocardial disease. Rupture of the aortic root at the right sinus of Valsalva may be detected in horses with acute onset of uniform ventricular tachycardia and colic.

Cardiac catheterization may reveal severe hypotension and low cardiac output. In healthy ponies with pacing-induced ventricular tachycardia, stroke volume decreased significantly when the ventricle was paced at 150, 200, and 250 beats/min.[279] Mean left atrial pressure, mean pulmonary arterial pressure, and right ventricular systolic pressure increased significantly when the ventricle was paced at 220 and 250 beats/min. Aortic pressure and cardiac output decreased in these ponies at 250 beats/min, but the decrease from resting values was not statistically significant. Myocardial perfusion in the papillary muscles and subendocardium decreased significantly with pacing-induced ventricular tachycardia at a rate of 250 beats/min. Decreases in cardiac output, arterial blood pressure, and myocardial perfusion are even more marked in animals with underlying myocardial disease or multiform ventricular tachycardia, as are the changes in left atrial, pulmonary arterial, and right ventricular pressure.

30.4.11.4 Pathophysiology

Ventricular tachycardia is probably initiated spontaneously by late coupled ventricular complexes, whereas one very early ventricular premature depolarization can often initiate ventricular tachycardia electrically.[264] Sympathetic stimulation may also provoke ventricular tachycardia by increasing the amplitude of the early afterdepolarizations, culminating in a run of ventricular tachycardia.[264] This may be the mechanism of some of the exercise-induced ventricular tachycardia in horses. Reentry in the ventricle is an important cause of sustained ventricular tachycardia, particularly in human patients with dilated cardiomyopathy and ischemic heart disease. The area of reentry is reportedly small, less than 1.4 cm^2.[2,264] Reentry is also thought to be an important mechanism in horses with sustained ventricular tachycardia.[273,280,281] Delayed afterdepolarizations may trigger ventricular tachycardia in humans and dogs and may be the mechanism for digitalis-induced ventricular tachycardia.[264] Abnormal action potentials have also been demonstrated in ventricular myocardium resected from human beings with recurrent ventricular tachycardia.[264] Depressed automaticity and afterdepolarizations have been associated with acute myocardial ischemia, whereas automaticity and afterdepolarizations are enhanced in Purkinje fibers surviving myocardial infarction. Idioventricular rhythms and parasystole may be caused by abnormal automaticity.

487
488

Fig. 30-33 Lead II ECG obtained from a horse with multiform ventricular tachycardia and acute onset of pulmonary edema. Notice the multiple different QRS and T configurations and the elevated ventricular rate.

Cardiac diseases such as endocarditis may result in septic myocardial emboli and myocardial ischemia. Aortic root rupture and the dissection of blood into the interventricular septum disrupts conduction and usually results in a uniform ventricular tachycardia. Myocarditis, myocardial necrosis, and fibrosis also may result in abnormalities of impulse formation and conduction, leading to ventricular tachycardia.[282] The excitement of the high-performance situation and the decreased myocardial perfusion that may occur at peak exercise may make exercise-induced ventricular tachycardia more common in racehorses and other types of high-performance horses.

30.4.11.5

Epidemiology

Ventricular tachycardia has been reported in all large animals, although horses may have the highest incidence. Ventricular tachycardia leading to ventricular fibrillation is thought to be one of the leading causes of sudden death in horses when other causes of death cannot be found on postmortem examination.[281] Male horses are at increased risk for aortic root and sinus of Valsalva rupture and are usually at least 10 years old at the time of rupture. Ventricular tachycardia is also more likely in large animals of any age with primary gastrointestinal disease.

30.4.11.6

Necropsy Findings

If the ventricular tachycardia is not associated with primary myocardial disease, the necropsy findings reflect the underlying disease. Gross and microscopic cardiac pathology has been found in horses with ventricular tachycardia, although in some horses no cardiac pathology is found. Areas of myocardial necrosis, inflammatory cell infiltrate, fibrosis, infarction, microvascular alterations, and cardiac nerve abnormalities have been reported in horses with ventricular tachycardia.[273,280–282] CHF is most likely in large animal patients with multiform ventricular tachycardia and heart rates in excess of 180 beats/min. A minority of large animal patients have bacterial endocarditis with septic emboli disseminated through the coronary arteries associated with ventricular tachycardia. Aortic root rupture and rupture of a sinus of Valsalva aneurysm with dissection of blood into the interventricular septum are infrequently detected in horses.

30.4.11.7

Treatment and Prognosis

The treatment and prognosis for ventricular tachycardia depends on the suspected cause of the arrhythmia, the severity of the animal's clinical signs, and the electrocardiographic abnormalities detected.[265,266] Relatively slow uniform ventricular tachycardia often resolves or improves significantly with the correction of the underlying electrolyte or metabolic imbalances, without requiring antiarrhythmic therapy. These animals usually have an excellent prognosis for conversion with correction of the underlying problem. Similarly, in large animals with sepsis or toxemia, hemodynamically and electrically stable ventricular tachycardia often resolves with treatment of the underlying disease. Uniform, hemodynamically stable ventricular tachycardia in animals with myocarditis may resolve with rest and/or corticosteroid therapy. A minimum of 4 to 8 weeks of rest is indicated in these patients before returning to work, once the ventricular tachycardia has resolved.

Treatment with antiarrhythmics is indicated in any animal with hemodynamically unstable or life-threatening ventricular tachycardia. Treatment with antiarrhythmics is indicated if clinical signs of CHF or cardiovascular collapse are present or if the rate of sustained ventricular tachycardia is extremely high. In horses with sustained uniform ventricular tachycardia, a heart rate in excess of 120 beats/min usually warrants

antiarrhythmic therapy, whereas in cattle, antiarrhythmic therapy may not be indicated until the heart rate exceeds 140 beats/min or greater. Horses with rapid sustained uniform ventricular tachycardia (120 beats/min or faster) need antiarrhythmic therapy because signs of CHF will develop after several days or weeks with this arrhythmia, if not already present. The rapidity of onset of CHF is related to the heart rate and type of primary myocardial disease, if present. These horses usually have a good prognosis for conversion and return to their previous performance level, with appropriate antiarrhythmic therapy (many times three or more antiarrhythmic drugs must be tried before conversion occurs) and rest before the horse is returned to work.

The electrocardiographic findings associated with life-threatening ventricular tachycardia include a multifocal origin for the ventricular premature depolarizations, torsades de pointes (wide ventricular tachycardia), and the presence of an R wave superimposed on the preceding T wave ("R on T"). Large animal patients with clinical signs of CHF and hemodynamic collapse with rapid (heart rate <120 beats/min) multiform ventricular tachycardia (±R on T) should be treated as a cardiovascular emergency, because sudden death from ventricular fibrillation is likely without antiarrhythmic therapy. Large animals with multiform ventricular tachycardia (±R on T) must be given a guarded to grave prognosis for survival, because most have severe underlying myocardial disease. Often conversion to sinus rhythm may not be successful before the animal develops ventricular fibrillation and dies. If successfully converted to sinus rhythm, many of these animals die or are euthanized because of the severity of the underlying cardiac disease.

488

489

Several antiarrhythmic choices are available to the large animal practitioner for the correction of life-threatening ventricular tachycardia (see Table 30-3). Lidocaine hydrochloride is the most readily available drug for most large animal practitioners, is rapidly acting, is administered IV, and has a short duration of action and minimal hemodynamic effects. Lidocaine hydrochloride does, however, have central nervous system side effects in horses (hyperexcitability and seizures) and must be used at a lower dosage than in cattle. Quinidine gluconate (or quinidine sulfate in cattle) is very effective in large animals but is less rapidly acting, has negative inotropic effects at large doses or if primary myocardial disease is present, causes hypotension, and can produce undesirable adverse or toxic reactions. Magnesium sulfate can cause hypotension but has no other recognized adverse cardiovascular effects. Magnesium sulfate is less rapidly acting than lidocaine but may be effective when other antiarrhythmics fail, in both normomagnesemic and hypomagnesemic patients. Intravenous procainamide, intravenous and oral propafenone and intravenous flecainide have also been used successfully in horses with ventricular tachycardia. Intravenous propafenone is indicated for refractory ventricular tachycardia and has been used successfully in several horses that did not respond to lidocaine, quinidine, procainamide, or magnesium sulfate. However, it is not available at this time in the United States. Other antiarrhythmics such as propranolol have been used with less success but have converted large animals with sustained ventricular tachycardia.

Amelia R. Woolums

31.1 DIAGNOSTIC PROCEDURES FOR THE RESPIRATORY SYSTEM

*PAMELA A. WILKINS, Consulting Editor**

* Based on chapters from previous editions authored by Angeline Warner.

31.2 GENERAL EVALUATION OF THE PATIENT WITH RESPIRATORY DISEASE

31.2.1 History

As with any disease process, acquisition of an accurate and appropriate history is the first step undertaken in evaluating the patient with a complaint thought to be related to the respiratory tract. Animals with respiratory disease may have widely varied histories, and it is important to gather as much information as possible. Age and breed may play a role in the development of respiratory disease such as congenital defects, neoplastic disease, or inherited or acquired immuno-deficiency syndromes seen in certain breeds. The environment in which the animal is maintained can contribute to the development or severity of respiratory disease—heaves in horses for example—and respiratory disease may become manifest after a change to new environment. In horses the work they are expected to perform can lead to important diagnostic clues, and recent events, such as long-distance transport, can predispose to diseases such as pleuropneumonia. It is important to know if certain diseases are either endemic or epidemic where the horse is kept or has recently moved from; diseases such as strangles and *Rhodococcus equi* bronchopneumonia of foals come to mind. Any recent traumatic or potentially traumatic event should be noted. If possible, a thorough vaccination history should be obtained, as should an accurate history of any administered treatments or supplements and the patient's response to those treatments.

31.2.2 Presenting Signs or Chief Complaints

Many presenting signs or chief complaints should lead to more thorough evaluation of the respiratory system; some are more directly associated with either the upper or the lower respiratory tract. Findings or complaints associated with respiratory disease include nasal discharge, either bilateral or unilateral. Respiratory noise at rest or during exercise is commonly associated with abnormalities of the upper airway, as may be inequalities of airflow present at the nares. Normal animals may periodically cough or sneeze, but an increase in either activity may indicate involvement of the respiratory tract. Exercise intolerance or apparent decrease in the ability of the animal to exercise should prompt evaluation of the respiratory system. Other clinical signs that indicate thorough evaluation of the respiratory tract include but are not limited to abnormal breathing patterns (tachypnea, hyperpnea, dyspnea), cyanosis, hemoptysis, epistaxis, unusual swellings (facial, pharyngeal, cervical), lymphadenopathy, ataxia or reluctance to move, foul smell to the breath, weight loss and ventral abdominal, and sternal or limb edema.

31.2.3 Physical Examination

The initial physical examination occurs at some distance from the patient and involves evaluation of the demeanor, posture, mental status, and way of movement of the patient. It is important to note whether the patient has an abnormal stance, such as standing with the head and neck extended; is unwilling to move; or is standing with elbows abducted, suggesting pleural pain. Ideally the respiratory rate can be determined by observation, as can the respiratory pattern. Although some respiratory diseases are not manifested at rest, important clues can be gained from observation of the patient at rest in many others. The normal resting respiratory rate of an adult horse is between 8 and 16 breaths/min; for adult cattle, 15 to 35 breaths/min; and for sheep and goats, 12 to 20 breaths/min. There is some small abdominal component during the expiratory phase, which is, along with inspiration, an active process for horses. The normal rate for neonates is up to 60 breaths/min at birth and less than 30 breaths/min by 1 month of age; respiratory rate decreases toward the adult rate with age. High ambient temperature, fever, and excitement can all increase respiratory rate. Normal breathing is quiet, is apparently effortless, and is termed *eupnea*. The term *dyspnea* refers to a breathing pattern that is inferred by the observer to reflect difficulty in breathing; the animal will appear distressed, and the work of breathing is obviously increased, although the actual rate may be within normal limits. Other terms used to describe breathing patterns include *tachypnea* (characterized by rapid rate and shallow depth or low tidal volume), *hyperpnea* (increased frequency and depth of breathing [e.g., postexercise recovery]), and *apnea* (no discernable breathing). Two additional terms are *hypoventilation* and *hyperventilation*, both of which require a change in arterial carbon dioxide partial pressure as a component of their definitions. Hyperventilation is a pattern that increases alveolar ventilation and causes arterial hypocapnia, whereas hypoventilation alters gas exchange in such a way as to cause arterial hypercapnia, or retention of carbon dioxide.

490

491

Closer examination can reveal some of the physical manifestations of the presenting complaints listed earlier. Beginning with the head, the clinician should determine that airflow is even from both nostrils, as differences can indicate either congenital or acquired abnormalities ranging from choanal atresia to the presence of upper airway masses. Abnormal respiratory sounds can sometimes be present at rest and may be heard at the nares; abnormal breath odors may be particularly prominent at the nares. The frontal and maxillary sinuses should be percussed; identification of abnormal resonance, usually dullness, may be made easier by performing this with the patient's mouth held open. Palpation of the submandibular regions, larynx, and pharyngeal and cervical regions should be performed to identify any abnormal lymph node enlargement, masses, or areas of muscular atrophy. Both jugular veins should be checked for both patency and the presence of any evidence of injection sites or infections that may contribute to abnormal upper airway function by interfering with normal recurrent laryngeal nerve or vagosympathetic trunk function.

Coughing represents a nonspecific irritation of receptors in the airway and can be induced by many mechanisms. It can be, and usually is, a normal protective reflex that allows the animal to clear material from the airway. Cough can be associated with increased mucus production, production of other respiratory secretions, or decreased mucociliary clearance. In older horses cough is most commonly associated with heaves; in younger horses an association has been made both with infectious diseases and small airway inflammatory disease. Normal animals should not cough when the larynx or trachea is palpated.

Nasal discharge can be unilateral or bilateral, scant or copious, clear, mucoid, mucopurulent, or even bloody. The nature and character of nasal discharge can provide some information about a possible source of the discharge but should not be overinterpreted. Horses, for example, have a tendency to swallow excess airway secretions, and the volume of secretions may be underestimated. Although unilateral nasal discharge seems to suggest a source in front of the larynx, bilateral nasal discharge can be of either upper or lower airway origin. Skin

depigmentation of the ventral nares or presence of mucoid material in feed or water containers is a clue to presence of a nasal discharge.

Hemoptysis is the coughing up of blood from the airways or lungs. It is important to determine conclusively that the blood has come from the respiratory system. Epistaxis is defined as blood seen at the nares and often originates in the nasal passages, sinuses, turbinates, nasopharynx, or equine guttural pouches, although the lung can be, and is, a source on occasion, as in exercise-induced pulmonary hemorrhage (EIPH) or after lung biopsy. Bilateral epistaxis generally indicates bleeding caudal to the choanae. Because animals tend to swallow excessive respiratory secretions, bleeding can be occult and may not be seen unless the animal drops its head toward the ground. Significant blood loss can occur in this manner, unseen by owners.

Examination of the oral mucous membranes may reveal cyanosis—bluish discoloration of the oral, nasal, or vulvar mucous membranes. Cyanosis does not become apparent until a level of 5 mg/100 mL of deoxygenated hemoglobin, about one third of the total normal hemoglobin, is present, reflecting a profound decrease in oxygen saturation of hemoglobin and suggestive of severe hypoxemia. As it is the total quantity of deoxygenated hemoglobin that lends the mucous membranes the bluish color, very anemic patients may lack sufficient deoxygenated hemoglobin to appear blue, making appreciation of cyanosis impossible in these patients. One caveat is that all newborns are cyanotic for the first few breaths and become pink only when they have established neonatal, as opposed to fetal, cardiorespiratory circulation and opened their lungs to allow for gas exchange.

It is important that auscultation of the thorax take place in as quiet an environment as possible. In addition, auscultation of the lung fields should be performed under two breathing conditions: eupnea and hyperpnea, with hyperpnea induced by the use of a rebreathing bag. Some common misconceptions regarding the use of a rebreathing bag exist. Simply occluding the animal's nostrils or using a rectal sleeve as a rebreathing bag are both inadequate methods of fully examining the patient. The purpose is to cause the animal to rebreathe its own expired carbon dioxide, not to necessarily deprive it of oxygen. Rebreathing expired carbon dioxide results in increased $Paco_2$, which stimulates deeper and more frequent breathing efforts, making recognition of abnormal lung sounds simpler. The bag used should be large enough to accommodate two to three times the normal tidal volume of the animal and should be held in such a manner as to prevent the bag from occluding the patient's nostrils. Once the bag is removed, the animal will usually take several very deep breaths and the examiner should take advantage of these very large breaths to reexamine areas where suspicious sounds were heard during rebreathing. Animals with significant lung pathology will not tolerate the bag well, may cough when the bag is removed, and may require more time to return to baseline respiratory patterns when the bag is removed.

Normal breath sounds are those produced by turbulence within the tracheobronchial tree and may vary considerably depending on location within the lung, breathing pattern, and condition of the animal.[1] Only airways from the larynx to segmental bronchi contribute to sound generation; bronchial and vesicular sounds both represent larger airway flow events. Vesicular sounds are the quietest sounds, heard over the middle and diaphragmatic lung regions, correlate best with regional ventilation, and mainly represent segmental bronchial sounds; they do not represent air flow in terminal conducting airways and alveoli, which is silent because of the nature of its flow. Bronchial sounds are louder and are heard best over the trachea and base of the lung. Common abnormalities found during auscultation include ventral areas of dullness if pleural effusion is significant, dorsal areas of dullness or hyperresonance with pneumothorax, and dorsal harsh lung sounds. The degree of variation in normal regarding lung sounds is large, and auscultatory findings do not always correlate well with the degree of lung abnormality. That said, abnormal lung sounds are always potentially clinically important.

Adventitious lung sounds are divided into short discontinuous sounds called *crackles* and longer continuous sounds called *wheezes*, replacing the older terms *rales* and *rhonchi*, respectively. Crackles are most commonly generated by sudden pressure equalization when collapsed airway segments open. Although an air-fluid interface is required, crackles do not necessarily imply excessive secretions or pulmonary edema. They are often end-inspiratory and associated with reinflation of atelectatic lung. Crackles may be normal when ausculted in the previously down lung of a laterally recumbent neonate. Disease processes that generate crackles include pneumonia, interstitial fibrosis, chronic obstructive lung disease, congestive heart failure, and atelectasis.[2]

Wheezes commonly represent oscillation of airway walls before complete closing (expiratory) or opening (inspiratory). Intrathoracic airways are usually involved in expiratory wheezes and include the lower trachea and main, lobar, and segmental bronchi. Disappearance of a wheeze after coughing indicates secretory rather than tissue-component origin. Disease processes responsible for wheezes include airway stenosis or external compression; airway luminal compromise by foreign body, purulent material, cyst, or neoplasm; airway wall thickening as in chronic bronchitis; and bronchoconstriction. Expiratory wheezes are a hallmark of obstructive lung diseases such as heaves. Crackles and wheezes may be variably present. A final category of adventitious sounds includes the “rubbing” or “creaking” sounds generated by sliding or stretching of inflamed pleural surfaces, commonly termed *pleural friction rubs*.

491
492

Percussion of the thorax is performed by methodic tapping over the intercostal spaces of the thorax using a variety of instruments, including plexors, pleximeters, spoons, fingers, neurologic hammers, and hands. It is an inexpensive and useful component of the physical examination and should be performed in all patients in which the respiratory system is suspect. Percussion of the thorax can reveal hyporesonance (dullness) ventrally when pleural effusion is present and hyperresonance dorsally in pneumothorax and can cause some patients to exhibit pleurodynia during the examination. Other conditions that can alter resonance of the thorax include but are not limited to diaphragmatic hernia with intrathoracic intestine, pericardial effusion, pulmonary and pleural abscessation, and consolidated lung. The point at which a change occurs from resonant to dull can be marked with adhesive tape. Thus the outline of aerated lung immediately beneath the chest wall is delineated. It is usually impossible to fully delineate the lung field cranially because of body fat and triceps musculature. There is a distinct region of cardiac dullness for all species on the left side.

Percussion allows delineation of pleural effusion and intrathoracic masses or consolidated lung up to 7 cm beneath the pleural surface but cannot distinguish between them. The procedure should be performed whenever pleural effusion is suspected on the basis of auscultatory findings and in all ruminants as part of the physical examination to uncover occult pneumonia.

31.3 ADDITIONAL DIAGNOSTIC EVALUATION OF THE RESPIRATORY TRACT

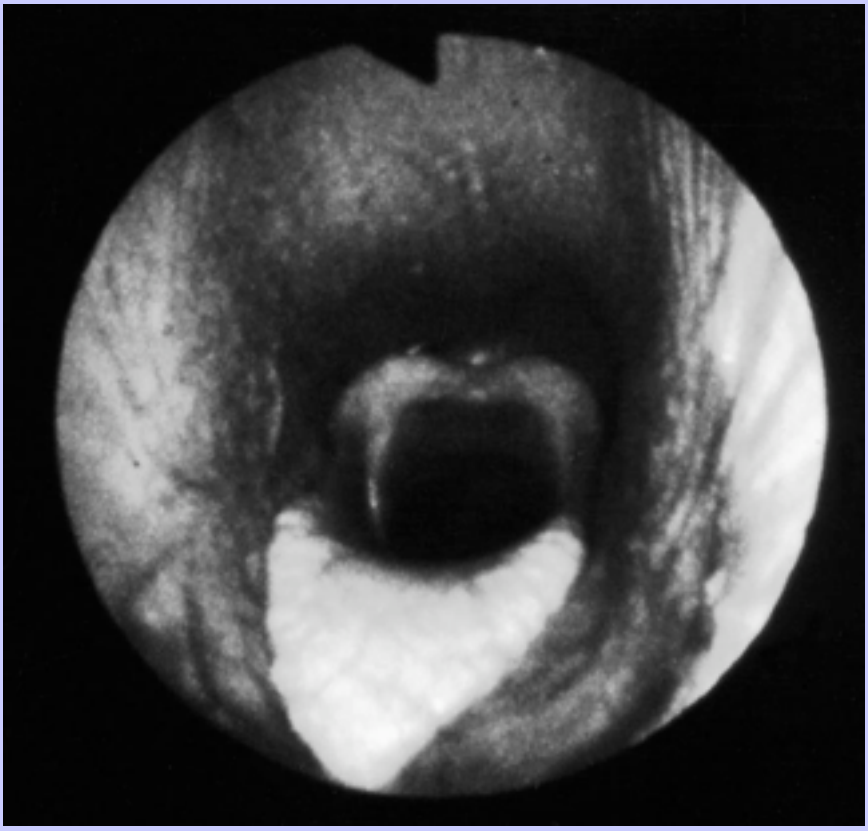
31.3.1 Endoscopy

The upper airway can be directly examined with the aid of an endoscope, the only limitations being the size of the patient, the patency of the airway, and the size of the available equipment. Standard flexible fiberoptic endoscopes, available to most practitioners and present now in virtually all referral hospitals, allow direct examination of the nasal passages, ethmoid turbinates, nasal maxillary opening of the sinuses, pharynx, guttural pouch openings, larynx, and cranial trachea (Fig. 31-1). Smaller (8- to 10-mm-diameter) endoscopes can be readily introduced into the equine guttural pouches with the aid of a biopsy instrument, and longer endoscopes (more than 150 cm long with diameters greater than 10 mm) are commonly employed to examine mainstem

bronchi and their initial branches in large animals.[3] Small brushes, used for collecting exfoliated cells for cytologic study, and a variety of biopsy instruments can be used for sampling the airway. The use of airway endoscopy has evolved to include videoendoscopy of the equine upper airway during treadmill exercise at high speed (12 to 14 m/sec) to evaluate dynamic respiratory function and make objective measurements by use of freeze-frame features.[4]

Sedation or tranquilization will facilitate many endoscopic examinations, but examinations aimed at evaluating pharyngeal and/or laryngeal function are best performed without any form of chemical restraint that might alter function. Most horses will allow standing examination of the upper airway with only physical restraint, such as judicious use of a nose twitch. Introduction of the endoscope into the trachea may elicit coughing, particularly in horses but less so in cattle. Small ruminants, such as sheep and goats, may require local tracheal anesthetic administration in the form of 2% lidocaine administered through small tubing passed through the biopsy channel of the endoscope. If used, care must be taken that lidocaine is diluted and does not reach a toxic dose in small ruminants. Diluted topical 2% lidocaine can similarly be used in horses and cattle if needed for evaluation of the distal trachea, main stem bronchi, and larger bronchial tree branches. Horses are more sensitive to tracheal and bronchial stimulation and are more likely to require topical anesthesia than cattle.

Fig. 31-1 Normal equine larynx. The larynx is directly visualized by endoscopy, with both structure and symmetry evaluated. Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.



Airway abnormalities such as pharyngeal lymphoid hyperplasia, laryngeal hemiplegia, epiglottic entrapment by arytenoepiglottic folds, dorsal displacement of the soft palate, pharyngeal cysts, retropharyngeal masses, and epiglottic deformities are all best diagnosed by endoscopic examination. Guttural pouch diseases and EIPH are also best evaluated using this technique. The degree and nature of airway secretions accumulating in the trachea can be easily assessed using an endoscope, and accumulated secretions may be sampled by aspirating the secretions through small tubing introduced into the trachea via the biopsy channel. Because the endoscope has passed through the nonsterile upper airway, these samples are best suited for cytologic, not microbiogic, evaluation but may be fully compatible with evaluation using newer molecular diagnostic techniques.[5–8] Endoscopy has also been used to facilitate removal of foreign bodies from the airway, generally aided by the biopsy instrument.

31.3.2 Radiography

Radiographs are indicated when the clinician suspects a congenital anomaly involving any thoracic structure; infectious disease of the pleura, pulmonary parenchyma, racheobronchial tree, or mediastinum; pneumothorax or pneumomediastinum; thoracic neoplasia of any origin; or trauma. Radiographs are frequently coupled with thoracic ultrasonographic evaluation. If significant accumulation of pleural fluid is suspected based on physical examination findings, the ultrasonographic portion of the examination should be performed first and radiographs obtained after drainage of excess fluid, as fluid may obscure potentially important parenchymal disease. The equipment needed to perform radiographic evaluation of the upper airway is available in most private practices, and most large referral and university practices have the equipment needed to perform thoracic radiography in larger patients such as adult horses and cattle. Digital radiography is becoming more commonplace and may replace more convention radiography in many practices and referral clinics over the next few years. Because of its configuration, the thorax in adult horses and cattle is filmed in the standing lateral position, generally requiring a series of three or four separate but overlapping images; thus the benefit of the ventrodorsal view in which the two lungs may be compared is lost. Neonates and small ruminants can be more readily handled and retained in recumbent positions, allowing for multiple recumbent views.

492
493

Skull and cervical radiographs offer diagnostic information for evaluation of the upper respiratory tract. For large animal species, standing lateral skull films are easily obtained, and, with practice and adequate sedation, ventrodorsal and oblique projections can also be obtained in most patients. Certain difficult patients may require general anesthesia in order to obtain radiographs of diagnostic quality. In these cases other imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) might also be considered if available. Skull radiographs image the sinuses, pharynx, and larynx, allowing for assessment of anatomic dimensions of the pharyngeal and laryngeal structures. Sinuses affected by neoplasia or inflammation may show abnormal tissue density, a horizontal fluid line on a standing lateral film, bone lysis around the affected sinus, or alveolar periostitis. Thorough evaluation of the sinuses and nasal passages requires lateral, dorsoventral, and oblique views. Foreign bodies can be assessed in many cases. The equine guttural pouches are evident on lateral skull projection, and abnormal fluid accumulation, distortion by enlarged retropharyngeal lymph nodes, or emphysema can be radiographically apparent.

Radiographic assessment of the thorax of large animals remains preferable to ultrasonographic examination for detection of diffuse parenchymal diseases such as interstitial pneumonia, pulmonary edema, equine multinodular pulmonary fibrosis (EMPF), fungal pneumonia, acute lung injury (ALI), acute respiratory distress syndrome (ARDS), chronic disorders, and deep parenchymal or mediastinal abscesses. Unfortunately, many radiographic changes in equine respiratory disorders tend to be nonspecific or, in certain disease such as EIPH, inflammatory airway disease (IAD), or heaves, minimal to nonexistent.

Four types of radiographic patterns are described for the thorax: alveolar (airspace), interstitial, bronchiolar, and vascular. Opaque areas coalesce and fully obliterate vessels and bronchi in the alveolar pattern; air bronchograms may be prominent. This pattern is common in pulmonary edema, pulmonary hemorrhage, EMPF, ALI, ARDS, lung consolidation, and neoplasia. Interstitial patterns are the most common patterns noted in equine thoracic radiographs and are characterized by a blurring of the edges of pulmonary vessels, a diffuse increase in lung density, and variable reticular, linear, and nodular opacities. The reticular pattern is most commonly associated with more diffuse infectious lung diseases, pulmonary edema, interstitial pneumonia, and pulmonary fibrosis, whereas the irregular linear pattern is seen most commonly with resolving bronchopneumonia. A nodular pattern is seen with abscesses, granulomata, and neoplasms. It is rare to see a pure bronchial pattern in a horse, and it usually seen in association with an interstitial pattern. An exception is paired linear opacities or numerous small circular opacities (donuts) representing thickening of large or medium airways in equine bronchitis and bronchiolitis. The vascular pattern is seen in horses radiographed immediately postexercise or in animals with left-to-right cardiac shunts. Finally, extraparenchymal problems such as pleural effusions or free gas may be seen on thoracic radiographs of large animals. Thoracic radiology may be used for evaluation of potential rib fracture but is far less sensitive than thoracic ultrasonography in this regard.

31.3.3 Ultrasonography

Thoracic ultrasonography, a companion to thoracic radiography, is useful for diagnostic, therapeutic, and prognostic evaluation of the extraparenchymal thorax, the pleural space, and the peripheral (superficial) parenchyma of the lung. Unlike thoracic radiography, in which specialized equipment is needed to image the adult large animal, thoracic ultrasonography is an imaging technique readily available to most practitioners. In many instances it is superior to thoracic radiography as an imaging method; examples include evaluation of pleural effusions, assessment of thoracic trauma, evaluation of neoplasms or granulomata, detection of mediastinal masses or abscesses, and guidance of transthoracic lung biopsy.[9,10] Ultrasonography is considered greatly superior to thoracic radiography in the detection of rib fractures.[11] This imaging technique should be considered for complete evaluation of any large animal with suspected or diagnosed pulmonary disease.

Ultrasonography is generally performed with the patient standing, although in neonates lateral recumbency may be preferred or even necessary, and sound waves are generated by piezoelectric crystals and transmitted to the area of interest through a skin coupling gel, with subsequently reflected echoes detected by the same crystal. Echo signals from all tissue interfaces are displayed on a screen; the image can be photographed for a permanent record or stored digitally. Air trapped beneath the haired skin can interfere with the process, as can excessive skin dirt, so preparation of the acoustic window usually involves hair removal and cleansing in order to get the best image possible.

Although ultrasound waves will not penetrate the aerated portion of the lung, limiting the examination to extraparenchymal surfaces in normal horses, ultrasonography is superior to thoracic radiography in evaluation of these areas of the chest. Small amounts of pleural fluid that would be missed on auscultation, percussion, or thoracic radiographs can be detected, and the amount and character of pleural effusion in each hemithorax can be separately evaluated.[9] Clear fluid is anechoic, but inflammatory cells, gas, and fibrin are echogenic, causing opacities that can be seen floating in pleural fluid and altering the general echogenicity of the fluid. Because of this, ultrasound is the method of choice for diagnosis and monitoring of pleural space disease. Ultrasonography should be used to guide catheter placement for drainage of accumulated fluid in the pleural space. The pleural surfaces are imaged well by ultrasound, with thickened or roughened areas easily detected. Lack of normal

independent movement of the visceral and parietal pleural surfaces during the respiratory cycle, suggestive of adhesion formation, can be readily monitored.[9,10]

Consolidated lung is a better acoustic medium than aerated parenchyma and can be well visualized. If there is pleuropneumonia with consolidation or atelectasis caused by compression of the ventral lung by pleural effusion, it will be evident. Pulmonary abscesses or masses extending to the lung surface can be imaged, and ultrasound can be used for guidance for transthoracic biopsy.[9,10] Thoracic radiography remains superior to ultrasound in diagnosis of pulmonary parenchymal disease and pneumothorax, but combined the two techniques will improve patient management diagnostically and therapeutically.

494

31.3.4 Nuclear Medicine Imaging

Nuclear medicine imaging is a very specialized technique available at a few university and private specialty referral practices. Gamma-emitting radioisotopes such as krypton-81 m or technetium-99 m can be used with an external detector (gamma camera) to assess regional pulmonary ventilation and perfusion in the horse. The procedure is safe and painless. Anesthesia is not needed, and the only requirement is that the patient stands quietly in front of the gamma camera. After the study the patient must be kept in an isolated area to allow decay and excretion of the radiopharmaceutical (normally no more than 48 hours), and, of course, all pertinent radiation regulations must be strictly adhered to.

The radioisotope is bound to albumin aggregates of 10 to 15 μm diameter. When injected into a peripheral vein (e.g., for a perfusion scan), the aggregates become trapped in the pulmonary arterial vasculature. Given even and thorough mixing in the right ventricle, the resulting image illustrates the perfusion distribution of the pulmonary arterial system. The ventilation scan is generated when the horse inhales aerosolized radioisotope particles through a close circuit system.[12] The particles have a small enough diameter to be deposited in the alveoli and small conducting airways with the gamma camera recording the sites of deposition. Together, the ventilation and perfusion scans allow for evaluation of the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio, important in evaluation of certain respiratory problems such as EIPH (high $\dot{V}/\dot{Q}$ areas), pulmonary thromboembolism (high $\dot{V}/\dot{Q}$ areas), and heaves (low $\dot{V}/\dot{Q}$ areas).[13] One final use is in the evaluation of mucociliary clearance or tracheal mucous transport. The time a bolus of radioisotope requires to cover a given tracheal distance is recorded in millimeters per minute and compared with normal ranges.[14]

This technology is specialized, expensive, and not readily available as of this writing. It has greatest potential application in the equine athlete or the valuable equine patient.

31.3.5 Arterial Blood Gas Analysis

Arterial blood gas determinations are the most sensitive indicator of respiratory function readily available to the clinician. The most accessed arteries for sampling are the metatarsal, temporal, facial, and brachial arteries (Fig. 31-2). In cattle the coccygeal artery on the ventral aspect of the tail head is easily accessible. Heparin is the only acceptable anticoagulant for blood gas samples, and all gas bubbles must be removed and the syringe capped to prevent equilibration of the sample with room air. Use a short (1-inch), small-gauge (25-gauge generally) needle and a 1- to 3-mL syringe for most samples. The syringe and needle can be purchased preheparinized especially for arterial blood gas sampling, or regular syringes and needles may be heparinized by aspirating a small volume of heparin into the syringe via the needle and then forcefully expelling the air and heparin from the syringe three times. This minimizes the effect heparin might have on any reported values from the blood gas analyzer. Pulsation of blood from the needle, spontaneous filling of the syringe, and bright color of the blood all confirm a

successful arterial puncture. If successful arterial puncture is questionable, then a comparison sample may be drawn from the jugular vein. Once the sample has been drawn, the vessel should be manually compressed for 2 to 5 minutes to prevent hematoma formation. If the sample will not be analyzed within 10 minutes, it should be placed on ice to slow metabolism of blood cells. The patient's body temperature at the time of sampling should also be recorded, as results are frequently reported at both 37° C and at the actual temperature of the patient, called *temperature-corrected values*, for pH, P_{O_2}, and P_{CO_2}, as these values are known to be temperature variable.

Fig. 31-2 Arterial blood sample drawn from temporal artery for arterial blood gas analysis. Courtesy Dr. Eric Birks, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.

Portable arterial and venous blood gas analyzers are now making arterial blood gas analysis more practical for use in the field, and the technique is no longer reserved for large institutions or referral practices.[15] It is virtually impossible to manage severe respiratory disease without knowledge of arterial blood gas parameters. Pulse oximetry is also being more commonly employed in some institutions and referral centers, but these monitors measure only oxygen saturation of hemoglobin, useful for severe hypoxemia but giving no measurement of actual arterial oxygen and carbon dioxide partial pressures. The most common abnormalities recognized with arterial blood gas analysis in animals breathing room air are hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. There are five primary means by which hypoxemia develops in any animal with a

heart and lungs. For our purposes, *hypoxemia* is defined as decreased oxygen tension of the arterial blood (decreased Pa_{O_2}) and *hypoxia* is defined as decreased oxygen concentration at the level of the tissue, with or without hypoxemia. Hypoxia results from hypoxemia, decreased perfusion of the tissue bed in question, or decreased oxygen-carrying capacity of the blood as a result of anemia or hemoglobin alteration.

Hypoxemia develops from (1) low content or concentration of oxygen in the inspired air (Fi_{O_2}) such as seen in high altitude or when an error is made during the mixing of ventilator gas; (2) hypoventilation; (3) ventilation-perfusion mismatch; (4) diffusion limitation; or (5) intrapulmonary or intracardiac right-to-left shunting of blood. Mild to moderate hypoxemia is not an uncommon finding in neonates but must be evaluated in terms of the current age of the foal and its position. The difficulty encountered obtaining the sample must also be considered, as severe struggling can variably affect the arterial blood gas results. If the lung is significantly involved in the underlying pathology, such as with severe pneumonia, ALI, or ARDS, increased Pa_{CO_2} may very well be present, representing respiratory failure.

494

495

Hypoxemia is usually treated with intranasal humidified oxygen insufflation at 4 to 10 L/min in neonates and 10 to 15 L/min in adults. Hypercapnia is not a simple matter to treat. It is important to try to distinguish between acute and chronic hypercapnia. Acute hypercapnia is usually accompanied by a relatively dramatic decrease in blood pH of 0.008 pH units for each 1-mm Hg increase in Pa_{CO_2}. This respiratory acidosis can promote circulatory collapse, particularly in the concurrently hypoxemic and/or hypovolemic patient. The effects of more chronic CO_2 retention are less obvious, as the time course allows for adaptation. The pH change is less, about 0.003 pH units per 1-mm Hg increase in Pa_{CO_2}, as it is balanced by enhanced renal absorption of bicarbonate by the proximal renal tubule. Most patients in acute respiratory distress are in the acute stages of respiratory failure, but chronic adaptation will begin to occur within 6 to 12 hours and will be maximal in 3 to 5 days. An increase in bicarbonate will be noted, particularly if the acidosis is primarily respiratory in origin.

Alveolar gas exchange is readily estimated by determining the alveolar-arterial (A-a) gradient for oxygen, computed by subtracting the Pa_{O_2} measured by the arterial blood gas from the calculated alveolar oxygen partial pressure (PA_{O_2}). The PA_{O_2} is effectively estimated using the partial pressure of inspired oxygen (Pi_{O_2}) as follows[16]:

$$PAo_2 = \frac{Pio_2 - Paco_2}{0.8}$$

The Pi_{O_2} equals the total barometric pressure (760 mm Hg) minus the partial pressure of water vapor (42 mm Hg) multiplied by the fraction of room air that is oxygen (0.21), and thus equals 150 mm Hg for room air. For patients on supplemental inspired oxygen, the practitioner must remember to recalculate the Pi_{O_2} with the new oxygen fraction (Fi_{O_2}) in the inspired gas, possible only in patients receiving inspiratory gas through a closed system. The Pa_{CO_2} is obtained from the arterial blood gas measurement. The A-a gradient is normally only 4 to 10 mm Hg; an increase beyond this indicates impaired gas exchange within the lungs, most often the result of ventilation-perfusion mismatching. The A-a gradient can be estimated only in patients receiving intranasal insufflation of oxygen.

A second useful measure is the Pa_{O_2}/Fi_{O_2} ratio, a component of most definitions of both ALI and ARDS.[17] The Pa_{O_2}/Fi_{O_2} ratio equals the Pa_{O_2} obtained from the arterial blood gas divided by the Fi_{O_2}, the oxygen fraction in the inspired gases. The normal Pa_{O_2}/Fi_{O_2} ratio is >300 mm Hg; a ratio <300 mm Hg is consistent with a

potential diagnosis of ALI, and a ratio <200 mm Hg suggests ARDS, a more severe form of ALI. The ranges of normal arterial blood gas values for various species are listed in Table 31-1.

Table 31-1 Normal Arterial pH and P_{CO_2} Values for Various Species (Nonneonate)

Species	Blood pH	P_{CO_2} (mm Hg)
Bovine	7.32–7.45	35–53
Ovine	7.32–7.54	37–46
Equine	7.32–7.44	38–46
Caprine	7.42–7.46	33–38

31.3.6 Respiratory Function Testing

The major functions of the lungs are to transport gas from the periphery to the site of gas exchange (i.e., the "bellows" function) and to provide gas exchange with the blood, facilitating gas transport to the tissues. The first of these is assessed by means of pulmonary function tests, and the second by arterial blood gas evaluation, discussed earlier.

Pulmonary function tests have historically primarily been used in horses and in most cases as a research tool in veterinary teaching hospitals. However, newer, portable technologies are beginning to allow use of some of the less invasive techniques in the field, and practitioners are becoming aware of the potential utility of these testing techniques.[18] Pulmonary function testing (PFT) involves measurement of pressure, flow, and volume during breathing to allow computation of ventilatory functional values. They are valuable in assessment of equine athletes, especially those suspected of inflammatory obstructive airway disease, and a portion of this section is dedicated to this subject. Baseline measurements can be compared, and airway hyperreactivity (AHR) can be evaluated using histamine or methacholine bronchoprovocation protocols.[19] Responses to environmental changes or therapy can be noninvasively evaluated.[20–22]

31.3.7 Collection and Evaluation of Respiratory Secretions

31.3.7.1 TRACHEAL ASPIRATES AND BRONCHOALVEOLAR LAVAGE

Various spaces in the respiratory system can undergo aspiration or lavage for diagnostic or therapeutic purposes. The most commonly performed procedure is the tracheobronchial aspiration. By aspirating from the airways caudal to the larynx, a sample without pharyngeal contamination is obtained.

In both the horse and the ruminant the procedure is performed with the animal standing. Sedation or restraint may be needed. A small area over the trachea in the middle third of the neck is clipped and routinely sterilely prepared. The skin is anesthetized using a local block of 2% lidocaine, generally less than 3 mL is given as a "bleb" subcutaneously, and a small stab incision is made. A trocar or angiocatheter needle is introduced on the midline between muscle bundles, with the beveled edge facing ventrally to decrease the opportunity for inadvertent cutting of the tubing when the needle is introduced or manipulated, and the ventral tracheal wall is

punctured between two cartilaginous rings. The distal end of the trocar or needle is then advanced distally in the trachea, taking care not to lacerate the dorsal tracheal mucosa. Sterile polyethylene tubing or the catheter from the angiocatheter is introduced through the trocar or needle for about 30 cm. A needle or sharp trocar should be withdrawn to prevent severing the tubing or catheter, but a cannula with rounded edges may be left in place. Approximately 20 to 30 mL of nonbacteriostatic sterile saline solution is introduced quickly. Intermittent aspiration is performed as the tubing is gradually withdrawn. The tubing can be advanced again if a guarding cannula has been left in place to prevent introduction of skin contamination. Additional saline solution aliquots can also be introduced. Once an adequate sample has been obtained, the tubing is completely withdrawn. Injectable antimicrobial solution or suspension can be infiltrated at the skin incision site if a septic sample is suspected, and in horses and small ruminants a sterile dressing can be applied for 24 hours if desired. Possible complications include subcutaneous (SC) emphysema (usually peritracheal but may extend into the mediastinum), local cellulitis, or cutting of the catheter at the needle and loss into the airway. The latter is usually resolved because the catheter is rapidly coughed up, but good technique should prevent this complication. The sample should be cultured for aerobic bacteria. Anaerobic colonization is possible, and appropriate cultures should be made if these organisms are suspected (evidence of pleural effusion, consolidation, abscessation, history of aspiration fetid breath). For patients with prior antimicrobial therapy, it is advised to discontinue antibiotics for 72 to 96 hours before culture, although a recent study has shown reliable recovery of bacteria using bronchoalveolar lavage (BAL) fluid from foals receiving therapy.[6]

495
496

Airway aspiration can also be performed during routine endoscopy of the trachea using an aspiration catheter advanced through the endoscope biopsy channel, but there is potential for pharyngeal contamination. Results comparing culture from a protected aspiration catheter passed through an endoscope compared favorably with culture from traditional percutaneous tracheobronchial aspiration (TBA).[5]

A direct smear and Gram stain can be used as an initial guide for antimicrobial therapy pending culture results. Cytologic evaluation can be extremely valuable in differentiating among infectious, allergic, parasitic, and neoplastic processes. Transtracheal aspirates (TTAs) from clinically normal horses contain columnar ciliated epithelial cells, a few neutrophils, and multiple mononuclear cells. Increased percentages of neutrophils and the presence of mast cells, eosinophils, giant cells, and hemosiderophages have been demonstrated in aspirates from normally performing thoroughbred racehorses, indicating some airway inflammation in “normal” equine athletes.[8] Mucus, large spores, and fungal hyphae may be found in the absence of airway disease and must not be overinterpreted. Heaves, or recurrent airway obstruction (RAO), is characterized by increased numbers of nondegenerate neutrophils and occasional eosinophils. In cases of pneumonia, neutrophils may constitute 40% to 90% of the cellular sample. Bacterial pneumonia causes a more degenerate appearance of neutrophils, and intracellular bacteria may be found. Equine lungworm is characterized by finding large numbers of eosinophils and occasionally a larva. In ruminants the most important information gathered in patients with bronchopneumonia is usually the result of culture and antimicrobial sensitivity testing.

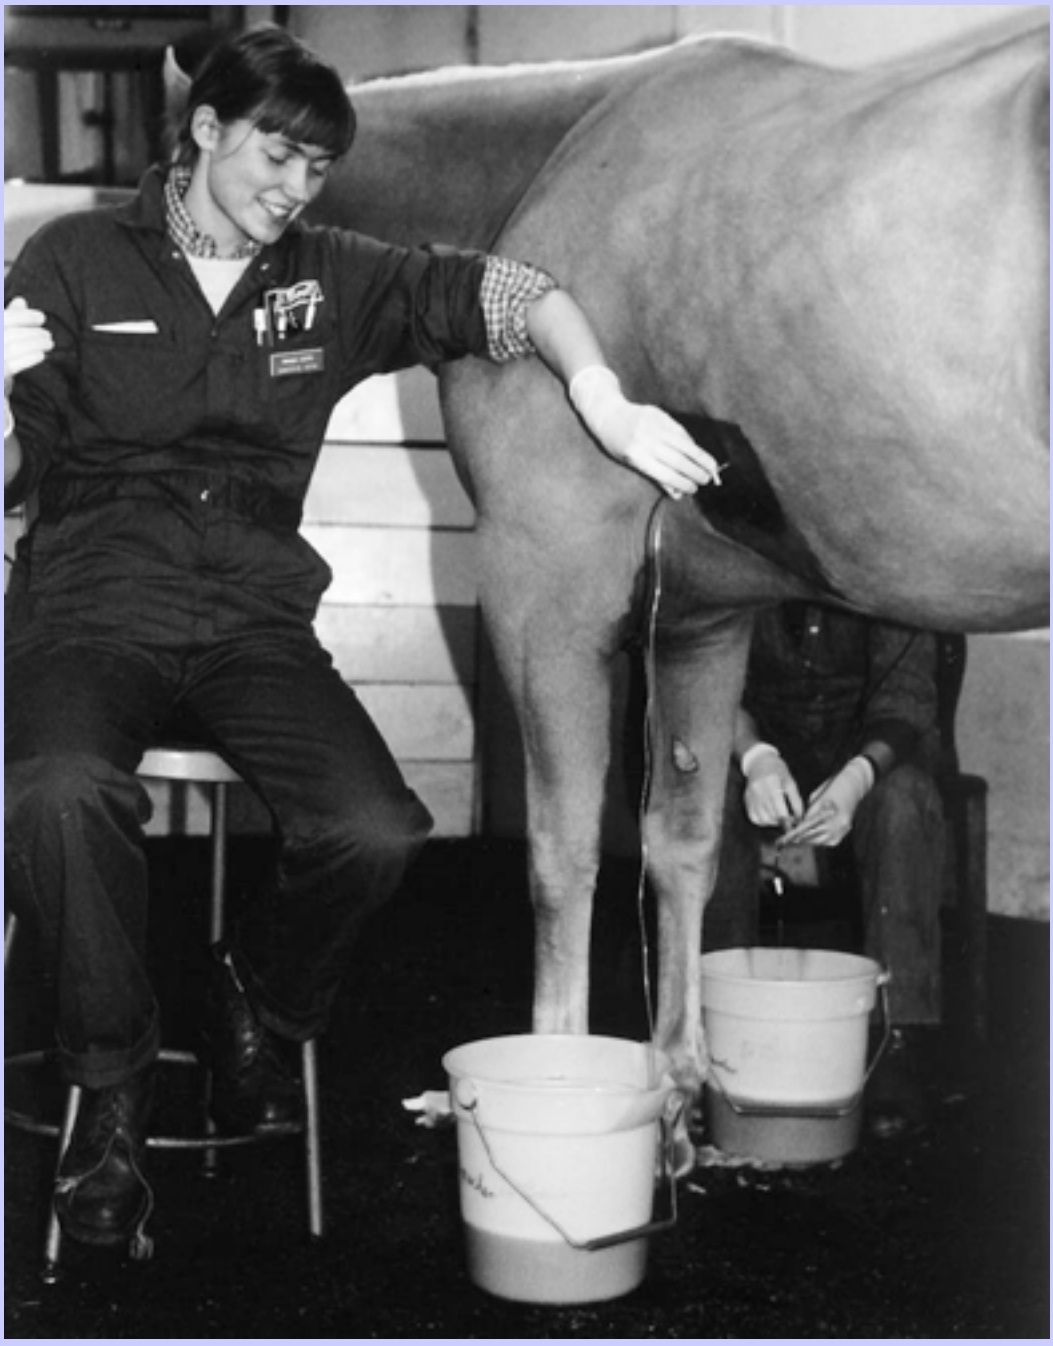
BAL involves obtaining a sample from the terminal airways and alveolar region. It is performed using a long endoscope or double-lumen tube introduced through the nares. Endoscopic BAL allows for more exact placement of the end of the endoscope, so a clear understanding of the anatomic location of the distal airway lavage is available. Use of the double-lumen tube is essentially a blind technique, but most frequently the dorsal lung of one hemithorax is sampled. The outer tube or the endoscope is wedged in a bronchus, and the smaller tube advanced. Saline solution aliquots of 60 to 300 mL are introduced, followed by continuous aspiration using low suction pressure. The procedure has the advantage of sampling the airways nearest the parenchymal region, but only a limited area of the lung is sampled instead of the pooled secretions from a tracheobronchial aspirate. Thus BAL may be superior to tracheobronchial aspiration in evaluation of horses with chronic lung diseases, but false-negative results can be obtained from horses with pneumonia or

pleuropneumonia. BAL cytology is valuable in evaluation of fungal infections and IAD and assessment of therapeutic response.

31.3.8 Thoracocentesis

Aspiration from the pleural space is a simple, easily performed, inexpensive procedure that can be both diagnostic and therapeutic. In the horse with septic or neoplastic effusions, sedation is often unnecessary because the procedure causes only minimal additional discomfort. After ultrasonographic evaluation of the thorax, a point is chosen at which drainage or fluid sampling would seem most appropriate—frequently in the sixth or seventh intercostal space 10 cm dorsal to the olecranon and above the lateral thoracic vein. The area should be clipped, if it was not clipped for the thoracic ultrasound examination, and surgically prepared. Multiple sites may be needed in horses with loculated pockets of fluid in the pleural cavity, and these sites should also be chosen using ultrasonography. The skin and intercostal tissue down to the pleura are anesthetized with lidocaine, and a stab incision is made. A sterile 2- to 3-inch teat cannula or bitch catheter is introduced immediately cranial to the rib border to avoid the intercostal nerve and vessel along the caudal aspect of the ribs. The cannula should be attached to sterile intravenous (IV) extension tubing and a three-way stopcock. When the cannula is advanced bluntly through the parietal pleura, a sudden loss of the force required to advance is felt. Aspiration should be attempted at this point. The orientation of the cannula can be varied to reach as much fluid as possible. Normally only a few milliliters of straw-colored fluid are obtained. In cases of pleural effusion, as much as 30 L may be removed from each side of the chest (Fig. 31-3). If fluid is excessive, the tubing can be extended over a bucket for gravity drainage, or a vacuum pump with fluid trap can be attached. Once the procedure is complete, a purse-string suture is placed around the stab incision, and the cannula is withdrawn while the suture is tightened. In 496
cases in which the effusion is large and expected to continue forming for several days, the initial drainage can be 497
performed by placing a chest tube instead of puncturing the pleural space with a teat cannula. If a chest tube is to be left in place it should be secured with a Chinese finger trap suture and the end covered by a Heimlich valve to prevent aspiration of air into the thorax through the tube. If the thorax is being drained rapidly, the patient should be watched carefully for signs of distress, as draining of large volumes can alter cardiovascular parameters significantly.

Fig. 31-3 Thoracocentesis and therapeutic drainage in the horse. Pleural effusion can be large and bilateral. Samples should be obtained for culture and cytologic examination at the time the chest is drained. Courtesy Dr. Corinne Sweeney, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.



Increasing opacity, presence of fibrin clumps, and malodor of pleural fluid all suggest relative progression from transudate to septic exudate containing inflammatory cells and debris. A putrid odor suggests the presence of anaerobic bacteria. Samples should be cultured for aerobic and anaerobic organisms. A white blood cell (WBC) count of 10,000/μL or less is considered normal; fewer than 60% are normally neutrophils, the remainder being lymphocytes and macrophages. The proportion and total number of neutrophils increase with pleuritis. Erythrocytes are normally not present in the absence of a traumatic tap. The protein concentration is normally less than 3.5 g/dL, and pH should be approximately 7.4. Additional metabolic values that give early indication of sepsis can be obtained on pleural fluid samples collected after filtration through a blood administration set to remove fibrin and debris potentially detrimental to analytic equipment. Pleural fluid pH, P_{CO_2}, and concentration of glucose, lactate, and bicarbonate can be directly compared with similar analysis of venous blood from the patient. A septic pleural exudate is acidic, with decreased glucose and bicarbonate but increased lactate and P_{CO_2} compared with venous blood concentrations or tensions, apparently reflecting metabolic activity of phagocytic cells and bacteria and development of an anaerobic environment.[23] Of these values, low pleural fluid glucose concentration (<40 mg/dL) has the best correlation with sepsis.[24]

Neoplastic cells may be found in cases of lymphosarcoma, adenocarcinoma, or other neoplasms. Equine gastric squamous cell carcinoma occasionally manifests with neoplastic pleural effusion. If neoplastic effusion is suspected but diagnostic cells do not exfoliate into the pleural fluid, pleuroscopy with the patient under sedation and local anesthesia can be used directly to visualize and obtain biopsy samples of intrathoracic lesions. The technique of pleuroscopy is beyond the scope of this chapter.

Mediastinal fenestrations may be occluded by fibrin and cell debris; therefore each side of the thorax should be evaluated separately. In the horse a transtracheal aspiration for culture should also be performed because of the common association of pleuritis with bacterial pneumonia and pulmonary abscessation. Although identical organisms are generally isolated from both samples, this is sometimes not the case.

31.3.9 Sinus Trephination

Sinus trephination is performed with some frequency in horses and ruminants. Clinical signs indicating a need for sinus trephination include foul-smelling purulent nasal discharge (the most consistent sign with dental disease or invasive tumors), facial malformation, exophthalmos, stertorous breathing, and epistaxis. Sinus cysts, neoplasms, and hematomas occasionally occur and result in serosanguineous discharge. When the physical examination, especially percussion, and radiographic findings indicate, the sinus should be trephined for diagnostic aspiration, drainage, and flushing, if necessary. In some cases sinoscopy may be indicated, particularly when the true extent of the disease process is difficult to determine or if biopsy samples are needed.

In the horse the frontal, sphenopalatine, and ethmoidal sinuses all communicate with the posterior chamber of the maxillary sinus and drain through the nasal maxillary opening into the middle meatus. The anterior chamber of the maxillary sinus is separated by an osseous septum that often breaks down with infection, making the posterior chamber of the maxillary sinus the most productive site for diagnostic aspiration. A line is drawn from the medial canthus of the eye perpendicularly to the facial crest. After tranquilization and local anesthesia, the sinus is approached with a Steinmann pin midway on this line. Once the sinus has been entered, aspiration should be performed by using a sterile 16-gauge needle or canine urinary catheter. One skin suture will suffice for closure. If purulent material or fluid within the sinus is under pressure, some leakage into the SC space may occur, with resulting cellulitis. The sample should be cultured for aerobic and anaerobic bacteria and examined cytologically for signs of septic inflammation or neoplastic cells.

The frontal sinus is trephined more often for flushing in chronic cases than for diagnostic purposes. The approach is 2.5 cm lateral to the midline of the face and 2.5 cm caudal to the point at which the nasal bones begin to diverge.

In cattle the frontal sinus is most often affected with septic inflammation as a consequence of dehorning. Purulent material frequently accumulates in the postorbital diverticulum of the sinus. This site is approached for trephination 4 cm from the edge of the orbital cavity just dorsal to the temporal (lateral) canthus of the eye.

Postdehorning sinusitis in goats can be a severe condition, especially in animals dehorned when mature. The frontal sinus contains numerous septa, creating poor drainage; the bony plate protecting the brain is thin, so that septic necrosis of bone leading to meningitis may occur. Therefore, in mature goats with sinusitis, appropriate systemic antimicrobial therapy and vigorous curettage of the affected areas should be used. A bone flap similar to the technique used in chronic maxillary sinusitis may be required to expose the frontal sinuses to curettage adequately.

31.3.10 Guttural Pouch Catheterization

When indicated by radiography and/or endoscopy, equine guttural pouches are easily catheterized for diagnostic sampling and flushing. Sampling can also be achieved by placing thin tubing through the biopsy channel and directly aspirating or aspirating after introduction of sterile saline, as TBA and lavage are performed through the biopsy channel. The patient should be tranquilized so that the head drops, facilitating drainage of the secretions by gravity. A Chambers mare catheter can be passed through the ventral meatus into the pharynx if the endoscope is not to be used for the sampling or lavage. The curved end is directed beneath the flap of the medial lamina of the pouch ipsilateral to the nostril used for passage. Successful passage is indicated by lack of resistance while the catheter is inserted deeper than if it were in the pharynx. The position of the catheter tip in the pharynx can be observed through an endoscope placed up the opposite nasal passage. Once the catheter is within the pouch, it can be used to obtain a sample, to drain excessive secretions, or to act as a conduit for flushing. A self-retaining uterine catheter can be left in place for repeated flushing, but the Chambers catheter can be passed repeatedly with no complications.

31.3.11 Lung Biopsy

Lung biopsy is most often done in the horse and should be used in conjunction with other, less invasive diagnostic techniques such as ultrasonography, radiography, and transtracheal aspiration. Lung biopsy is indicated to obtain a histologic diagnosis or prognostic information primarily in cases of diffuse lung disease, because the sample obtained is generally very small. A more useful parenchymal sample is obtained by means of percutaneous rather than endobronchial biopsy; complications of percutaneous biopsy are uncommon but do occur. A large gauge (14-gauge) 15-cm or longer biopsy needle, with a sample “slot” length of 22 mm, provides an excellent sample. Lung biopsy is easier with newer spring-loaded biopsy instruments than with older hand-operated biopsy instruments. Discomfort is minimal, and sedation may or may not be needed. The site for biopsy should be determined after ultrasonographic evaluation of the thorax, and the procedure should be performed away from common locations of major pulmonary vessels. Caudal and dorsal locations are generally chosen. The site should be widely clipped, surgically prepared, and infiltrated with local anesthetic down to the pleura. The biopsy needle is inserted through a stab incision just cranial to the rib, similar to catheter placement for pleural fluid sampling and drainage, and directed medially through the intercostal muscles and parietal pleura. The needle should be advanced the distance indicated by ultrasonographic measurement and then sharply advanced <1 cm to enter the lung parenchyma. The biopsy is obtained by “firing” the spring-loaded instrument, and the

biopsy instrument is then withdrawn. If no specimen is obtained, the procedure can be repeated. After sufficient biopsy specimens have been obtained and the biopsy instrument withdrawn, a single skin suture can be placed at the incision site, but no additional aftercare is needed. The specimen should be placed directly in 10% formalin or glutaraldehyde for fixation. If additional samples can be safely obtained, they should be submitted for bacterial and fungal culture and potentially for more advanced molecular diagnostic techniques and handled appropriately for the desired test. Complications of lung biopsy have been reported to range from transient epistaxis or hemoptysis, which is to be expected, to more severe pleural and parenchymal hemorrhage. Lung biopsy is not indicated for pleuropneumonia cases but is generally required to differentiate among EMPF, discrete fungal lesions, and potential neoplasia, when accurate diagnosis is required for therapeutic and prognostic purposes.

31.3.12 Molecular Techniques

Infectious pulmonary disease represents a diagnostic challenge for the equine practitioner. A presumptive diagnosis can often be made based on the history, physical examination, clinical impression, complete blood cell count, radiography, and endoscopy. Definitive identification of the causative agent(s) is necessary to ensure that the appropriate therapeutic and prophylactic protocols are instituted.

Culture of infectious pathogens is an indispensable diagnostic technique and should be attempted in all cases of pulmonary disease. However, cultivating infectious pulmonary pathogens from clinical specimens is time-consuming and may require from days to months before an organism is identified, potentially delaying appropriate management. Molecular recognition systems that can be used for rapid identification can improve response time and reduce the number of susceptible animals exposed to the infectious pathogen.

Several technologic innovations have improved the rapidity and sensitivity with which microorganisms are identified.[25] Immunologic assays and nucleic acid—based methods for the identification of bacterial, viral, and fungal pathogens have found clinical application in the diagnosis of pulmonary disease.

31.3.12.1 IMMUNOLOGIC TECHNIQUES

Immunologic detection of bacterial, viral, and fungal pulmonary pathogens have been developed. Immunoassays rely on interaction between the bacterial, viral, and fungal antigens and enzyme- or fluorescent-labeled antibody. The use of polyclonal antibodies tends to increase the sensitivity of the assay, as the preparation may contain antibodies to multiple epitopes on the target antigen, thus increasing the chance of antigen detection, but tends to decrease assay specificity because of their heterogenous nature. Test specificity can be improved by the use of monoclonal antibodies, as these antibodies interact with only a single well-defined epitope or very similar epitopes.

Immunohistochemistry (IHC) is rapidly becoming a standard diagnostic tool for the identification of viral, bacterial, and protozoal pathogens in tissue sections. This technique depends on polyclonal or monoclonal antibodies binding to a target antigen and the demonstration of this interaction by colored histochemical reactions visible by light microscopy or by emittance of fluorescence detectable after ultraviolet light illumination. IHC is highly versatile, and assays have been developed to detect a variety of equine pulmonary pathogens including, but not limited to, equine herpesviruses (EHVs), equine viral arteritis (EVA) virus, Hendra virus (HeV), *R. equi*, and *Pneumocystis carinii*, in tissue sections. Recent advancements in methodology have increased the ability to detect antigens in formalin-fixed tissues.

31.3.12.2 NUCLEIC ACID-BASED TECHNIQUES

Nucleic acid—based techniques for the diagnosis of equine pulmonary disease are becoming widely accepted because of the sensitivity, specificity, and speed with which results can be obtained. These assays can detect nucleic acid of both live and dead pathogens at very low concentrations, often less than 100 copies per microliter. Bacterial, viral, and fungal pulmonary pathogens can be discriminated based on nucleic acid sequences unique to those particular organisms. Polymerase chain reaction (PCR) testing is the most widely used molecular diagnostic technique in both research and clinical laboratories. PCR testing involves the enzymatic replication of a target region of deoxyribonucleic acid (DNA) as defined by a set of oligonucleotide primers. DNA polymerase synthesizes each complementary strand of the target region in the 5' to 3' direction, and the amount of DNA that is synthesized increases exponentially. For viruses whose genome is composed of ribonucleic acid (RNA), an initial reverse transcriptase (RT) step is required to generate a complementary strand of nucleic acid because the DNA polymerase requires a double-stranded template to amplify the target sequence.

Real-time PCR combines PCR amplification with detection of the amplified products, allowing quantification of PCR products. In real-time PCR the PCR reaction is carried out in a reaction tube to which an optical device is attached to read the fluorescent signal generated during each cycle of PCR reaction. Increases in the reporter fluorescence are proportional to the increase in PCR product. By monitoring the changes in degree of fluorescence, the time in which a transition from exponential to log phase amplification occurs can be determined and compared with that of a standard control to determine the initial template concentration.

Hydrolysis probes, such a TaqMan (Applied Biosystems, Foster City, Calif.), are commercially available and can be tailored for use in diagnostic tests to detect specific pathogens. In the TaqMan assay a probe is labeled with fluorescence and binds to a nucleic acid sequence within the target region. During amplification the *Thermus aqaticus* (Taq) polymerase hydrolyses the probe that separates the fluorescein from a quenching dye and allows the emission of fluorescence. The amount of fluorescence emitted is proportional to the accumulation of specific PCR product. TaqMan assays reduce the risk of contamination, as there is less sample handling compared with traditional PCR techniques, and the results are produced rapidly.

498

499

With the increased use of PCR assays as diagnostic tests, there is increased demand for standardized techniques and internal control measures. PCR is a highly sensitive test and may produce false-positive results, commonly attributed to contamination. False-negative results may occur as a result of the presence of enzyme inhibitors in the sample that suppress DNA amplification. Control plasmids, which contain a DNA sequence that is amplified at the same time as the target DNA but is sufficiently mutated that it can be distinguished from the target DNA sequence after PCR testing, are increasingly being used to identify the presence of inhibitory molecules within the assay either resulting from tissue or sample handling problems or associated with collected tissues.

These assays do not substitute for careful clinical evaluation but can shorten the time to confirmed, accurate diagnosis and thus allow for early initiation of therapeutic strategies and prevention protocols. With further understanding of the molecular biology and immunology of pulmonary disease, diagnostic and management techniques will become further refined.

31.4 PULMONARY FUNCTION TESTING

DANIELA BEDENICE

PFT has emerged as an essential tool in equine referral practice and is largely aimed at describing the severity, anatomic pattern, stability (reactivity), and reversibility of bronchoconstriction caused by noninfectious airway obstruction and inflammation, such as is seen in heaves and airway inflammatory disease.[26] Clinical indications for noninvasive PFT include assessment of horses with intermittent cough, exercise intolerance, abnormal breathing pattern, and excess mucus, as well as early detection of subclinical disease, evaluation of treatment response, intensive care monitoring, and prediction of outcome. PFT is generally divided into the assessment of respiratory mechanics (mechanical properties of the respiratory system) and gas exchange. Analysis of gas exchange investigates ventilation-perfusion matching, shunt, diffusion capacity, and dead space—to—tidal volume ratio (V_D/V_T). Lung mechanics, on the other hand, determines the static and dynamic properties of the lung, including resistance, compliance, functional residual capacity (FRC), and ventilatory parameters.[26]

31.4.1 Mechanics of Breathing

The mechanical function of the lung is essentially defined by static and dynamic properties. Tests that are performed with the respiratory system at equilibrium and zero flow are referred to as *static tests*. Examples include measurement of lung volume subdivisions (e.g., FRC) and compliance of the lung and chest wall.[26]

FRC is a measure of the amount of gas that remains in the lungs at end-expiration (end-expiratory volume). FRC is lower in patients with increased "lung stiffness" (reduced elastic recoil of the lung) as well as airway inflammation, whereas FRC increases in patients with expiratory airway obstruction and gas trapping.[27] This test can be easily performed in awake clinical patients via a helium dilution technique.[28] In short, the patient is connected to a reservoir bag at end-expiration to rebreathe a standard, commercial breathable gas mixture of 10% helium (He), 20% oxygen, and the remainder nitrogen for 90 seconds. The dilution of He (a nonexchangeable gas) gives a measure of end-expiratory lung volume.[28]

Measurements of static compliance or "elastic recoil of the lung" require breath holds and have applications only to the anesthetized patient. So-called *pressure-volume curves* are generated in the relaxed patient during lung deflation from total lung capacity (TLC), using an esophageal balloon technique. Compliance is defined as the lung volume change per unit of pressure change[27]:

$$\text{Compliance} = \Delta V / \Delta P$$

Reduced lung compliance (i.e., increased lung stiffness) may be associated with increased fibrous tissue (pulmonary fibrosis), atelectasis (e.g., underventilated lung), or an increased pulmonary venous pressure, in which the lung becomes engorged with blood. Emphysema and normal aging of the lung, which leads to alteration in elastic tissue, are causes of increased lung compliance.[27]

In contrast to static tests, tests that are performed with the respiratory system in motion (e.g., during quiet breathing) are referred to as *dynamic*. An example of a dynamic measurement is resistance, a measurement that requires flow. Resistance arises from friction of air molecules against airway walls (see formula[26]).

$$\text{Resistance} = \frac{\text{Change in pressure } (\Delta P)}{\text{Change in flow } (\Delta V)}$$

The measurement of pulmonary resistance (R_L) using a flow meter attached to a face mask and an esophageal balloon catheter to measure transpulmonary pressure changes is conventional in the horse but is rarely used in

the clinical setting.[26] This technique allows computation of both R_L and dynamic compliance (C_{dyn}) at spontaneous breathing frequencies. Maximal transpulmonary pressure change ($\Delta P_{PL_{max}}$) and R_L both increase in cases of obstructive airway disease, whereas C_{dyn} decreases. However, this classic technique is fairly insensitive in detecting subclinical disease[29,30] and has greater utility in the diagnosis of IAD if coupled with a challenge test (i.e., histamine bronchoprovocation [see later]).[31,32]

31.4.2 Forced Oscillation Techniques

In contrast to the conventional methods, noninvasive measurements of total respiratory system resistance via forced oscillation techniques (FOT) are used in the diagnosis of IAD in horses. In short, oscillometry is the study of lung mechanical function via the application of external forces to the respiratory system.[33] Either a loudspeaker (e.g., Impulse Oscillometry System [IOS]) or air pressure (e.g., Monofrequency Forced Oscillatory Mechanics [FOM]) is used to superimpose pulses of flow (4 to 5 L/sec peak) through a face mask on the horse's respiratory system during spontaneous breathing. The generated reciprocal pressure waves are subsequently recorded at the airway opening (i.e., face mask). The magnitude and phase relationship between the input of flow and output of pressure are then used to perform the calculations of impedance (total opposition to airflow) and its components, resistance and reactance, at a variety of oscillatory frequencies (generally 1 to 7 Hz).[26] In most horses with IAD there is a frequency dependence of resistance, with higher values for resistance recorded at the lower oscillatory frequencies (1 to 2 Hz), indicative of bronchoconstriction.[34–36] Higher frequencies (≥2 Hz) provide information concerning central airway resistance (R_{aw}). Baseline respiratory resistance measurements using FOT are commonly combined with bronchoprovocation tests for the early diagnosis of IAD (see later).

31.4.3 Histamine Bronchoprovocation

Bronchoprovocation is a challenge test that assesses the response of the respiratory system to a bronchoconstrictor agonist (e.g., inhaled histamine).[26] The provocatory concentration necessary to cause a 100% increase in baseline respiratory system resistance is commonly termed $PC100_{RRS}$. Horses with a low $PC100_{RRS}$ (e.g., less than 6 mg/mL of histamine) are designated as having hyperreactive airways. Airway hyperreactivity (AHR) is an exaggerated narrowing response to a bronchoconstrictive stimulus, was first found in horses with heaves,[37] and is considered a hallmark of IAD. There is a correlation between airway reactivity and mast cell percentage in BAL fluid (BALF) in horses with a history of exercise intolerance.[38] The clinical symptoms associated with AHR are thought to include coughing (increased sensitivity) and exercise intolerance, whereas bronchoconstriction causes uneven ventilation and hypoxemia.[39]

31.4.4 Respiratory Inductive Plethysmography

The objective assessment of respiratory function and breathing pattern may also be obtained through the concurrent application of respiratory inductive plethysmography (RIP) and pneumotachography, which has been validated for the use in humans,[40,41] horses,[42] and sheep.[43] In summary, two elastic bands, each containing a single sinusoidal conducting wire, are temporarily placed around the animal's thorax and abdomen (Fig. 31-4). Stretch and contraction of the bands resulting from normal respiratory movements are measured as voltage changes, which are proportional to the change in circumference and volume of the thorax and abdomen.[44] Simultaneous measurements of nasal flow are obtained at the airway opening (face mask). This technique rapidly assesses the synchronicity of breathing pattern (e.g., thoracoabdominal asynchrony due to diaphragmatic

paralysis)[44] and the individual contribution of the thorax and abdomen to respiration. It further quantifies changes in flow resulting from airway obstruction.

31.4.5 Forced Maneuvers

Forced expiratory maneuvers are commonly performed in humans with suspected asthma. Simplistically, the patient is asked to blow out hard from TLC until the lung is empty. The volume of air expelled in 1 sec (FEV_1) corrected for vital capacity (FVC) is used as a measure of lower airway obstruction.[26] Couetil adapted the method of forced maneuvers for routine clinical application in heavily sedated, nasotracheally intubated horses.[45] He further demonstrated flow limitation in horses with early signs of obstructive airway disease (IAD) that was worse in animals with heaves. Remission from heaves showed improvement in flow limitation.[26]

PFT is considered instrumental in the understanding of the pathogenesis, pathophysiology, epidemiology, diagnosis, and treatment of lung disease in the horse.[26] The described tests are aimed at quantifying airway obstruction, airway reactivity, and lung stiffness in the clinical setting. PFT will thus facilitate the diagnosis of

subclinical disease and improve the clinician's assessment with regard to aggressive management of lung disease, decisions for ventilation, intensity of monitoring, and assessment of treatment response and prognosis.

31.5 EQUINE RESPIRATORY SYSTEM

PAMELA A. WILKINS, Consulting Editor

31.6 DISORDERS OF THE LUNGS

31.6.1 BACTERIAL PNEUMONIA AND PLEUROPNEUMONIA IN ADULT HORSES

STEEVE GIGUÈRE

Bacterial infections of the lower respiratory tract are common in adult horses. Lower respiratory tract infections may be localized to the lumen of the airways (termed *bacterial bronchitis* or *septic inflammatory airway disease*) or may involve the pulmonary parenchyma (termed *pneumonia*). In equine medicine the term *bronchopneumonia* is often used to refer to lower respiratory tract infection regardless of whether the infection is localized to the bronchi or involves both the bronchi and the lung parenchyma. When there is subsequent extension of the infection from the pulmonary parenchyma to the visceral pleura and pleural space, the disease is referred to as *pleuropneumonia*. The spectrum of clinical signs shown by horses with bronchopneumonia is broad and reflects the severity of the disease process. Early identification of affected animals and immediate initiation of appropriate therapy are essential to prevent mortality and functional impairment of the respiratory system. Expenses incurred by owners of affected horses include cost of medical care, loss of income during the illness and the recovery period, cost of training after a prolonged period of inactivity, and financial loss resulting from death of some animals or diminished performance of others after recovery.

500

501

31.6.2 Infectious Agents Involved

Adult horses most commonly acquire bacterial pneumonia by aspiration of microorganisms that normally inhabit their nasopharynx or oral cavity.[46,47] β-hemolytic streptococci, particularly *Streptococcus equi* subsp. *zooepidemicus*, are by far the most common bacterial pathogens isolated from adult horses with bronchopneumonia.[48] Nonenteric gram-negative bacteria such as *Pasteurella* species and *Actinobacillus* species are also frequently isolated, either alone or in combination with *S. zooepidemicus*. Enteric gram-negative bacteria such as *Klebsiella* species*, Escherichia coli, Enterobacter* species, and *Salmonella enterica* may also be isolated. Other aerobic gram-positive organisms such as *Staphylococcus* species and *R. equi* or gram-negative organisms such as *Pseudomonas* species and *Bordetella bronchiseptica* are occasionally isolated. *Pseudomonas* species are rarely a primary cause of pneumonia in horses, and their presence often reflects contamination of equipment used for taking airway samples (such as endoscopes). *Streptococcus pneumoniae*, a common pathogen of humans, has been positively correlated with lower airway inflammation in young thoroughbred racehorses in the United Kingdom.[49] The microorganism can also induce pneumonia in ponies after heavy intrabronchial challenge.[50] However, *S. pneumoniae* is rarely isolated from pneumonic horses in the United States.

Anaerobic bacteria are isolated from approximately one third of adult horses with severe bronchopneumonia, pleuropneumonia, or pulmonary abscessation. The most common anaerobes isolated are *Bacteroides* species., particularly *Bacteroides fragilis, Clostridium* species, and *Peptostreptococcus* species; *Fusobacterium* and *Eubacterium* species may also be isolated.[48,51] Isolation of anaerobes from horses with pneumonia or

pleuropneumonia has been associated with a less favorable prognosis in some studies. In one study the survival rate for 221 pneumonic horses with strictly aerobic isolates from tracheobronchial aspirates was 81.4% compared with 38.3% for the 81 horses in which anaerobes were cultured.[48] Mixed bacterial infections are very common and may represent synergy between aerobic or facultative aerobic and anaerobic bacteria.

The importance of *Mycoplasma* species in the development of equine bronchopneumonia and pleuropneumonia is controversial. Several *Mycoplasma* species have been isolated from the respiratory tract of both diseased and healthy horses, with *Mycoplasma felis* and *Mycoplasma equirhinis* being the most common isolates. In one study, isolation of *M. equirhinis* was positively correlated with lower airway inflammation in a group of young thoroughbred racehorses in the United Kingdom,[52] whereas isolation of *Mycoplasma* species was not significantly associated with disease in a similar population in Australia.[53] An outbreak of lower respiratory tract disease caused by *M. felis* infection has been described.[54] *M. felis* has also been isolated from horses with pleuropneumonia, and at least in one instance experimental infection with *M. felis* has resulted in pleuropneumonia.[55,56]

31.6.3 Epidemiology

Bacterial bronchopneumonia may affect horses of any age and breed. In one retrospective study of 327 horses with pneumonia or pleuropneumonia, there was no sex predilection but 82% of the horses were less than 5 years of age.[48] In a retrospective case-control study of risk factors for development of pleuropneumonia, thoroughbreds were at greater risk whereas standardbreds were at lower risk for developing the disease.[57] In the same study the most significant risk factor for development of pleuropneumonia was long-distance transport within the week before the onset of clinical signs.[57] In another study, 24.4% of 90 horses with pleuropneumonia had recently been transported over long distances, and 12.2% had recently undergone general anesthesia.[58] Five of the postsurgical cases had undergone upper airway surgery.[58] Whether these horses had preexisting lung disease or whether they developed aspiration pneumonia as a result of surgery and general anesthesia could not be ascertained.

Other factors significantly associated with increased risk of developing pleuropneumonia include recent viral respiratory tract infection or exposure to horses with viral infections and racing within 48 hours before developing clinical signs.[57] One study in the United Kingdom identified a higher incidence of pneumonia and pleuropneumonia in show jumpers, presumably reflecting the greater distance over which these horses are transported compared with racehorses in that country.[59]

31.6.4 Pathophysiology

Colonization of the lungs by opportunistic bacteria occurs when the pulmonary defense mechanisms are compromised or are overwhelmed by massive numbers of bacteria. Several factors can contribute to causing increased numbers of bacteria in the lower airways. Dysphagia or esophageal obstruction will lead to aspiration of large numbers of pharyngeal bacteria, and these disease processes often result in pneumonia. However, the vast majority of horses with bacterial pneumonia or pleuropneumonia do not have a history of dysphagia or esophageal obstruction. Other factors that have been shown to significantly increase bacterial contamination of the lower respiratory tract include confinement with the head elevated, transportation, and high-intensity exercise.[60–62] In one study, confinement of horses with the head elevated resulted in a significant increase in bacterial numbers as well as neutrophilic inflammation in the lower respiratory tract as early as 6 hours after

initiation of confinement.[61] *Actinobacillus* species, *Pasteurella* species, and β-hemolytic streptococci were the predominant bacterial isolates. Lowering the head for 30 minutes every 6 hours to facilitate postural drainage during a 24-hour confinement did not prevent multiplication of bacteria.[61] Clearance of accumulated secretions and bacteria occurred within 8 to 12 hours after release from confinement.[61] In similar confinement experiments, pretreatment with penicillin considerably reduced the number of β-hemolytic streptococci but did not reliably reduce total bacterial numbers.[63] Cilia of many other species such as dogs and humans can transport mucus effectively against gravity, and posture has no effect on tracheal mucociliary transport in these species.[64,65] In contrast, periods of lowered head posture are absolutely essential for normal mucociliary clearance in horses.[66]

In one study, long-distance transport by road over 12 hours resulted in increased bacterial contamination and neutrophilic inflammation in tracheal aspirate fluid when the horses' head were restrained in an elevated position.[67] This is in contrast to another study in which there was no significant cytologic or bacteriologic change in BALF from mares whose heads not restrained in an elevated position during transportation for 12 hours.[68] Collectively, these findings suggest that duration of time with a raised head position is more important than the stress of transport alone in development of airway colonization. Finally, the last factor shown to increase bacterial contamination of the large airways of horses is exercise. In one study a single bout of high-intensity exercise resulted in a tenfold increase in aerobic and a hundredfold increase in anaerobic bacterial counts in tracheal aspirate samples compared with preexercise values.[60]

Pulmonary defense mechanisms can be compromised by numerous factors. These include stress (e.g., transport and intense exercise), viral infections, malnutrition, exposure to dust or noxious gases, immunosuppressive therapy, immunodeficiency disorders, and general anesthesia. Infections with influenza virus and EHV-4 have been shown to significantly decrease mucociliary clearance for up to approximately 30 days after infection in horses.[69] In one study, long-distance transportation resulted in a significant reduction in phagocytosis by peripheral blood neutrophils for approximately 36 hours after transportation.[67] The effect of long-distance transport on number, viability, and function of cells in BALF has given conflicting results with no clear pattern emerging.[68,70–72] Similarly, the effects of exercise on the immune system are complex and depend on a multitude of factors including the intensity or duration of exercise, the specific immune function being analyzed, and the timing of the measurement in relation to exercise. In general, moderate exercise enhances immune function whereas strenuous exercise tends to be detrimental to immune function.[73] High-intensity exercise in horses leads to a significant decrease in blood neutrophil and bronchoalveolar macrophage phagocytic activity, which may lead to decreased bacterial clearance from the lungs.[74–76] Exercise also affects the adaptive immune system, as lymphocyte proliferation responses and interferon (IFN)-γ production are decreased after high-intensity exercise.[77–79] Strenuous exercise has also been shown to increase susceptibility to experimental influenza virus infection in ponies compared with rested animals, indicating that alterations of the immune function after exercise is a real phenomenon and not just an in vitro artifact.[77]

Regardless of the exact mechanism predisposing to bacterial colonization, the inflammatory response induced by bacterial invasion results in infiltration of neutrophils and other inflammatory cells into the airways and pulmonary parenchyma. Inflammatory cells and their mediators cause damage to the airway epithelium and capillary endothelium, leading to flooding of the terminal airways with inflammatory cells, serum cellular debris, and fibrin. This process is generally more severe in the ventral portions of the lung. In early stages the lungs may be simply edematous, reflecting inflammation and early exudation, whereas in chronic severe cases the airways may be filled with purulent material and necrotic debris. Affected areas may show various degrees of consolidation, although in some cases focal abscesses may develop. These lesions interfere with gas exchange,

and if the condition is severe enough the resulting ventilation-perfusion mismatch leads to hypoxemia and clinical signs of respiratory disease.

In severely affected animals, inflammation extends to the pleural space. The first stage of bacterial pleuropneumonia is an exudative stage, which is characterized by rapid outpouring of sterile pleural fluid into the pleural space in response to inflammation of the pleura. The associated pneumonic process is usually contiguous with the visceral pleura and results in increased permeability of the capillaries in the visceral pleura. If appropriate antimicrobial therapy is initiated at this stage, the pleural effusion may not become septic and may resolve. With progression, the bacteria invade the pleural fluid from the contiguous pneumonic process and the second, fibropurulent, stage evolves. This stage is characterized by the accumulation of large amounts of pleural fluid with many degenerate neutrophils, bacteria, and cellular debris. Fibrin is deposited in a continuous sheet covering both the visceral and parietal pleura adjacent to affected areas. As this stage progresses, there is often loculation and formation of limiting membranes. These loculations prevent dissemination of the infection but make drainage of the pleural space with chest tubes increasingly difficult. The last stage is the organization stage, in which fibroblasts grow into the exudate from both the visceral and parietal pleura surfaces and produce the membrane called the *pleural peel*. This inelastic pleural peel encases the lung and renders it virtually functionless. At this stage the exudate is generally thick.

31.6.5 Clinical Signs and Physical Examination

The spectrum of clinical signs shown by horses with bacterial lung infection is broad and usually reflects the severity of the disease process. Horses with septic IAD and no or minimal involvement of the lung parenchyma may be completely normal at rest. Clinical signs may be limited to exercise intolerance and poor performance, or affected horses may cough or have bilateral nasal discharge during or immediately after exercise. Even in cases of early bronchopneumonia, clinical signs may not be obvious. As the disease progresses clinical signs may include any combination of fever, anorexia, depression, bilateral nasal discharge, cough, weight loss, tachypnea, and respiratory distress. Nasal discharge is usually mucopurulent but may be hemorrhagic in some cases with pulmonary infarction and necrotizing pneumonia.[80] Halitosis and a foul-smelling nasal discharge may be present and has been associated with infection by anaerobic bacteria. However, the absence of a putrid odor does not rule out anaerobic infections.

Because the parietal pleura are highly innervated and painful when inflamed, horses with acute pleuropneumonia often exhibit pleurodynia (pleural pain). Pleurodynia can often be detected by applying digital pressure to the intercostal space, resulting in grunts, intercostal muscle spasm, or even escape maneuvers by the patient when pain is present. Pleurodynia may also be manifested as pawing, stiff forelimb gait, abducted elbows, and reluctance to move. The condition may easily be mistaken for colic, exertional rhabdomyolysis, or laminitis. As more fluid accumulates in the pleural space and the disease becomes chronic, pain is less evident. A plaque of sternal edema is a common clinical finding in horses with pleuropneumonia. This is not a specific finding, as it can occur with many other disease processes.

Careful auscultation after application of a rebreathing bag (if not precluded by respiratory distress) is extremely valuable in defining the presence and sometimes extent of lung involvement. Horses with a large amount of secretions in the trachea often have an audible tracheal rattle. Most horses with bronchopneumonia cough when the rebreathing bag is applied, whereas normal horses do not. Occasional inspiratory or expiratory crackles and/or wheezes may be heard over affected areas, which are more commonly located ventrally. Because consolidated lung parenchyma is a good acoustic medium, mild consolidation sometimes results in only increased bronchial sounds. In contrast, the lung sounds may be diminished in areas of severe consolidation, extensive abscess formation, or pleural effusion.

Auscultation of horses with pleuropneumonia reveals normal lung sounds in the dorsal lung fields with no or considerably decreased lung sounds ventrally. Pleural friction rubs are often not heard because they are present only in the acute stage of the disease. If they are heard, friction rubs are present predominantly at the end of inspiration and the early part of expiration. They disappear as inflammation decreases or as pleural fluids accumulate. Cardiac sounds are often heard over a wider area of the chest than normal, probably as a result of enhanced conduction of sound through the pleural fluid. Thoracic percussion is useful to detect and delineate pleural effusion with resonant sounds dorsal and dull sounds ventral to the horizontal line of effusion.

502

503

31.6.6 Differential Diagnosis

When physical examination and auscultation indicate pulmonary disease, the major clinical task is differentiating infectious from noninfectious causes. Among infectious causes, bacterial pneumonia is most common. Viral infections are usually confined to the upper respiratory tract. Pulmonary aspergillosis most often follows severe gastrointestinal (GI) disease that resulted in mucosal compromise. Severe respiratory disease unresponsive to antimicrobial therapy should arouse suspicion of fungal pneumonia.[81] Parasitic pneumonitis is rare in adult horses but may be seen in horses pastured with donkeys or mules. The two major noninfectious causes of pulmonary disease that may be confused with bacterial pneumonia include heaves and nonseptic IAD. Other uncommon causes of noninfectious pulmonary disease that may result in similar clinical signs include pneumothorax, pulmonary edema, smoke inhalation, neoplasia, and idiopathic interstitial pneumonia. The diagnostic tests described in the following sections aid in the differentiation between infectious and noninfectious causes of lower respiratory tract disease.

When pleural effusion is present, several differential diagnoses should be considered. Bacterial pleuropneumonia is by far the most common cause of pleural effusion in horses. In one study, 90 of 122 horses (73.8%) with pleural effusion had pleuritis secondary to bacterial pneumonia or lung abscessation.[58] Other, less common causes of pleural effusion in horses include hemothorax, penetrating chest wounds, esophageal ulceration or rupture, neoplasia, fungal pneumonia, pericarditis, congestive heart failure, diaphragmatic hernia, hypoproteinemia, and chylothorax.

31.6.7 Diagnostic Approach

Presumptive diagnosis of lower respiratory tract infection is generally based on clinical signs and careful auscultation of the lungs with a rebreathing bag. The need for additional diagnostic procedures is determined by the severity and duration of clinical signs, the number of affected animals, and the value of the affected animal(s), as well as prior treatment used and response to such therapy. Bacterial pneumonia or pleuropneumonia most commonly affects an individual horse on a given farm. In horses suspected of having bacterial pneumonia, the goal of diagnostic evaluation is to rule out diseases of the upper respiratory tract and to determine the cause and severity of lung involvement.

31.6.7.1 HEMATOLOGY AND BIOCHEMISTRY

Horses with bacterial bronchopneumonia commonly have an inflammatory hematologic profile. Leukocytosis and absolute neutrophilia with or without a left shift are supportive of a diagnosis of bacterial infection. Neutropenia with a toxic left shift may also be evident in the acute stages in severely affected animals. Increased fibrinogen concentrations, hyperglobulinemia, and mild hypoalbuminemia are common. Anemia of chronic inflammation may develop in chronically affected animals. There does not seem to be a good

correlation between the severity of clinical signs and the presence or the magnitude of hematologic changes. When plasma fibrinogen concentrations are elevated, their sequential measurement provides a useful means of monitoring response to treatment and is a useful guide in the decision to discontinue treatment. It must be remembered that a normal hematologic profile does not rule out bacterial bronchopneumonia.

31.6.7.2 ENDOSCOPY

Endoscopy may be useful to rule out upper airway infection when physical examination and auscultation of the lungs are not conclusive. Presence of mucopurulent secretions in the trachea and bronchi confirms lower respiratory tract disease. However, the presence of mucopurulent secretions does not necessarily indicate a bacterial infection, as this is also a common finding in horses with heaves and horses with nonseptic IAD. Bronchoscopy may also be useful in locating the affected lung segment in horses with focal pneumonia or draining pulmonary abscesses. It should be noted that exploration of the trachea and lower airways via bronchoscopy may contaminate subsequent samples taken for culture.

31.6.7.3 TRACHEOBRONCHIAL ASPIRATION FOR CYTOLOGY AND CULTURE

TBA for cytologic examination and bacterial culture is one of the most helpful diagnostic procedures available when bronchopneumonia is suspected. BAL is not as useful as tracheobronchial aspiration in cases of bronchopneumonia, because with BAL only a small portion of a lung is sampled. In contrast to BAL, TBA yields a pooled sample of secretions from all portions of the lung, thus increasing chances of culturing the pathogen of interest. In one study involving 22 horses diagnosed with pneumonia or pleuropneumonia based on thoracic radiographs or ultrasonography, cytology of BAL was abnormal in only 10 horses despite attempts at selectively sampling the affected area.[82] In contrast, all horses had evidence of septic inflammation based on tracheobronchial aspirate cytology.[82] Whenever possible, antimicrobial therapy should be discontinued at least 24 hours before tracheobronchial aspiration is performed. Tracheobronchial aspirate is preferably obtained by sterile percutaneous transtracheal aspiration to avoid contamination from the upper airway. Alternatively, the sample can be collected with a sterile guarded aspiration catheter passed through the biopsy channel of a flexible endoscope.[83,84] Endoscopy has the advantage of allowing selective aspiration of exudate when it is present, which may therefore enhance recovery of bacteria. However, bacterial contamination of nasal or pharyngeal origin more commonly occurs in tracheobronchial aspirate samples collected via endoscopy. Airway fluid specimens should be submitted for cytology and Gram stain, as well as for aerobic and anaerobic bacterial culture. The fluid used for anaerobic cultures should be transferred to the laboratory immediately after collection in a manner that prevents or minimizes exposure to air. Anaerobic transport media are commercially available and should be routinely used. Specimens submitted for isolation of anaerobes should not be refrigerated, because many anaerobes are intolerant to cold. In horses with pleural effusion, a tracheobronchial aspirate should be obtained even if pleural fluid is available for bacterial culture. In one study, culture of the pleural fluid was negative in 43% of 111 horses with pleuropneumonia, whereas tracheobronchial fluid yielded growth in all cases.[48] Only approximately 5% of cases had growth from the pleural fluid but not from the tracheobronchial aspirate.[48]

Macrophages and columnar ciliated epithelial cells predominate in tracheobronchial aspirates from healthy horses. The percentage of neutrophils in tracheobronchial aspirates from apparently healthy horses can be quite variable. In one study approximately 75% of apparently healthy thoroughbred racehorses in training had less than 20% well-preserved neutrophils.[85] Occasionally plant spores and fungal hyphae may be present, either free or in large mononuclear cells. Their presence does not necessarily indicate fungal infection and

probably reflects the horse's environment. Degenerated neutrophils displaying karyolysis and cytoplasmic vacuolization are the predominant cell type in horses with bacterial lower respiratory tract infections. Bacteria may be found intracellularly or extracellularly. Presence of squamous epithelial cells indicates contamination with the upper respiratory tract or pharynx and is more common in samples obtained via the endoscope. The trachea is not a perfectly sterile site, and potentially pathogenic bacteria can be isolated from the trachea of normal horses.[83] Therefore culture results should always be interpreted in the context of clinical signs and cytologic examination. If small numbers of bacteria are cultured in the absence of cytologic evidence of sepsis, it is unlikely that they are the cause of the respiratory problem. Similarly, growth of various molds is common in tracheobronchial aspirate cultures, and the clinical signs and cytologic findings should be considered before treatment with antifungal agents is initiated.

31.6.7.4

THORACIC ULTRASONOGRAPHY

Thoracic ultrasonography can be performed using a range of transducers and machine types. The normal aerated lung parenchyma is not penetrated by the ultrasound beam, rendering only the pleural space and superficial lung surface available for study. Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas but may not be as useful as radiography to evaluate the full extent of lung lesions because lesions with overlying aerated lung will not be detected. However, in most horses with bronchopneumonia the periphery of the lung is affected, enabling the clinician to successfully image some of the lesions. Early ultrasonographic lesions are nonspecific and may include only irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes. Consolidated lung varies in appearance from dimples of the pleural surface to large wedge-shaped areas of sonolucent lungs (Fig. 31-5).

Ultrasonography offers a considerable advantage over radiographs in the study of the pleural surfaces and space. Small amount of pleural effusion that would otherwise be missed clinically or by radiography can be easily detected by ultrasonography. Ultrasonography can also be used to assess the nature and approximate volume of fluid, to select the optimal site and depth for thoracocentesis, and to detect sequelae such as fibrin deposition, pleural adhesion, abscess formation, and pneumothorax. Pleural effusion appears as hypoechoic to anechoic fluid between the parietal pleural surface and the lungs (Fig. 31-6). The echogenicity of the fluid typically reflects the degree of cellularity. Fibrin appears as filamentous strands floating in the effusion (Fig. 31-7). The presence of small (<1 mm) bright echoes (gas echoes) often indicates anaerobic infections (see Fig. 31-7).[86] Gas echoes may also be seen with gangrenous pneumonia or bronchopleural fistulas, or they may result from leakage of air during thoracocentesis.

Fig. 31-5 Sonogram of the left thorax obtained from a 3-year-old thoroughbred gelding. The ventral aspect of the lung is completely consolidated. Note the liver-like appearance of the wedge-shaped area of the lung. Fluid bronchograms are indicated by an *arrow*.

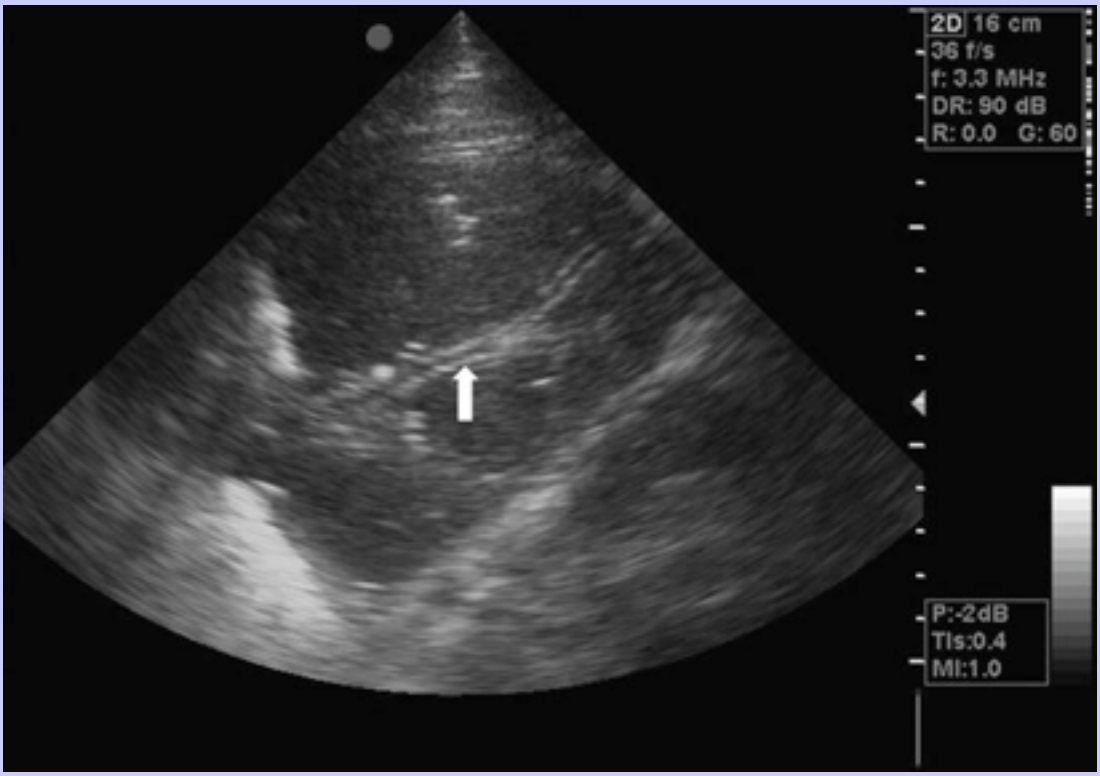

Fig. 31-6 Sonogram of the thorax obtained from a 4-year-old horse with pleuropneumonia. The ventral tip of the lung is atelectatic and covered with fibrin. There are adhesions between the tip of the lung and the diaphragm and chest wall *(arrows)*.

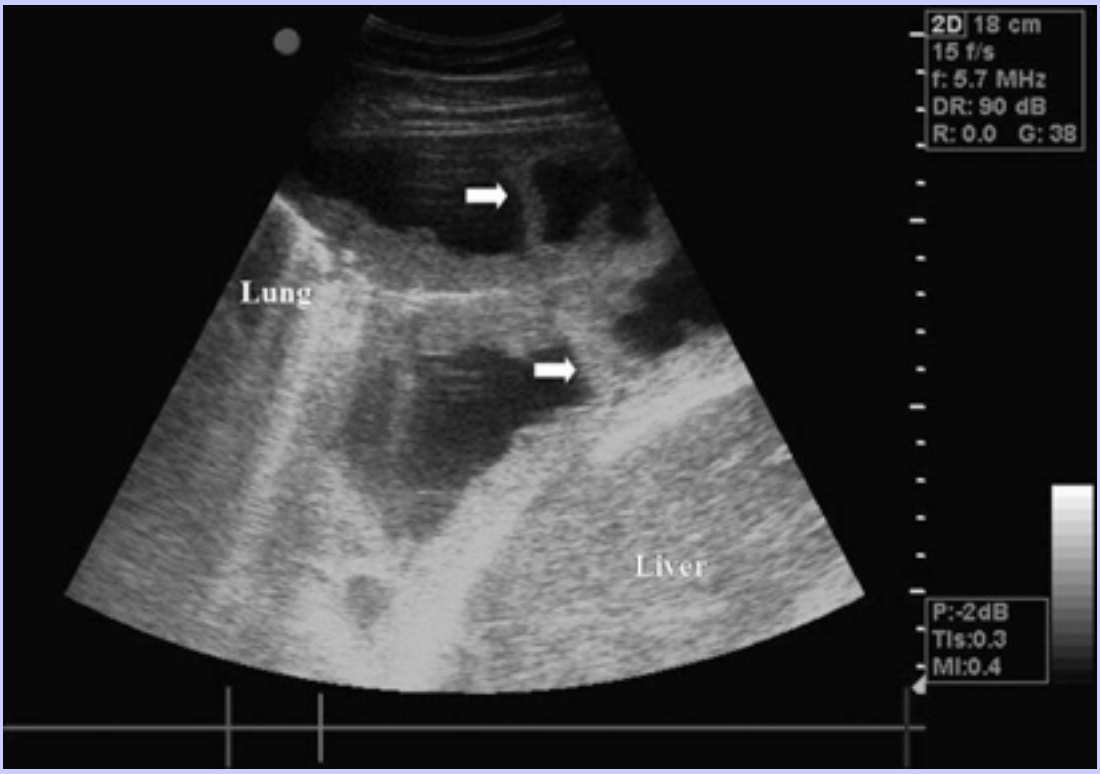

Fig. 31-7 Sonogram of the ventral thorax obtained from a horse being treated for pleuropneumonia. The sonogram shows a pleural abscess filled with fluid dorsally and with hyperechoic material ventrally. There are multiple gas echoes (some indicated by *arrows*). Multiple anaerobes were obtained on culture of an aspirate.

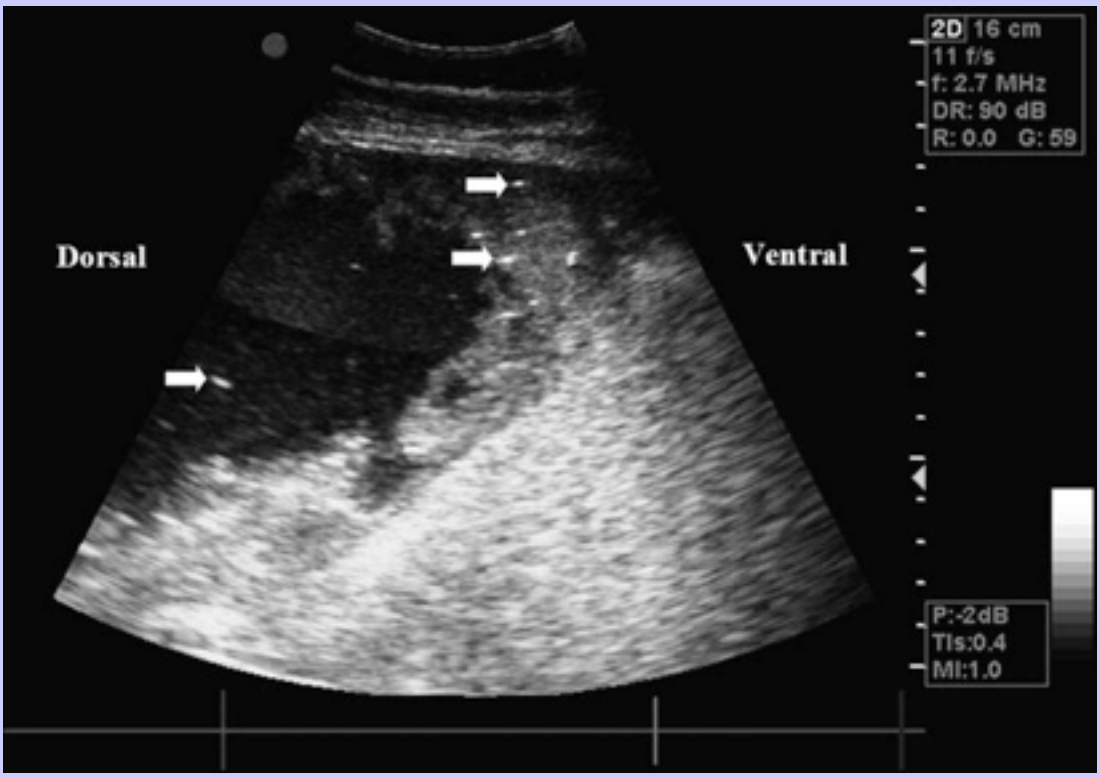

31.6.7.5

RADIOGRAPHY

In horses with mild septic IAD, thoracic radiographs may be normal or may reveal only mild bronchial or bronchointerstitial patterns. In more severely affected animals, radiographs demonstrate irregular opacities in the ventral thorax that may obscure the normal vasculature and cardiac silhouette (Fig. 31-8). Air bronchograms are sometimes visible. Abscesses are often present as circular soft-tissue opacities of varying sizes. In some cases they may be cavitated with thick walls and a distinct horizontal line representing fluid-gas interface (Fig. 31-9). Pleural effusion appears as a horizontal line demarcating a ventral soft-tissue opacity that obscures the heart and ventral lung fields (Fig. 31-10). When severe pleural effusion is present, it is most efficient to perform thoracic radiographs after the pleural fluid has been drained. Although ultrasonography is superior to radiographs in horses with pleuropneumonia, radiography should still be performed when possible to detect and monitor resolution of deep pulmonary abscesses that may be missed during ultrasonography.

31.6.7.6

THORACOCENTESIS FOR CYTOLOGY AND CULTURE

Thoracocentesis should be considered in horses with pleural effusion. The procedure can be of diagnostic value by allowing differentiation of septic pleuritis from effusion caused by other disease processes. It can also be of therapeutic value via removal of excessive chest fluid, which allows pulmonary reexpansion and a reduction in respiratory distress. Thoracocentesis is best performed using ultrasound guidance to determine the most appropriate site. A blunt teat cannula is typically used if a small volume of effusion is being sampled strictly for diagnostic purposes. Depending on the volume of effusion, a 16-, 24-, or 32-French chest tube is used when pleural drainage is also indicated (see later). An aliquot of pleural fluid is placed into tubes containing anticoagulant solution (ethylenediaminetetraacetic acid [EDTA]) so that cytologic evaluation may be performed. Part of the fluid should be saved in sterile containers with appropriate transport media for subsequent Gram stain and aerobic as well as anaerobic bacterial culture.

Fig. 31-8 Lateral thoracic radiograph of the caudoventral lung field from a 4-year-old thoroughbred mare showing a pronounced alveolar pattern with air bronchograms. The caudal silhouette of the heart is almost completely obscured.

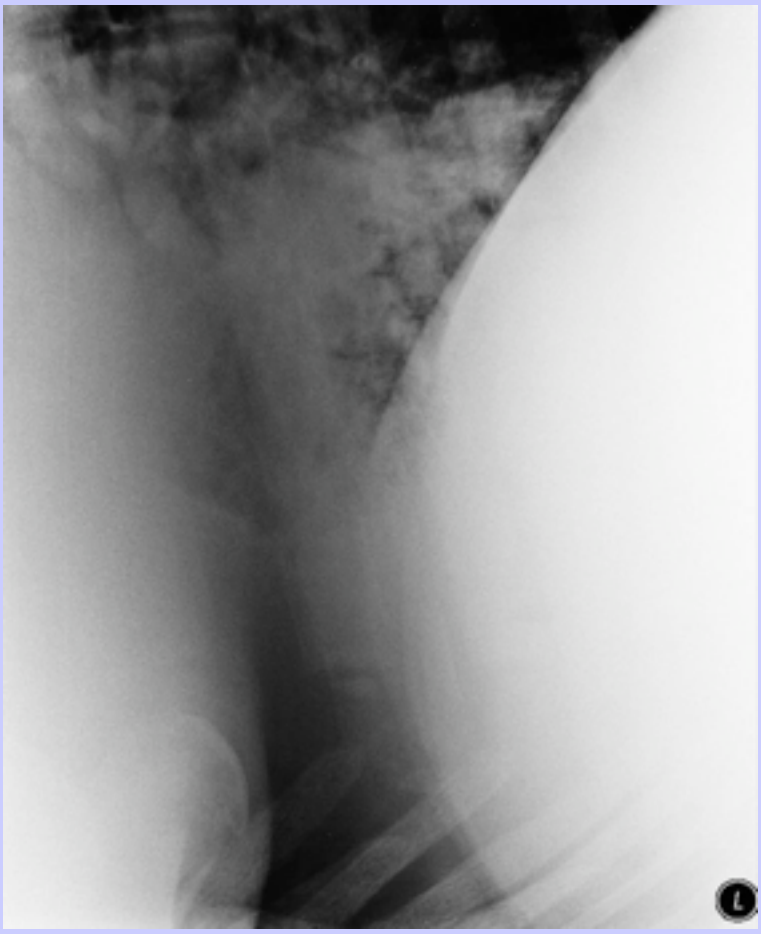

Fig. 31-9 Lateral thoracic radiograph of the caudodorsal lung field from a 3-year-old thoroughbred filly showing two cavitary abscesses with distinct horizontal lines representing fluid-gas interface.

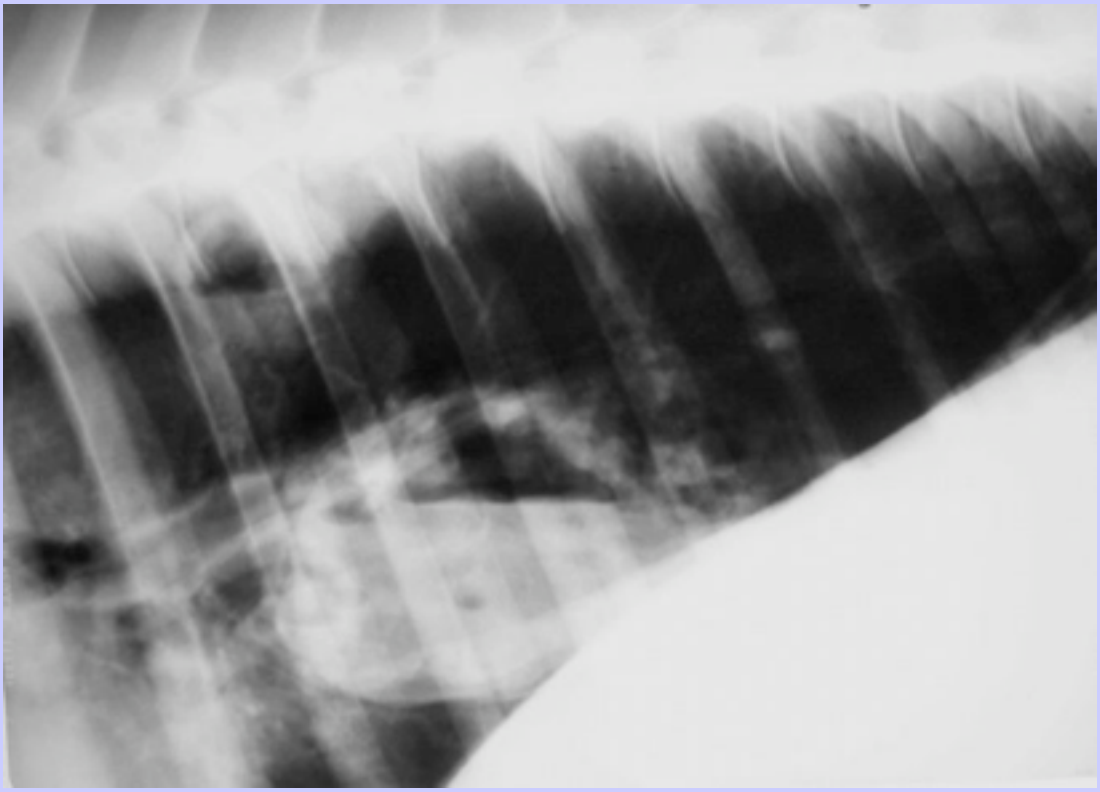

Fig. 31-10 Lateral thoracic radiographs from a four-year-old thoroughbred gelding with pleuropneumonia. There is a large amount of pleural effusion obscuring the ventral lung fields. The dorsal aspect of the fluid line is indicated by *arrows*. An interstitial pattern is noted in the caudodorsal lung fields.

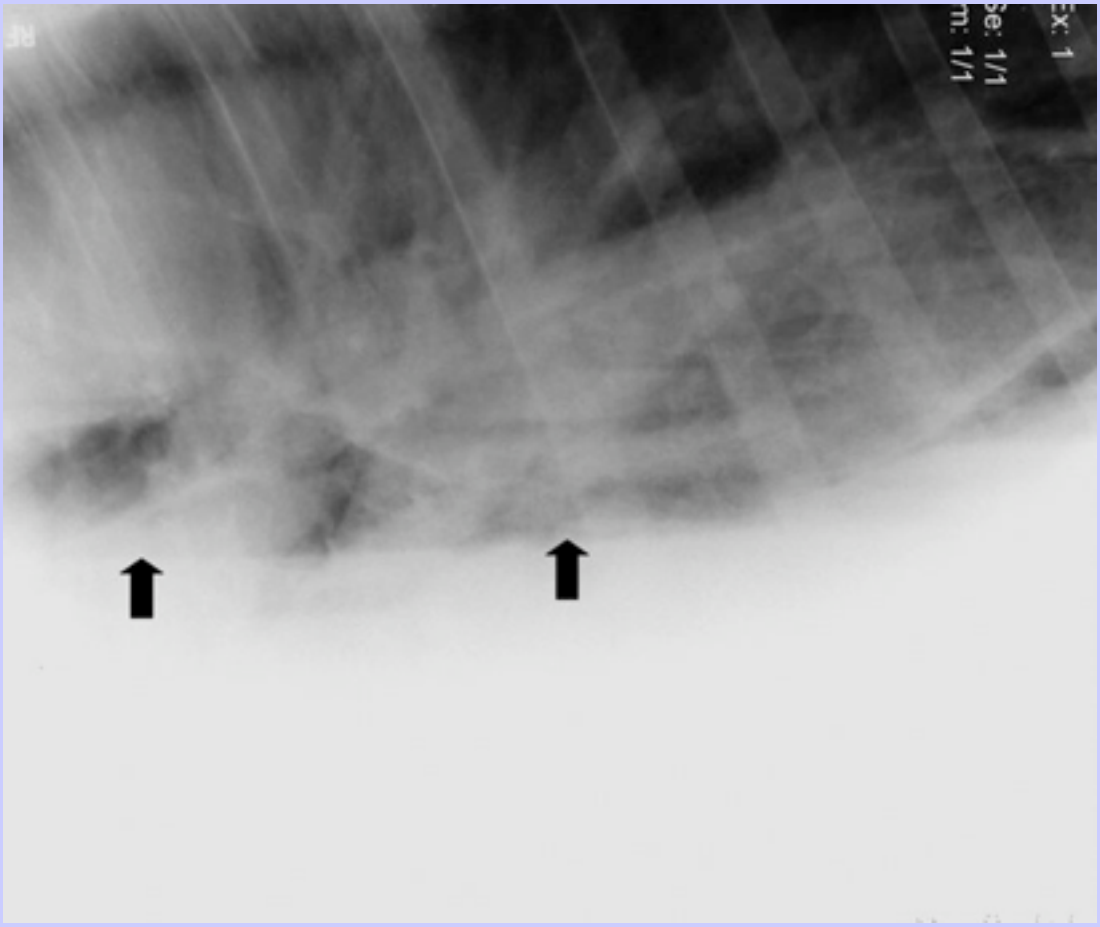

Normal equine pleural fluid is clear to light yellow and odorless. Protein concentration is <3.4 g/dL (range 0.2 to 4.7 g/dL), and nucleated cell count is <8000/µL (range 800 to 12,100/µL) in approximately 95% of apparently healthy horses.[87] In horses with bacterial pleuropneumonia the effusion is typically exudative, cloudy, and yellow to red, with increased nucleated cell count and protein concentration. Such effusion usually contains greater than 90% neutrophils, most of which exhibit degenerative changes. Putrid-smelling pleural fluid is a hallmark of anaerobic infection; however, the absence of odor does not exclude anaerobic infection. There is no association between the WBC count or protein concentration in pleural fluid and survival.

Biochemical analysis of the pleural fluid may also provide a rapid assessment of the likelihood of sepsis, hence the need for pleural drainage. Values for pH, P_{O_2}, P_{CO_2}, bicarbonate, lactate, and glucose in pleural

fluid from horses with nonseptic pleural effusion are similar to those in concurrent venous blood samples.[88] Horses with septic pleural effusion have significantly lower pH, bicarbonate, and glucose in their pleural fluid compared with paired venous blood samples. In contrast, their pleural fluid has a significantly higher P_{CO_2} and lactate concentration.[88] Pleural fluid pH <7.1 and glucose concentration <40 mg/dL are suggestive of septic effusion in horses.[89]

31.6.7.7 THORACOSCOPY

Thoracoscopy is rarely necessary in the initial evaluation of horses with pleuropneumonia. However, the technique may be of diagnostic and therapeutic value in more chronic cases in which pleural abscesses or pleural adhesions develop (see section on treatment).[90]

31.6.8 Treatment

31.6.8.1 SYSTEMIC ANTIMICROBIAL THERAPY

505

506

Administration of appropriate antimicrobial agents is the most important part of the therapeutic plan. The choice of the antimicrobial agent depends on the severity of the clinical signs, cost, ease of administration, and, when available, results of bacteriologic culture and susceptibility testing of a tracheobronchial aspirate. Doses for commonly used antimicrobial agents are presented in Table 31-2. In early cases of mild bronchopneumonia, the practitioner is justified in suspecting *S. zooepidemicus* as the causative organism and treating accordingly. *S. zooepidemicus* is almost invariably susceptible to penicillin, ampicillin, and cephalosporins such as ceftiofur (Table 31-3). The possibility of a mixed infection, especially involving gram-negative organisms, must be kept in mind when such empiric therapy is unsuccessful. Ceftiofur offers the advantage of having a good spectrum of activity against common nonenteric gram-negative pathogens such as *Pasteurella* species and *Actinobacillus* species. Therapy of horses with mild lower respiratory tract infections should be continued for a minimum of 10 days or until clinical signs resolve. In some cases the duration needed may preclude continuous intramuscular (IM) therapy because of muscle soreness. Trimethoprim-sulfonamide (TMS) combinations offer the advantage of oral administration. Unfortunately, the usefulness of TMS combinations for the treatment of bacterial respiratory tract infections in horses is limited by their lack of in vivo activity against *S. zooepidemicus*. In contrast to penicillin, TMS is ineffective in eradicating *S. equi* subsp. *zooepidemicus* in a tissue chamber model of infection in horses.[91,92] This failure of in vivo response was observed despite in vitro susceptibility of the isolate and high concentrations of TMS in the tissue chamber fluid.[91,92]

Table 31-2 Antimicrobial Agents Commonly Used to Treat Bacterial Bronchopneumonia in Adult Horses

Antimicrobial Agents*	Dose	Frequency (h)	Route
β-LACTAMS			
Benzyl Penicillins			
Penicillin G (Na, K)	25,000 IU/kg	6	IV
Penicillin G (procaine)	25,000 IU/kg	12	IM
Aminobenzyl Penicillins			
Ampicillin sodium	20 mg/kg	8	IV
Ampicillin trihydrate	20 mg/kg	12–24	IM
Cephalosporins			
Cefazolin	10–20 mg/kg	6	IV
Ceftiofur	2.2–4.4 mg/kg	12–24	IV or IM
AMINOGLYCOSIDES			
Amikacin	10 mg/kg	24	IV or IM
Gentamicin	6.6 mg/kg	24	IV or IM
FLUOROQUINOLONES			
Ciprofloxacin†	5.5 mg/kg	24	IV
Enrofloxacin†	5.5 mg/kg	24	IV
	7.5 mg/kg	24	PO
TETRACYCLINES			
Oxytetracycline‡	6.6 mg/kg	12	IV
Doxycycline§	10 mg/kg	12	PO
OTHERS			
Chloramphenicol	50 mg/kg	6	PO
Metronidazole	25 mg/kg	12	PO
	35 mg/kg	12	Per rectum
Rifampin	5 mg/kg	12	PO
Trimethoprim-sulfonamide	30 mg/kg (combined)	12	PO

IM, Intramuscular; *IV*, intravenous; *PO*, by mouth.

* Pharmacokinetics data are available for horses, but in most cases safety studies have not been performed in the equine species.

† Should not be used in young growing horses because of the risk of arthropathy.

‡ Dilute and give by slow IV infusion.

§ Administer orally only. IV doxycycline has resulted in severe cardiovascular effects including collapse and death in some horses.

In more severe cases of bronchopneumonia and in all cases of pleuropneumonia, antimicrobial therapy should ultimately be selected based on results of culture and in vitro susceptibility testing. Before these results are obtained, selection should be based on knowledge of the prevalence and susceptibility pattern of bacteria commonly isolated from affected horses (see Table 31-2). Polymicrobial and mixed aerobic and anaerobic infections are common; thus broad-spectrum antimicrobial therapy is initially required. A combination of gentamicin for gram-negative coverage and penicillin for gram-positive and anaerobic coverage is commonly used as initial broad-spectrum therapy for moderate to severe bronchopneumonia. Enrofloxacin can be used as a substitute for gentamicin for gram-negative coverage in adult horses. Advantages of enrofloxacin over gentamicin include greater activity against Enterobacteraceae, better penetration in phagocytic cells and tissues, and better activity in purulent material. However, enrofloxacin should never be used as standalone initial therapy in horses with bronchopneumonia because of its lack of activity against anaerobes and against streptococci such as *S. zooepidemicus*. Ampicillin or cefazolin can replace penicillin for gram-positive coverage and offers the supplementary advantage of providing additional gram-negative coverage.

Treatment of anaerobic pleuropneumonia is usually empiric, because antimicrobial susceptibility testing of anaerobes is difficult owing to their fastidious nutritive and atmospheric requirements. Thus familiarity with antimicrobial susceptibility patterns is helpful in formulating the treatment regimen when an anaerobe is suspected. The majority of anaerobic isolates are susceptible to relatively low concentrations of penicillin. However, *B. fragilis*, a frequently encountered anaerobe in horses with pleuropneumonia, is routinely resistant to penicillin. Other members of the *Bacteroides* family are known to produce β-lactamases and are potentially penicillin resistant. Metronidazole has excellent in vitro activity against a variety of obligate anaerobes including *B. fragilis*. Oral administration rapidly results in adequate serum levels and thus is an acceptable route of administration for horses with pleuropneumonia. Therefore, if anaerobic infection is suspected, oral metronidazole is usually added to the combinations mentioned previously. Malodorous nasal discharge, halitosis, or the presence of gas echo in pleural effusion on ultrasonographic examination suggests the presence of an anaerobic infection. However, the absence of these findings does not rule out anaerobic bacterial infection. Horses with extensive lung consolidation and horses with pleuropneumonia may benefit from adding metronidazole to the treatment regimen. Metronidazole is not effective against aerobes and therefore should always be used in combination therapy. Chloramphenicol is active against most aerobes and anaerobes cultured from horses with bronchopneumonia or pleuropneumonia. However, because of human health concerns, its use should be limited to the treatment of horses with severe anaerobic bacterial infections refractory to metronidazole therapy in countries where its use is allowed. 506 507 Rifampin is bactericidal and active against streptococci and most species of *Bacteroides* and *Clostridium*. It penetrates well into abscesses and may be helpful in anaerobic infections with walled-off abscesses. Rifampin should always be used in combination with another antimicrobial agent to decrease the likelihood of emergence of resistant mutants.

Table 31-3 In Vitro Antimicrobial Susceptibility of Aerobic Bacterial Isolates That Are Commonly Isolated from Horses with Bronchopneumonia or Pleuropneumonia*

* Data from the clinical microbiology laboratory, University of Florida (2003–2005). Isolates were obtained from multiple equine clinical specimens including but not restricted to tracheobronchial aspirates and pleural fluid.

† Percent of susceptible isolates (number of susceptible isolates/number of isolates tested × 100).

‡ In vivo, ceftiofur is rapidly metabolized to desfuroylceftiofur. Desfuroylceftiofur is as effective as ceftiofur against most bacterial pathogens but most coagulase positive *Staphylococcus* species are resistant. Therefore, despite in vitro susceptibility, ceftiofur is not the ideal choice for the treatment staphylococcal infections.

—Not tested or testing not warranted.

In cases of severe bronchopneumonia, lung abscesses, or pleuropneumonia, long-term antimicrobial therapy ranging from 3 weeks to sometimes several months may be required. In the initial stages of therapy IV antimicrobials are preferred to achieve higher serum concentrations. Oral antimicrobial agents can be used later in the course of the disease if appropriate based on susceptibility testing. Clinical signs, lung auscultation, fibrinogen concentrations, and repeated ultrasonographic and radiographic examination are useful in assessing response to therapy and deciding when to discontinue antimicrobial therapy. Stall rest must be enforced during therapy of pneumonia, and return to exercise should be gradual and permitted only after the horse is clinically normal and antibiotic therapy has been completed.

31.6.8.2

AEROSOLIZED ANTIMICROBIAL AGENTS

Aerosolized antimicrobial agents may be a useful adjunct to oral or systemic administration, particularly in horses with chronic septic IAD and no or minimal involvement of the lung parenchyma. The rate and extent of penetration of a drug into most sites outside the vascular space such as lung tissue are determined by the drug's concentration in plasma, molecular charge and size, extent of plasma protein binding, and blood flow.[93] In other tissues such as the central nervous system (CNS) and the eye, a lipid membrane provides a barrier to drug diffusion.[93] There is a similar barrier between blood and the bronchial epithelium, restricting penetration of some drugs into bronchial secretions and epithelial lining fluid of the lower airways.[94] Aerosol administration of antimicrobial agents can result in high drug concentrations in the respiratory tract while minimizing systemic concentrations and their resulting toxicity.

Antimicrobial delivery by inhalation is greatly influenced by the product formulation and type of nebulizer. Aerosol use of IV formulations can lead to exposure to potentially irritant or toxic additives and inappropriate pH or osmolality ranges. In one study the particle size distribution and particle density of gentamicin sulfate and ceftiofur sodium aerosols were affected by the antimicrobial concentration of the solution.[95] Gentamicin concentrations of 50 mg/mL or ceftiofur concentrations of 25 mg/mL produced the optimal combinations of particle size and aerosol density with the use of a medical ultrasonic nebulizer.[95] In healthy horses, aerosolization of 20 mL of the commercially available IV gentamicin sulfate solution (diluted to 50 mg/mL) using an ultrasonic nebulizer resulted in bronchial lavage fluid concentrations approximately 12 times higher than concentrations achieved by IV administration at a dose of 6.6 mg/kg.[96] In the same study, serum concentrations after aerosol administration were below 1 μg/mL at all times.[96] Once-daily aerosol administration of gentamicin to healthy horses for 7 consecutive days did not result in pulmonary inflammation or drug accumulation in the respiratory tract.[97] The major limitation to the use of aerosolized gentamicin in horses is its lack of activity against *S. zooepidemicus*, the most common bacterial pathogen of the equine respiratory tract. Additional studies are required to assess the efficacy of aerosolized antimicrobial agents for the treatment of bacterial respiratory tract infections in horses.

31.6.8.3

ANCILLARY TREATMENTS

The need for ancillary treatments depends on the severity of the disease and is most often necessary in horses with pleuropneumonia. Nonsteroidal antiinflammatory drugs (NSAIDs) such as flunixin meglumine (1 mg/kg IV or by mouth [PO] once or twice daily) or phenylbutazone (2.2 mg/kg IV or PO once or twice daily) may be beneficial to minimize inflammation, provide analgesia, and control high fevers. Additional analgesia may be

necessary in horses with severe pleurodynia. Adequate hydration should be maintained in patients receiving these agents for extended periods, especially if aminoglycosides are used concurrently. IV fluid therapy may be necessary to correct hypovolemia in acute stages, but it is rarely required in chronic cases. Intrapharyngeal insufflation of oxygen is indicated in horses that remain severely hypoxemic despite adequate drainage of the pleural cavity. Adequate parenteral or preferably enteral nutritional support via a nasogastric tube (NGT) is beneficial in horses that remain anorectic for several days. In horses presented with severe systemic illness, additional therapies aimed at treating endotoxemia may be beneficial (see section on endotoxemia).

507

508

31.6.8.4

PLEURAL DRAINAGE

Small amounts of pleural effusion may be resorbed quite readily with appropriate antimicrobial therapy. Therefore although a small sample of pleural fluid is diagnostically useful, pleural drainage is not necessarily indicated in all cases of pleuropneumonia. Drainage of pleural effusion results in removal of exudate and debris and allows for reexpansion of the lungs. Indications for drainage include a poor response to conservative therapy or the presence of pleural fluid with at least one of the following characteristics: sufficient volume to cause respiratory distress, empyematous character, fetid odor, or cytologic or biochemical evidence of sepsis. If indicated, the procedure should be attempted as early as possible before deposition of fibrin results in loculations and impairs drainage. The ventral mediastinum is perforated in normal horses in such a way that the left and right pleural spaces communicate. During severe inflammation the small perforations in the ventral mediastinum may be become obstructed by fibrin. Therefore, depending on the severity of the inflammatory response present, draining one side of the thorax may or may not be sufficient to resolve bilateral pleural effusion. Repeat ultrasonography of the opposite hemithorax should always be performed before the placement of a chest tube to determine if draining one side has actually emptied both sides of the thorax. Pleural drainage is best performed using ultrasound guidance to determine the most appropriate site. Pleural drainage can be accomplished either with intermittent thoracocentesis or indwelling chest tubes. Thoracocentesis is easily accomplished in the field and may not need to be repeated unless considerable pleural effusion reaccumulates. Indwelling chest tubes are indicated when continued pleural fluid accumulation makes intermittent thoracocentesis impractical. If properly placed and managed, indwelling tubes provide a method for frequent fluid removal and do not exacerbate the underlying pleuropneumonia or increase the production of pleural effusion. A one-way valve may be attached to allow for continuous drainage without leakage of air into the thorax. A Heimlich valve or an unlubricated condom with the tip cut off may be used for that purpose. As an alternative to continuous drainage, the tube can be temporarily occluded and periodically attached to a one-way valve for intermittent drainage. Heparinization of tubing after drainage may help maintain patency. The chest entry site and end of the drainage tube must be maintained aseptically. If a chest tube is placed aseptically and managed correctly, it can be maintained for several days to weeks. Local cellulitis may occur at the site of entry into the chest but is considered a minor complication. Pneumothorax is another potential complication of indwelling chest tubes. It should be removed as soon as it is no longer functional. A purse-string suture must be preplaced and tied as the tube is removed to prevent pneumothorax.

31.6.8.5

PLEURAL LAVAGE

Pleural lavage may be helpful to dilute thick viscous pleural fluid and remove fibrin, debris, and necrotic tissue. Pleural lavage is most helpful in subacute stages before loculated pockets of pleural fluid develop. However, pleural lavage may help break down fibrous adhesions and establish communication between loculae. Pleural lavage is typically performed by using the same chest tube for infusion and drainage of lavage fluid. Alternatively, lavage can be performed by infusing fluid through a dorsally positioned tube and draining it through a ventrally positioned tube. Five to 10 liters of sterile, warm isotonic fluid solution is infused by

gravity flow. After infusion, the chest tube is reconnected to the unidirectional valve for drainage. Allowing the horse to walk once the continuous flow stops will often result in drainage of additional fluid. Pleural lavage is probably contraindicated in horses with bronchopleural communications because it may result in spread of septic debris up the airways and into normal areas of the lungs.[98] Coughing and drainage of lavage fluid from the nose during infusion suggest the presence of a bronchopleural fistula (see discussion of complications, later).

31.6.8.6

THORACOSCOPY

Thoracoscopy allows direct evaluation of the lungs and pleural cavity. In selected cases thoracoscopy may be a useful tool to facilitate placement of thoracic drains in abscesses, transect pleural adhesions, and disrupt loculations.[90] The technique can also be used to perform biopsy or aspiration of specific lesions affecting the periphery of the lungs. The procedure can be performed in the standing sedated horse with local anesthesia and is usually very well tolerated.[99]

Adhesions between the lung and the diaphragm or body wall may prevent complete collapse of the lung, making insertion of the instruments more difficult and sometimes limiting the view of the pleural cavity. Adhesions are easier to disrupt during the first week after formation when the tissue is fibrinous rather than fibrous. Transection of mature adhesion is more difficult and can result in severe hemorrhage. Creation of a pneumothorax is a necessary feature of thoracoscopy, and horses should be monitored carefully throughout the procedure. Transient exacerbation of clinical signs of pulmonary disease caused by pneumothorax can be alleviated by reinflation of the lungs.

31.6.8.7

THORACOTOMY

Surgical intervention in horses with pleuropneumonia is not a substitute for adequate medical management, but in carefully selected cases it can save the lives of horses that would have to be euthanized otherwise. The criteria for surgical intervention include: (1) failure to respond to antimicrobial therapy, pleural drainage, and pleural lavage; (2) stable systemic medical condition; (3) presence of a large amount of fibrin, debris, or pus in the pleural space; and (4) presence of either a walled-off lesion or a complete mediastinum to avoid creation of a bilateral pneumothorax. Surgical intervention is most beneficial in chronic cases with large unilateral localized pockets of thick debris, especially if there is resolution or at least a significant improvement of the disease in the opposite hemithorax. Before surgical exploration, the nature and location of the lesion must be thoroughly characterized by ultrasonography or thoracoscopy to determine the ideal surgical site. When there is bilateral disease, thoracotomy is performed on the most severely affected side. If necessary a second thoracotomy can be performed on the opposite side at a later time. Thoracotomy is typically performed with the horse standing. It is common practice to place a large chest tube into the targeted cavity and leave it open to atmospheric air for at least 2 hours before thoracotomy.[98] The onset of respiratory distress indicates development of bilateral pneumothorax, in which case standing thoracotomy is contraindicated and pneumothorax must be corrected. Unilateral pneumothorax is usually well tolerated.

The standing surgical procedures most commonly performed include thoracotomy via an intercostal approach and thoracotomy and rib resection. For the intercostal approach the surgical site is prepared and infiltrated with local anesthetic. The lateral thoracic vein must be identified to avoid inadvertent incision. A vertical incision is made through the skin, intercostal musculature, and pleura. The length of the incision is dictated by the size of the pleural abscess and consistency of its content. When necessary, partial excision of the intercostal muscles will facilitate manual exploration of the cavity and removal of fibrin and necrotic debris

508
509

(Fig. 31-11). The major advantage of the intercostal approach over rib resection is preservation of thoracic wall integrity and compliance. Thoracotomy with rib resection is elected when the cavity is very large and it is anticipated that extensive manual debridement of fibrin and necrotic debris will be necessary. The advantage of the thoracotomy with rib resection over the intercostal approach is improved access to the thorax, allowing manual removal of large fibrin clumps and necrotic debris (Fig. 31-12). With both rib resection and intercostal approaches, the incision is left open and irrigated once or twice daily with a sterile isotonic fluid solution. The cavity is periodically debrided via gentle massage, taking care not to disrupt mature adhesions. After adequate formation of granulation tissue, tap water may be used. Depending on the size of the incision, it may take a few weeks to 2 to 3 months for complete closure by second intention. Complications during thoracotomy may include bilateral pneumothorax (if the cavity is not walled off and the mediastinum is not complete) and cardiac arrhythmias (if the lesion is in close proximity to the heart). The most common long-term complication is the formation of a chronic draining fistula, but by itself, this complication does not prevent the horse from returning to its usual occupation.

Fig. 31-11 Intercostal thoracotomy with partial excision of the intercostal muscles in a 7-year-old horse with a large pleural abscess. The image was obtained 3 weeks after surgery.

31.6.9 Complications of Pleuropneumonia

Several complications may occur during medical therapy of severe pneumonia and pleuropneumonia. These complications include jugular vein phlebitis or thrombosis from catheter placement, diarrhea resulting from antimicrobial therapy, pneumothorax or cellulitis secondary to thoracocentesis, endotoxemia, coagulopathies, and laminitis. In a retrospective study of 153 horses with pleuropneumonia presented to a referral hospital, complications included pleural abscesses (21.6%), cranial thoracic masses (7.2%), bronchopleural fistulas (6.5%), pericarditis (2.6%), and laminitis (1.3%).

Pleural abscesses refractory to antimicrobial therapy are treated by thoracocentesis or thoracotomy (see earlier). In some cases of pleuropneumonia, the heart may act as a valve to trap effusion and inflammatory debris in the cranial thorax. Small cranial thoracic masses may result in nonspecific clinical signs such as fever, tachycardia, and sternal edema. Larger abscesses may result in jugular vein distention, forelimb extension (pointing), and caudal displacement of the heart. Diagnosis is made by ultrasonography (Fig. 31-13). It is necessary to pull a forelimb forward to successfully image the cranial thorax. Most horses with cranial thoracic masses will respond to conservative therapy with antimicrobial agents.[100] Drainage of the abscess should be performed in cases refractory to medical therapy or when the mass interferes with normal cardiac function. Cranial thoracic abscesses may be sampled in the standing horse with a front limb pulled forward. However, when drainage and lavage are required, the procedure is best performed under short-term general anesthesia to avoid damage to the heart and major blood vessels present in the cranial thorax. It is not recommended to leave an indwelling tube because the triceps musculature often causes the tube to kink. Repeated drainage and lavage may be necessary in some cases.

509

510

Fig. 31-12 Thoracotomy and rib resection in a thoroughbred filly with a large pleural abscess in the right hemithorax communicating with another abscess cranial to the heart. In this case a rib resection was performed to facilitate manual removal of purulent material and necrotic debris from both abscesses.

Fig. 31-13 Sonogram of the cranial thorax obtained from the third intercostal space of a 2-year-old thoroughbred filly with distended jugular veins and pitting edema of the ventral thorax. A large fluid-filled loculated abscess was imaged.

Bronchopleural fistulas develop when necrosis of lung tissue leads to direct communication between the airways and the pleural cavity. Diagnosis may be confirmed by thoracoscopy or by injecting sterile fluorescein dye into the pleural fluid and looking for the presence of dye at the nostrils or within the trachea by endoscopy. Horses with bronchopleural fistula often cough during pleural lavage, and lavage fluid may be noted at the nostrils. Most bronchopleural fistulas spontaneously seal as a result of adhesions to the chest wall or fibrin deposition on the visceral pleura. Sealing may take several weeks to months. In one case partial pneumonectomy was successful in resolving a chronic bronchopleural fistula and pulmonary abscess.[101]

31.6.10 Prognosis

The prognosis for survival and return to normal athletic function depends on the severity and duration of clinical signs before therapy. Horses with septic IAD or mild to moderate bronchopneumonia have a very good prognosis for a return to previous athletic performance. The prognosis for horses with pulmonary abscesses and without concurrent pleuritis is also good. In one study, 45 of 50 (90%) adult horses with pulmonary abscesses survived.[102] In the same study, 92% of standardbreds and 52% of thoroughbreds raced after treatment of

pulmonary abscesses.[102] For horses that returned to racing, performance after successful treatment of lung abscesses was not significantly different from that before the illness.[102]

In a retrospective study of 327 horses with pneumonia or pleuropneumonia, the overall survival rate was 75%.[93] In the same study, the survival rate for 81 horses from which anaerobic bacteria were cultured was only 4.3%.[93] However, another study failed to identify an association between the presence of anaerobic bacteria and decreased survival.[103] In cases of pleuropneumonia, retrospective studies have shown survival rates ranging from 43.3 to 87.6%.[103,104] Differences in survival rates among studies may reflect differences in referral populations as well as advances in therapy in more recent years. Many horses that would have been euthanized owing to chronicity and lack of response to medical therapy several years ago are now successfully treated with the surgical approaches described earlier. This is evidenced by a retrospective of 153 horses with pleuropneumonia in which the survival rate was 95.7% when horses electively euthanized were excluded.[104]

The effect of pleuropneumonia on subsequent racing performance has not been examined extensively. In one retrospective study, 43 of 70 (61%) horses that had recovered from pleuropneumonia returned to racing, and 24 of the 43 (56%) won at least one race.[104] In the same study, horses that required placement of an indwelling thoracic drain did not have a worse prognosis for return to performance compared with horses that did not require placement of a drain.[104] In contrast, horses that developed complications such as pulmonary abscesses, cranial thoracic masses, or bronchopleural fistulas were significantly less likely to return to racing.[104]

31.7 *RHODOCOCCUS EQUI* INFECTIONS

STEEVE GIGUÈRE

R. equi, a gram-positive facultative intracellular pathogen, is one of the most common causes of pneumonia in foals between 3 weeks and 5 months of age. *R. equi* has also emerged as a significant opportunistic pathogen in immunosuppressed people, especially those infected with the human immunodeficiency virus.[105,106] Although *R. equi* can be cultured from the environment of virtually all horse farms, the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on most. On farms where the disease is endemic, costs associated with veterinary care, long-term therapy, and mortality of some foals may be very high. This section reviews the clinical manifestations, pathogenesis, epidemiology, diagnosis, treatment, and prevention of *R. equi* infections in foals.

31.7.1 Clinical Manifestations

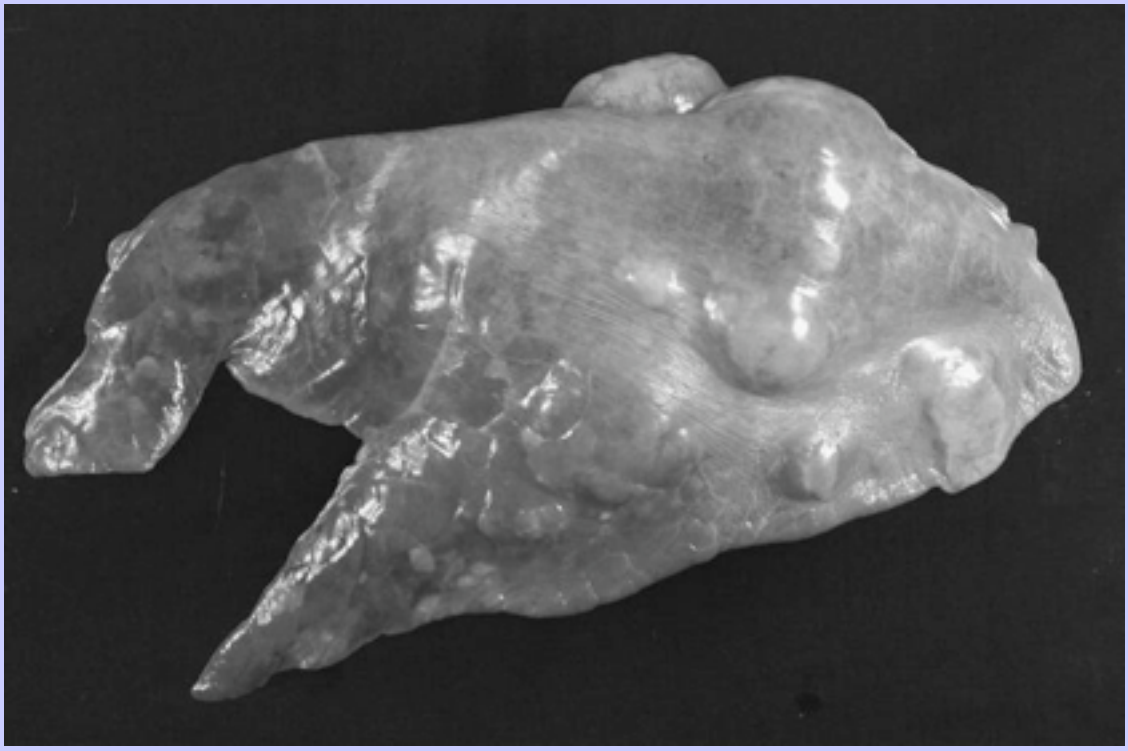
The most common manifestation of *R. equi* infections in foals is a chronic suppurative bronchopneumonia with extensive abscessation (Fig. 31-14). The slow spread of the lung infection combined with the remarkable ability of foals to compensate for the progressive loss of functional lung make early clinical diagnosis difficult. Early clinical signs often consist of only a mild fever or a slight increase in respiratory rate that may not be apparent unless foals are exercised or stressed by handling. As the pneumonia progresses, clinical signs may include decreased appetite, lethargy, fever, tachypnea, and labored breathing characterized by nostril flaring and increased abdominal effort. Cough and bilateral nasal discharge are inconsistent findings. A smaller percentage of affected foals may have a more devastating subacute form. These foals may be found dead or more commonly are presented in acute respiratory distress with a high fever and no previous history of clinical respiratory disease. Foals with the subacute form of the disease have a poor prognosis despite appropriate therapy.

Extrapulmonary manifestations of rhodococcal infections may also occur. Intestinal lesions are present in approximately 50% of foals with *R. equi* pneumonia presented for necropsy.[107] However, the majority of foals with *R. equi* pneumonia do not show clinical signs of intestinal disease. In the same study, only 4% of the foals had intestinal lesions without pneumonia.[107] The intestinal form of *R. equi* infection is characterized by a multifocal ulcerative enterocolitis and typhlitis over the area of the Peyer's patches, with granulomatous or suppurative inflammation of the mesenteric and/or colonic lymph nodes.[107] In some cases, the only abdominal lesion noted may be a single large abscess (usually in a mesenteric lymph node) that often adheres to the large or small bowel. Clinical signs associated with the abdominal form of the disease may include fever, depression, anorexia, weight loss, colic, and diarrhea.[108] Marked GI lymphatic obstruction associated with increased protein concentration in the peritoneal fluid and hypoproteinemia may lead to ascites, giving affected foals a pot-bellied appearance. Such foals have a poor prognosis because of the extensive granulomatous inflammation of the colonic mucosa and submucosa and mesenteric lymph nodes.

510

511

Fig. 31-14 Left lung from a foal with severe pneumonia caused by *R. equi*. There is marked consolidation of the cranial portion of the lung, and multiple abscesses are present caudodorsally. Courtesy Dr. William Castleman.



Polysynovitis is present in approximately one third of cases of *R. equi* infection; in some cases effusion of multiple joints may even be the presenting complaint.[109,110] The tibiotarsal and stifle joints are most commonly affected. Occasionally all joints are affected. The degree of joint effusion is variable, and in most cases lameness

is not apparent or is limited to a stiff gait. Cytologic examination of the synovial fluid usually reveals a nonseptic mononuclear pleocytosis, and bacteriologic culture of the synovial fluid is negative.[110] Histologic examination of the synovial membrane of a few affected foals revealed lymphoplasmacytic synovitis.[109,111] Fluorescein-labeled antiequine immunoglobulin G (IgG) staining of the synovial membrane of three affected foals revealed evidence of immunoglobulin within the synovial membrane, and rheumatoid factors (i.e., antibodies directed against autologous or heterologous Fc portion of immunoglobulin) were identified in the synovial fluid of a foal with nonseptic joint effusion and *R. equi* pneumonia.[109,111] These findings are suggestive of an immune-mediated process. However, experimental infection with a heavy intrabronchial inoculum of virulent *R. equi* consistently results in polysynovitis without associated lameness.[112] Culture of the synovial fluid within a few days of the onset of synovial effusion in these foals often yields *R. equi*, and histologic examination of the synovial membrane reveals suppurative inflammation.[112] Therefore it is possible that the synovitis is septic in origin but that the infection is rapidly cleared from the synovial structures, resulting in chronic nonseptic inflammation at the time of diagnosis. Regardless of the inciting cause, local therapy of the affected joints in clinical cases of *R. equi*–associated polysynovitis is usually not indicated because the effusion resolves without any apparent consequences as the primary infection responds to appropriate antimicrobial therapy. The presence of a nonseptic polysynovitis in a foal between 3 weeks and 6 months of age is highly suggestive of *R. equi* infection and deserves further investigation (see section on diagnosis). Immune-mediated processes may also contribute to the development of uveitis, anemia, and thrombocytopenia in some foals infected with *R. equi*.[113]

Bacteremic spread of the organism from the lungs or GI tract may occasionally result in septic arthritis and, more commonly, osteomyelitis. However, foals can occasionally develop *R. equi* septic arthritis or osteomyelitis without apparent lung or other source of infection. The degree of lameness of foals with septic arthritis distinguishes them from foals with nonseptic polysynovitis. In equivocal cases bacterial culture and cytologic examination of the synovial fluid should be performed. In addition to appropriate antimicrobial therapy (see treatment), foals with *R. equi* septic arthritis and osteomyelitis often require aggressive local therapy. *R. equi* vertebral osteomyelitis or diskospondylitis resulting in spinal cord compression has also been reported.[114–116]

Other rare extrapulmonary manifestations of *R. equi* infections in foals include panophthalmitis, guttural pouch empyema, sinusitis, pericarditis, nephritis, and hepatic, renal, and intracranial abscessation.[113,117] Ulcerative lymphangitis, cellulitis, and SC abscesses have also been reported. Disease caused by *R. equi* is rare in adult horses. Sporadic reports of infection involving primarily lungs or abdominal lymph nodes (similar to infection observed in foals), or rarely of wound infection, exist. In one adult horse, acquired combined immunodeficiency of unknown origin led to *R. equi* septicemia and lung abscessation.[118] Rarely the organism has also been isolated from infertile mares and aborted fetuses.[107,119,120]

R. equi has been isolated from many species other than humans and horses. *R. equi* is frequently cultured from the submaxillary lymph nodes of pigs with granulomatous lymphadenitis. However, *R. equi* can also be isolated from the submaxillary lymph nodes of 3% to 5% of apparently healthy pigs, and experimental infection studies in pigs have failed to reproduce the lesions.[121,122] The causative role of *R. equi* in granulomatous lymphadenitis in pigs thus remains unproven. Isolation of *R. equi* from other domestic animal species is rare. *R. equi* can be isolated from lymph node granulomas in 0.008% of cattle at abattoir postmortem inspection.[123] *R. equi* has also been cultured in rare cases of bronchopneumonia, mastitis, metritis, ulcerative lymphangitis, and septic arthritis in cattle. In goats *R. equi* has a tendency to cause liver abscesses with concurrent bronchopneumonia or pulmonary abscessation.[124] *R. equi* has been isolated from cases of pneumonia as well as from wound infections, SC abscesses, vaginitis, hepatitis, osteomyelitis, myositis, and joint infections in dogs and cats.[125]

31.7.2 Virulence

The ability of *R. equi* to induce disease in foals likely depends on both host and microbial factors. *R. equi* is a facultative intracellular pathogen, and its ability to persist in and eventually destroy alveolar macrophages seems to be the basis of its pathogenicity. Knowledge of the virulence mechanisms of *R. equi* were largely speculative until the discovery of a virulence plasmid.[126,127] Unlike most environmental *R. equi*, isolates from pneumonic foals typically contain an 80- to 90-kb plasmid. Plasmid-cured derivatives of virulent *R. equi* strains lose their ability to replicate and survive in macrophages.[112] Plasmid-cured derivatives also fail to induce pneumonia and are completely cleared from the lungs of foals within 2 weeks after heavy intrabronchial challenge, confirming the absolute necessity of the large plasmid for the virulence of *R. equi*.[112,128]

Nucleotide sequencing of the large plasmid of two foal isolates revealed the presence of 69 open reading frames (ORFs).[129] Comparisons of the plasmid sequence with genes previously identified in other microorganisms has identified three functional regions. Two of these regions contain genes encoding proteins involved in conjugation, plasmid replication stability, and segregation.[129] The third region of 27.5 kb bears the hallmark of a pathogenicity island and contains the genes for a family of eight closely related virulence-associated proteins designated VapA and VapC to VapI.[127,129–133] With the exception of *vapF* and *vapI*, which are not functional, all *vap* genes encode proteins with a clear signal sequence, indicating that they are extracellular proteins.[129,133,134] VapA is expressed on the bacterial surface, and its expression is temperature regulated, occurring between 34° C and 41° C.[135] VapC, VapD, and VapE are secreted proteins concomitantly regulated by temperature with VapA.[136] In a recent study, an *R. equi* mutant lacking a 7.9-kb DNA region spanning six *vap* genes *(vapA, vapC, vapD, vapE, vapF, vapI)* was attenuated for virulence in mice and failed to replicate in macrophages.[137] Complementation with *vapA* alone could restore full virulence, whereas complementation with *vapC, vapD*, or *vapE* could not. Conversely, a recombinant plasmid-cured derivative expressing wild-type levels of VapA failed to survive and replicate in macrophages and remained avirulent in foals, showing that expression of VapA alone is not sufficient to restore the virulence phenotype.[112] These findings show that although VapA is essential for virulence, other plasmid-encoded products also contribute to the ability of *R. equi* to cause disease. Consistent with these findings, it was recently demonstrated that two *R. equi* mutants lacking expression of pathogenicity island genes (ORF4 and ORF8) were fully attenuated despite enhanced transcription of *vapA*.[138] All *vap* genes as well as five other ORFs within the pathogenicity island are upregulated when *R. equi* is grown in macrophage monolayers.[139] Regulation of expression of the genes of the pathogenicity island is complex and depends on at least five environmental signal including temperature, pH, oxidative stress, magnesium, and iron.[135,139,140] The precise role of each of these genes in the pathogenesis of *R. equi* infections remains to be determined.

511
512

R. equi isolates are often classified as virulent, avirulent, or intermediately virulent based on their ability to induce disease or death in mice. Virulent *R. equi* isolates contain the large plasmid described previously and express VapA. Intermediately virulent *R. equi* isolates contain one of four distinct large plasmids encoding a 20-kDa antigen (VapB) that is related to, but distinct from, VapA. In contrast, avirulent *R. equi* isolates do not express Vap antigens. All three categories of *R. equi* have the ability to cause disease in immunosuppressed humans. Analysis of *R. equi* isolates from immunocompromised human patients with and without acquired immunodeficiency syndrome (AIDS) reveals that only approximately 20% of isolates contain an 80- to 90-kb plasmid and express VapA.[141,142] Therefore the pathogenesis of *R. equi* infection in immunocompromised human patients appears to be different from the pathogenesis in foals, in which the virulence plasmid is always

found. To my knowledge, intermediately virulent isolates (expressing VapB) have never been isolated from foals with naturally acquired *R. equi* infections. Experimentally, heavy intrabronchial challenge of foals with intermediately virulent *R. equi* results in pneumonia but at a dose much higher than that required for induction of pneumonia with VapA-expressing strains.[143] Almost all isolates from the submaxillary lymph nodes of pigs produce VapB and are intermediately virulent to mice, suggesting that pigs or their environment may be the source of infection for some human cases.[144] Most isolates from cattle, goats, and dogs are avirulent and do not contain plasmids encoding *vapA* or *vapB*.[123–125] In contrast, most isolates from cats contain a large plasmid and express VapA.[125]

Although it has been firmly established that the virulence plasmid is essential for infection of foals, it is also clear that chromosomally encoded factors, such as regulatory genes and metabolic pathways are also important for allowing the pathogen to thrive within the host.[145–148] *R. equi* is closely related to *Mycobacterium tuberculosis* as evidenced by a partial genome sequence of *R. equi*, which showed that the majority of *R. equi* genes have most homology with *M. tuberculosis*.[149] The unique cell wall of *R. equi* and other mycolata such as *Mycobacterium, Corynebacterium*, and *Nocardia* species is completely different from those of gram-negative and other gram-positive bacteria. Mycolata are characterized by a unique cell envelope that consists of mycolic acid anchored to an arabinogalactan wall polysaccharide.[150] The mycolic acid—containing cell wall is likely to be of importance for survival of *R. equi* under harsh environmental conditions such as those that occur within macrophages. Consistent with this theory, *R. equi* isolates with a longer carbon chain and mycolic acid are more virulent than those with shorter chains as determined by lethality and granuloma formation in mice.[151]

31.7.3 Epidemiology and Pathogenesis

R. equi is a soil organism with simple growth requirements. The highest numbers of *R. equi* are found in surface soil, whereas the organism cannot be found at depths exceeding 30 cm.[152] *R. equi* can be isolated from the feces of most adult horses at concentrations ranging between 10 and 10^3 colony-forming units (CFUs) per gram of feces. The number of *R. equi* in the feces of mares on endemic farms does not increase in the weeks before or after foaling.[153] In the same study, *R. equi* could be isolated from the feces of only 19% of the foals at 1 week of age and from all foals by 4 weeks of age.[153] In another study, virulent *R. equi* could be isolated from the feces of all sampled mares during at least one sampling period, indicating that mares can be an important source of virulent *R. equi* for their surrounding environment.[154] However, dams of affected foals did not shed more *R. equi* in feces than did dams of unaffected foals, indicating that heavier shedding by particular mares does not explain infection in their foals.[154]

Intestinal carriage in adult herbivores is mainly passive, as the organism cannot replicate in the anaerobic environment of the adult large intestine. However, the organism multiplies in the intestine of the foal up to about 3 months of age, reaching numbers up to 10^5 CFUs per gram of feces.[155] Virulent *R.* equi present in the sputum of pneumonic foals will be swallowed and thus can multiply in the intestine. Therefore the manure of *R. equi*–affected foals is likely a major source of progressive contamination of the environment with virulent organisms. Under suitable conditions of high summer temperatures, *R. equi* can multiply in the environment by 10,000-fold in only 2 weeks.[156] A single gram of soil contaminated with foal manure may therefore, under favorable conditions, contain millions of virulent *R. equi* organisms. *R. equi* can also be cultured from the air in the stalls on endemic farms, particularly on dry and windy days.[153] In a recent study, the odds of detecting airborne

virulent *R. equi* in stables were approximately 17 times greater than in paddocks of a given farm, and concentrations of virulent *R. equi* were also significantly higher in stables than in paddocks.[157]

Inhalation of virulent *R. equi* is the major route of pneumonic infection. The incubation period after experimental intrabronchial challenge varies from approximately 9 days after administration of a heavy inoculum to approximately 2 to 4 weeks when a lower inoculum is administered.[112,158] Lung consolidation can be detected as early as 3 days after heavy intrabronchial challenge.[112] The incubation period under field conditions likely depends on the number of virulent bacteria in the environment as well. Ingestion of the organism is a significant route of exposure, and likely also of immunization, but rarely leads to hematogenously acquired pneumonia unless the foal has multiple exposures to large numbers of bacteria.[159] Indeed, oral administration of live virulent *R. equi* to foals on day 2 and day 7 of life is highly effective in preventing development of pneumonia after subsequent heavy intrabronchial challenge.[160] Clearly, oral vaccination with live *R. equi* would not be an acceptable way to immunize foals because it would lead to progressive contamination of the environment with virulent bacteria. However, it undoubtedly shows that newborn foals have the ability to mount protective immune responses against *R. equi* (see section on immunity).

Epidemiologic evidence suggests that most foals on endemic farms become infected early in life.[161] The median age at the time of diagnosis is approximately 37 days on endemic farms with a screening program to promote early diagnosis.[162] Given the fairly long incubation period of the disease, this finding would also support the fact that many foals become infected within the first few weeks of life. In one study, foals aged 3 to 13 days (mean 6.4 days) were more susceptible to experimentally induced *R. equi* pneumonia than foals aged 14 to 36 days (mean 25 days). Collectively these findings indicate that many foals on endemic farms become infected at a young age and that younger foals may be more susceptible to infection caused by *R. equi*. However, these findings do not indicate that foals are susceptible to *R. equi* only during the neonatal period. Much older foals are still highly susceptible to infection by *R. equi*, particularly if they have never been exposed to *R. equi*. In one study, intatracheal administration of *R. equi* to 10 foals aged 27 to 67 days (mean 49 days) resulted in disease in all foals, including those receiving a low-dose challenge.[128] In addition, some foals are diagnosed with *R. equi* pneumonia at 3 or 4 months of age. There is no evidence to support a 90- to 120-day incubation period, which would be required if all foals were infected shortly after birth.

512
513

Although *R. equi* can be cultured from the environment of virtually all horse farms, the clinical disease in foals is endemic and devastating on some farms, sporadic on others, and unrecognized on most. This probably reflects differences in environmental and management conditions, as well as differences in the virulence of isolates, but the exact basis for the difference in the prevalence of the disease among farms remain unknown. Breeding farms with a large acreage, a large number of mares and foals, a high foal density, and a population of transient mares and foals have greater odds of being affected by *R. equi* pneumonia.[163,164] In contrast, *R. equi* pneumonia does not appear to be associated with lack of attention to routine preventative health practices.[165] Although the total numbers of *R. equi* isolates in the environment may be similar in farms with and without a history of *R. equi* infections, farms with endemic disease may be more heavily infected with virulent *R. equi*.[166] In a survey of the prevalence of *R. equi* at horse-breeding farms in Japan, the organism was isolated from almost all soil samples, at numbers of 10^2 to 10^5 CFUs per gram of soil. The vast majority of these isolates did not contain plasmids and were avirulent. Virulent *R. equi* isolates containing 80- to 90-kb plasmids and expressing VapA were cultured from 24 of the 31 farms examined. On those farms, virulent *R. equi* represented 1.7% to 23.3% of all isolates.[167] However, quantification of virulent *R. equi* from a single soil sample cannot be used to determine whether foals on a given farm are at increased risk for developing disease caused by *R. equi*.[168] There is considerable

chromosomal variability among isolates of *R. equi* obtained from the same farm and among isolates from various continents.[169] However, a small number of strains on a given farm are often responsible for the majority of clinical cases.[170] It is interesting to note that multiple *R. equi* strains were isolated in five of the six cases in which more than one isolate from a single foal was examined, indicating that disease is commonly caused by simultaneous infection with multiple strains.[170] Differences in disease prevalence among farms cannot be explained by soil geochemistry factors, as there is no association between soil pH, salinity, nitrate, phosphorus, potassium, calcium, magnesium, sodium, sulfur, zinc, iron, manganese, and copper and *R. equi* disease status on a given farm.[171]

R. equi can also be cultured from the soil of areas not inhabited by horses. In one study, *R. equi* was isolated from approximately 73.9% of soil samples collected from 115 parks and 49 household yards in Japan. The number of *R. equi* in those samples ranged from 10 to 10^5 CFUs per gram of soil. None of the 1294 isolates from those samples expressed VapA or VapB, suggesting that the human environment is not a significant route of exposure to virulent or intermediately virulent *R. equi*.[122]

31.7.4 Rhodococcus equi-*Phagocytic Cell Interactions*

The infectivity of *R. equi* in vitro is largely limited to cells of the monocyte-macrophage lineage.[172] Optimal binding of *R. equi* to mouse macrophages in vitro requires complement and is mediated by MAC-1, a leukocyte complement receptor type 3 (CR3, CD11b/CD18).[172] After entry through Mac-1, virulent *R. equi* can survive and even replicate in macrophages.[173] In contrast, opsonization of *R. equi* with specific antibody significantly enhances killing of *R. equi* by equine macrophages.[174] These findings suggest that cellular entry by non-Fc receptors may allow *R. equi* to avoid antibody-associated killing pathways. Entry of several microorganisms into macrophages after adherence to complement receptors, rather than Fc receptors, has been shown to allow them to avoid the toxic consequences of the oxidative burst.[175] The lipoarabinomannan, an important component of the cell envelope of *R. equi*, has the ability to bind to mannose-binding protein.[176] Binding of mannose-binding protein by lipoarabinomannan in vivo may activate complement C3b deposition onto *R. equi* via the lectin pathway, thereby promoting Mac-1 mediated uptake into macrophages. Alternatively the lipoarabinomannan of *R. equi*, like that of *M. tuberculosis*, may mediate bacterial entry through the macrophage mannose receptors. Recent studies have shown that *R. equi* can also activate macrophages through Toll-like receptor 2 (TLR2), leading to the release a variety of proinflammatory mediators.[177] In the same study VapA was identified as one of the bacterial components leading TLR2-mediated macrophage activation.[177] However, plasmid-cured derivatives of *R. equi* induced cytokine release by macrophages to the same degree as the parent strain, indicating that the presence of VapA is not necessary for activation of the innate immune response.[178] Consistent with these findings, the lipoarabinomannan of *R. equi* has been shown to be a potent inducer of cytokine induction by equine macrophages.[176]

During phagocytosis, bacteria are wrapped in a portion of the plasma membrane and taken up into macrophages, forming a new organelle called a *phagosome*. The phagosome matures over time by consecutive interactions with early endocytic, late endocytic, and lysosomal vesicles, leading to the formation of a phagolysosome. During phagosome maturation, bacteria are exposed to a number of microbicidal products, such as acid, reactive oxygen and nitrogen intermediates, and lysosomal hydrolases, that all contribute to killing and degradation of ingested bacteria. Intracellular persistence of *R. equi* in equine macrophages is associated with absent or decreased phagosome-lysosome fusion, and phagocytosis of *R. equi* is not associated with a functional

respiratory burst.[174,179,180] Recent studies in mouse macrophages have shown that *R. equi* has the ability to block maturation of endocytic organelles after completion of the early endosome stage but before a fully mature late endosome compartment is reached.[181] After ingestion by macrophages both virulent strains of *R. equi* and their avirulent plasmid-cured derivatives replicate in single membrane vacuoles for approximately 6 hours. Thereafter, virulent *R. equi* suppresses acidification of the vacuole and replicates intracellularly. In contrast, the vacuoles containing plasmid-cured derivatives progressively acidify, leading to complete eradication of the bacteria.[181,182] These findings indicate the importance of plasmid-encoded products in preventing acidification of *R. equi*–containing vacuoles within macrophages. Similarly, necrotic death of *R. equi*–infected macrophages is also regulated by plasmid-encoded products.[183]

As stated earlier, *R. equi* can survive and even replicate in resident or nonactivated macrophages. Killing of *R. equi* by mouse macrophages is dependent on the presence of IFN-γ, which activates macrophages to produce both reactive oxygen and reactive nitrogen intermediates. These two radicals combine to form peroxynitrite, which efficiently kills *R. equi*.[184] Neither reactive oxygen nor reactive nitrogen intermediates alone are sufficient to mediate killing of *R. equi*.[184] Additional cytokines such as TNF-α may have a similar effect on macrophages, as both IFN-γ and tumor necrosis factor (TNF)-α are both required for clearance of virulent *R. equi* in mice.[185]

513

514

Neutrophils play an important role in early host defense against virulent *R. equi*.[186] As opposed to macrophages, neutrophils from foals and adult horses are fully able to kill *R equi*.[187–189] As seen with macrophages, killing of *R. equi* by neutrophils is considerably enhanced by specific opsonizing antibody.[187–191]

31.7.5 Immunity

31.7.5.1 ANTIBODY-MEDIATED IMMUNITY

Immunity to *R. equi* pneumonia in foals likely depends on both the antibody and cell-mediated components of the immune system, but its exact basis remains to be determined. The strongest evidence for a role of antibody in protection against *R. equi* is the partially protective effect of passively transferred anti—*R. equi* hyperimmune (HI) equine plasma (see section on prevention). The mechanisms by which HI plasma confers protection are not completely understood. The list of possible effector molecules includes antibody and nonspecific factors such as fibronectin, complement components, collectins, cytokines, and acute phase proteins. Opsonization of *R. equi* with specific antibody has been shown to promote phagocytosis and killing of *R. equi* by alveolar macrophages, identifying antibody as a critical component of HI plasma.[174] In most studies evaluating the protective effect of HI plasma, plasma donors were immunized with whole cell vaccines or a mixture of several soluble antigens, making it impossible to determine the role of antibody against defined antigens of *R. equi*.

Recent studies have focused more specifically against the role of antibody against plasmid-encoded virulence-associated proteins (Vap). First, a monoclonal antibody to VapA and serum from horses immunized with partially purified VapA have opsonizing activity.[192] Moreover, purified immunoglobulins obtained from horses vaccinated with partially purified VapA protected mice against intraperitoneal challenge with virulent *R. equi* compared with mice administered immunoglobulins from nonimmunized horses.[193] More recently, IV administration of purified immunoglobulins obtained from horses immunized with recombinant VapA and VapC to foals was found to reduce the severity of pneumonia after heavy experimental challenge with *R. equi*.

[194] In the same study the degree of protection conferred by purified anti-VapA and anti-VapC immunoglobulins was similar to that provided by commercially available HI plasma.[194]

In adult horses the concentrations of *R. equi*-specific and VapA-specific IgGa and IgGb antibodies (the IgG isotypes that preferentially opsonize and fix complement in horses) are dramatically enhanced after intrabronchial administration with virulent *R. equi*. This occurs in conjunction with clearance of the bacteria from the lungs.[195] In foals, production of antibody to VapA and VapC but not to other Vap proteins, increases after natural exposure to *R. equi*.[194] Characterization of the subisotype response in naturally infected foals revealed mainly an increase in IgGa, IgGb, and IgG(T).[194,196]

31.7.5.2

CELL-MEDIATED IMMUNITY

Because of the facultative intracellular nature of *R. equi*, cell-mediated immune mechanisms are thought to be of major importance in resistance to infection. A large part of the knowledge of cell-mediated immunity to *R. equi* infections comes from infection of mice. Deficiencies in the complement component C5 and natural killer (NK) cells in mice do not impair the pulmonary clearance of virulent *R. equi*.[197] In contrast, functional T lymphocytes are absolutely required for the clearance of virulent (plasmid and VapA positive) *R. equi* in mice.[198–200] However, athymic nude mice (lacking functional T lymphocytes) clear plasmid-cured derivatives from their lungs within 1 week of infection, suggesting that, as opposed to virulent organisms, clearance of avirulent plasmid-negative strains in mice does not require functional lymphocytes and depends mainly on innate defense mechanisms.[198]

The two major mechanisms by which T lymphocytes mediate clearance of intracellular pathogens are secretion of cytokines and direct cytotoxicity. Although both $CD4^+$ (helper) and $CD8^+$ (cytotoxic) T cells contribute to host defense against *R. equi* in mice, $CD4^+$ T lymphocytes play the major role and are absolutely required for complete pulmonary clearance.[199,201,202] The mouse $CD4^+$ Th cells can be divided into two subsets based on the cytokines they produce. The Th1 subset produces primarily IFN-γ and IL-2 and is mainly responsible for macrophage activation and cell-mediated immunity. The Th2 subset produces mainly IL-4, IL-5, and IL-10, which primarily promotes humoral immunity. Studies in mice have clearly shown that a Th1 response is sufficient to effect pulmonary clearance of *R. equi*, whereas a Th2 response is detrimental.[200,203]

Clearance of virulent *R. equi* in adult horses is associated with a significant increase in BALF $CD4^+$ and $CD8^+$ lymphocytes, lymphoproliferative responses to *R. equi* antigens, development of *R. equi*–specific cytotoxic $CD8^+$ T lymphocytes, and IFN-γ but not IL-4 induction by $CD4^+$ and $CD8^+$ lymphocytes.[195,204–206] How these findings in mice and adult horses relate to the foal is currently being elucidated. Even on endemic farms on which exposure to virulent *R. equi* is high, most foals do not develop clinical signs of respiratory disease, suggesting that most foals develop protective immune responses that continue to operate throughout adult life. Age-related deficiencies in *R. equi*—specific cytotoxic T lymphocyte activity have been documented in 3-week-old foals.[206] Cytotoxic T lymphocyte activity was improved by 6 weeks of age and was similar to that in adult horses by 8 weeks.[206] In another study, foals with a peripheral blood CD4:CD8 T lymphocyte ratio <3 between 2 and 4 weeks of age were more likely to develop *R. equi* pneumonia than foals with a higher ratio.[207] These findings may represent important immunologic mechanisms associated with increased susceptibility of individual foals to *R. equi* infections.

The fact that young foals are deficient in their ability to produce IFN-γ in response to mitogens has led to the hypothesis that IFN-γ deficiency may be at the basis of their peculiar susceptibility to *R. equi* infections.[208] A comparison between cell-mediated immune responses of foals and adult horses after intrabronchial challenge with virulent *R. equi* has recently been completed. The results indicate that foals can mount an appropriate IFN-γ response to a low inoculum of virulent *R. equi* but that their immune system is naive compared with that of adult horses.[209] A heavy intrabronchial challenge overwhelms their immune system, leading to a significant increase in IL-4 induction.[209]

In another study, foals infected intrabronchially with a heavy inoculum of a virulence plasmid—containing strain of *R. equi* had significantly lower IFN-γ mRNA expression by bronchial lymph node $CD4^+$ T lymphocytes than foals infected with an avirulent plasmid-cured derivative of the same strain.[210] In addition, IL-10 (a cytokine known to downregulate Th1 responses in other species) and many inflammatory cytokines (IL-1β, TNF-α) were expressed at significantly higher levels in the lungs of foals infected with the virulent strain.[210] The cytokine response in the lungs of foal infected with virulent *R. equi* is at least partially mediated by NF-κB activation.[211] Taken together, these findings suggest that plasmid-encoded products of *R. equi* may have an immunomodulating effect in the respiratory system of foals.

514

515

31.7.6 Diagnosis

The distinction between lower respiratory tract infections caused by *R. equi* and those caused by other pathogens is problematic, especially on farms with no previous history of *R. equi* infections. Many diagnostic tests including complete blood count (CBC), measurement of fibrinogen concentrations, ultrasonography, radiographs, and serology may help distinguish *R. equi* pneumonia from that caused by other pathogens. However, bacteriologic culture and/or PCR amplification combined with cytologic examination of a tracheobronchial aspirate are necessary to make a definitive diagnosis of *R. equi* pneumonia.

31.7.6.1 CLINICAL LABORATORY TESTS

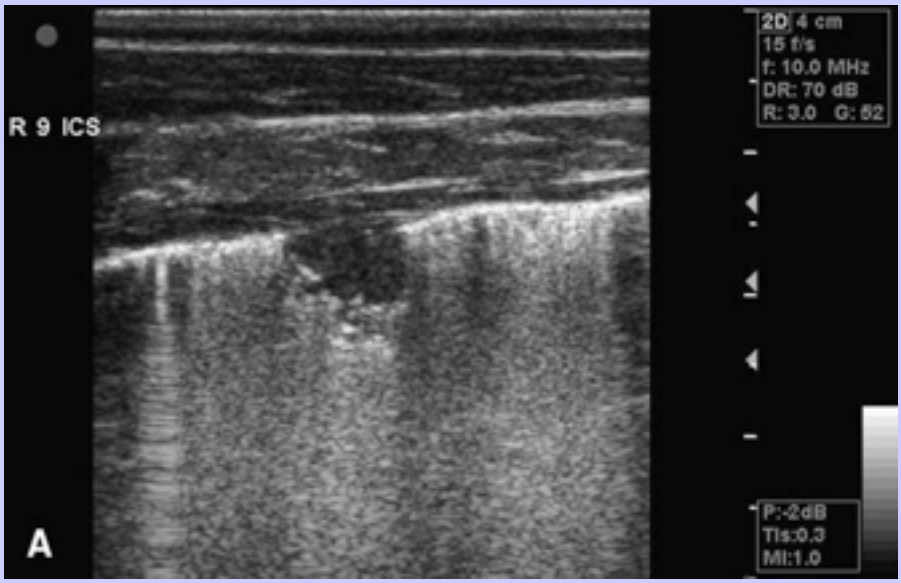
Hyperfibrinogenemia is the most consistent laboratory finding in foals with *R. equi* pneumonia, although in rare cases patients may have normal fibrinogen concentrations. Neutrophilic leukocytosis with or without monocytosis is also common. One study showed significantly higher fibrinogen concentrations and WBC counts in nonsurvivors than in survivors,[212] whereas other studies showed no difference between the two groups.[213,214] In a review of 40 cases of lung abscesses, there was a trend toward higher fibrinogen concentrations and WBC counts for the foals from which *R. equi* was isolated from a tracheobronchial aspirate as opposed to foals from which another pathogen was isolated.[214] However, in all these studies there was a considerable overlap in ranges, which precludes the use of fibrinogen concentrations and WBC as diagnostic tests or prognostic indicators for an individual animal.

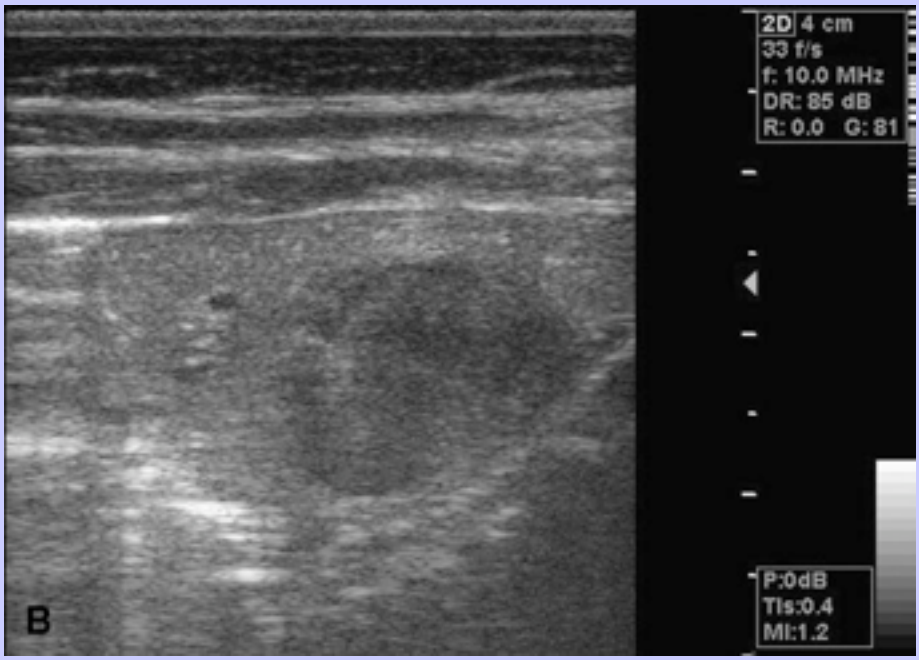
31.7.6.2 IMAGING TECHNIQUES

Thoracic radiography is useful in evaluating the severity of pneumonia and in assessing response to therapy. A prominent alveolar pattern characterized by ill-defined regional consolidation is the most common radiographic abnormality.[212] The consolidated lesions are often seen as more discrete nodular and cavitary lesions consistent with pulmonary abscessation. Although in one study nonsurvivors tended to have more

severe radiographic lesions than survivors, many survivors have very severe radiographic lesions; thus radiographs should not be used as the sole criterion for prognostication and euthanasia.[110,212,213] In foals less than 4 months of age radiographic evidence of nodular lung lesions and tracheobronchial lymphadenopathy is highly suggestive of *R. equi* infections. However, in foals of 4 months and older *S. zooepidemicus* is another common cause of lung abscesses.[214] Ultrasonography is a helpful diagnostic tool when lung involvement includes peripheral areas but may not be as useful as radiography to evaluate the full extent of lung lesions because abscesses with overlying aerated lung will not be detected. However, in most horses and foals with pulmonary abscessation the periphery of the lung is affected, enabling the ultrasonographer to successfully image some of the abscesses.[215] Early ultrasonographic lesions are nonspecific and may include only irregularities of the pleural surface. These lesions may progress to form focal areas of consolidation of various sizes (Fig. 31-15, *A*). In more chronic cases, well-circumscribed, encapsulated abscesses can be detected (Fig. 31-15, *B*). Ultrasonography is very useful in evaluating the severity of pneumonia and in assessing response to therapy, especially for equine practitioners who do not have access to thoracic radiography. Ultrasonography is also a useful tool for detection of some abdominal abscesses (Fig. 31-16) and for screening for *R. equi*–infected foals on farms where the disease is endemic (see section on control).

Fig. 31-15 **A**, Sonogram of the right thorax in a foal with mild pneumonia caused by *R. equi*. There is an approximately 1 cm^2 area of focal consolidation. **B**, Sonogram of the left thorax in a foal with severe pneumonia caused by *R. equi*. There is consolidation of the ventral aspect of the lung surrounding a large encapsulated abscess.





31.7.6.3

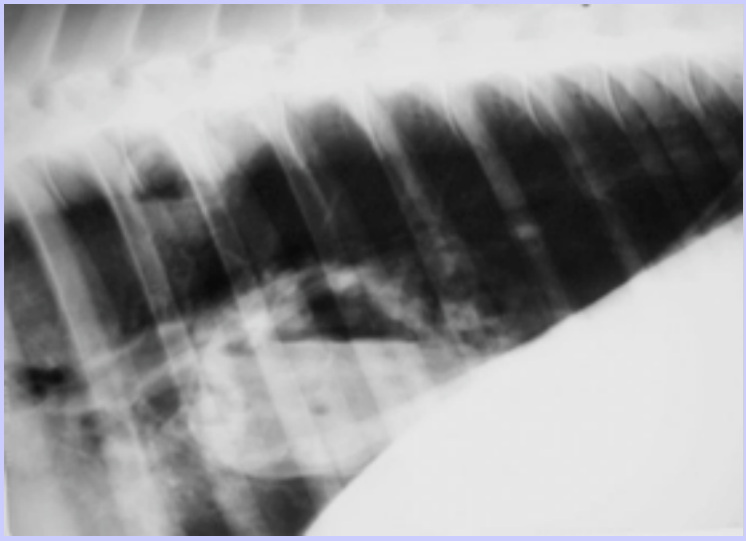
SEROLOGY

A number of workers have investigated serologic approaches to diagnose *R. equi* infections in foals. The two most commonly used types of assays are agar gel immunodiffusion (AGID) and the enzyme-linked immunosorbent assay (ELISA). Serologic diagnosis of *R. equi* infections is problematic because the widespread exposure of foals to this organism at a young age leads to antibody production without necessarily producing clinical disease. In addition, maternally derived antibody causes positive reactions with sensitive ELISA assays, which further confound the interpretation of the test. Several independent studies have recently evaluated the performance of available serologic tests for diagnosis of infection caused by *R. equi* on endemic farms.[186,216–218] The serologic tests evaluated were found to have low sensitivity, low specificity, or both. Improving either sensitivity or specificity of ELISA by changing the cutoff value of the tests could be done only at the detriment of the other. The performance of each assay was not improved by sequential sampling of each foal at 2-week intervals over time.[186] Reliance on serology as the sole diagnostic test for *R. equi* infections results in overdiagnosis of the disease and in missing infections in the early stages. Serologic tests may be more useful at the farm level to detect overall exposure, but they have little value in establishing or excluding a diagnosis of *R. equi* pneumonia.

515

516

Fig. 31-16 Radiograph of the caudodorsal lung of a foal with severe *Rhodococcus equi* pneumonia demonstrating the classically described “Easter Basket” abscess. The appearance of the abscess results from the thick capsule, the fluid within the abscess, and the gas cap above the fluid, creating the gas-fluid interface line contained within the capsule. This radiographic appearance is not as common as a more usual radiographic appearance of bronchointerstitial pneumonia with associated variably sized abscesses.



31.7.6.4 CYTOLOGY, CULTURE, AND POLYMERASE CHAIN REACTION AMPLIFICATION

Bacteriologic culture or PCR amplification combined with cytologic examination of a tracheobronchial aspirate is the only acceptable way of making a definitive diagnosis of *R. equi* pneumonia. In one study only 7 of 11 foals (64%) with positive *R. equi* culture at necropsy and 57 of 89 foals (64%) with radiographic evidence of lung abscessation yielded *R. equi* on culture of a tracheobronchial aspirate.[219] However, in two other studies all 17 foals in which *R. equi* was isolated from the lung parenchyma at necropsy had previously undergone culture of a tracheobronchial aspirate that had yielded the organism, suggesting that culture of a tracheobronchial aspirate is a consistent and reliable method of diagnosing *R. equi* pneumonia.[214,220] Larger case series are required to determine the exact sensitivity of tracheobronchial aspirate culture for the diagnosis of *R. equi* pneumonia in foals. Multiple other pathogens are often isolated along with *R. equi*. Foals without clinical disease exposed to contaminated environments may have *R. equi* in the trachea as a result of inhalation of contaminated dust. In one study conducted on a farm with endemic *R. equi* pneumonia, 77 of 216 foals sampled (36%) had positive tracheobronchial aspirate cultures but no signs of respiratory disease.[221] For this reason, bacteriologic culture of a tracheobronchial aspirate should be interpreted in the context of cytologic evaluation, physical examination, and laboratory results. A light growth of *R. equi* from a foal with no clinical signs of respiratory disease, normal fibrinogen concentrations and WBC count, and no cytologic evidence of airway inflammation is likely an incidental finding. The use of PCR amplification based on the VapA gene sequence is a more sensitive mean of identifying *R. equi* in tracheobronchial aspirate samples than bacterial culture, especially if the foal sampled is concurrently being treated with antimicrobial agents.[222] However, increased sensitivity may also result in a higher incidence of false-positive results owing to the detection of very small numbers of *R. equi* present as environmental contaminants. Several conventional and real-time PCR assays have been developed for the detection of virulent *R. equi*.[222–225] PCR amplification may be done in association with, but should not replace, bacterial culture because it does not permit identification of concurrent bacterial pathogens and in vitro antimicrobial susceptibility testing of *R. equi* isolates.

Positive *R. equi* culture from nasal or fecal swabs cannot be taken as evidence of infection. *R. equi* can be cultured from the feces of normal horses even if they live on farms with no history of *R. equi* pneumonia.[155,226,227] The quantitative culture of the feces of foals at weekly intervals has been advocated as an aid in early diagnosis of *R. equi* infections in foals because the bacterial count per gram of feces increased at the same time as clinical signs appeared.[226] However, a single fecal sample from a foal has no diagnostic value because of individual as well as farm-to-farm variation in the number of *R. equi* in the feces.[155,226,227] Furthermore, a negative fecal culture may not be helpful in ruling out *R. equi* infection; in one study only 5 of 30 foals (17%) with confirmed *R. equi* pneumonia had positive fecal cultures.[221] Similarly, bacterial culture and PCR amplification of nasal swabs are poorly sensitive for the diagnosis of *R. equi* pneumonia.[222,228]

31.7.7 Treatment

A wide variety of antimicrobial agents are active against *R. equi* in vitro. However, because *R. equi* is a facultative intracellular pathogen surviving and replicating in macrophages and therefore causes granulomatous lesions with thick caseous material, many of these drugs are ineffective in vivo. For example, in one study all 17 foals with *R. equi* pneumonia treated with the combination of penicillin and gentamicin died despite the fact that all isolates were sensitive to gentamicin.[214] The combination of rifampin and erythromycin became the treatment of choice in the 1980s and has dramatically reduced foal mortality since its introduction.[110,219] In recent years

clarithromycin or azithromycin, two newer generation macrolides, often replaces erythromycin in the combination with rifampin.[229] Macrolides and rifampin are highly active against *R. equi* in vitro but exert only bacteriostatic activity.[230] As a result, macrolides exert time-dependent activity against *R. equi* in vitro. Of the three macrolides listed previously, clarithromycin is the most active against *R. equi* in vitro. The minimum inhibitory concentrations at which 90% of *R. equi* isolates are inhibited (MIC_{90}) are 0.12, 0.25, and 1 μg/mL for clarithromycin, erythromycin, and azithromycin, respectively.[231] The combination of a macrolide and rifampin is synergistic both in vitro and in vivo, and the use of the two classes of drugs in combination reduces the likelihood of *R. equi* resistance to either drug.[230,232] Rifampin and macrolides are lipid soluble, allowing them to penetrate cell membranes and caseous material.

The recommended doses are listed in Table 31-4. Several formulations of erythromycin are commercially available. Although they all show slight differences in bioavailability and elimination, they all result in therapeutic concentrations at recommended doses. Advantages of azithromycin and clarithromycin over erythromycin in foals include enhanced oral bioavailability, prolonged half-lives, and much higher concentrations in bronchoalveolar cells and pulmonary epithelial lining fluid.[233–235] These properties of the newer generation macrolides contribute to their lower doses and longer dosing intervals. Concentrations of clarithromycin in pulmonary epithelial lining fluid and bronchoalveolar cells of foals at steady state are considerably higher than concentrations reported after daily administration of azithromycin to foals.[234,235] However, clarithromycin concentrations at these sites decrease rapidly, whereas the release of azithromycin from cells is much slower, resulting in sustained concentrations of azithromycin in tissues for days after discontinuation of therapy.[233–235] In a retrospective study, the combination clarithromycin and rifampin was significantly more effective than erythromycin-rifampin or azithromycin-rifampin, especially in foals with severe radiographic lesions.[229]

516

517

Table 31-4 Recommended Doses, Oral Bioavailability, and Serum Half-Lives of Antimicrobial Agents Commonly Used for the Treatment of *R. equi* Infections in Foals

Class	Drug	Dose (mg/kg)	Route	Frequency (h)	Oral Bioavailability (%)	Serum $t_{1/2}$ (h)	References
Macrolides	Erythromycin*	25	PO	6–8	18	1	163c, 163d
		5	IV	6	NA	1	163c, 163d
	Clarithromycin	7.5	PO	12	57	5.4	131, 163e
	Azithromycin	10	PO	24–48†	56	18	129, 130
		5	IV	24–48†	NA	16	129, 130
Rifamycins	Rifampin	5	PO	12	49	15	163a, 163b, 163f

IV, Intravenous; *PO*, by mouth; *NA*, not applicable.

* Erythromycin base, stearate, phosphate, estolate, or ethylsuccinate.

† Administration q24h for 5 days and q48h thereafter.

Because polymicrobial infections are common, a third antimicrobial agent may be necessary if another pathogen resistant to macrolides and rifampin is isolated in significant number along with *R. equi*. The combination of gentamicin or amikacin with erythromycin or rifampin in vitro gives significant antagonistic activity against *R. equi* compared with either drug alone.[230,232] However, the clinical significance of this in vitro finding has not been established. Resolution of clinical signs, normalization of plasma fibrinogen concentrations, and radiographic or ultrasonographic resolution of lung lesions are commonly used to guide the duration of therapy, which generally ranges between 2 and 12 weeks depending on the severity of the initial lesions.

Although well tolerated by most foals, macrolides commonly cause diarrhea. Most of the time the diarrhea is self-limiting and does not necessitate cessation of therapy, but affected foals should be monitored carefully because some may develop severe diarrhea, leading to dehydration and electrolyte loss that necessitate intensive fluid therapy and cessation of oral macrolides. The incidence of diarrhea in foals treated with erythromycin-rifampin has ranged from 17% to 36%.[229,236] In one study, foals treated with clarithromycin had a higher incidence of diarrhea (28%) than those treated with azithromycin (8%).[229] In most cases diarrhea was mild and self-limiting. In the same study the incidence of severe diarrhea necessitating administration of IV fluids was not significantly different among groups of foals treated with azithromycin-rifampin, clarithromycin-rifampin, or erythromycin-rifampin.[229] During surges of very hot weather an idiosyncratic reaction characterized by severe hyperthermia and tachypnea has been described in foals treated with erythromycin.[236] Anecdotal reports suggest that these reactions may occasionally occur with newer macrolides as well. Administration of antipyretic drugs and placement of the foal in a cool environment will treat this problem. Severe enterocolitis has also been reported in mares whose foals are being treated with erythromycin, presumably resulting from disruption of the mare's normal colonic microflora after ingestion of small amounts of active drug during coprophagia or after contamination of feeders or water buckets with drug present on the foal's muzzle.[237]

Even though the vast majority of *R. equi* isolates from foals are highly susceptible to macrolides and rifampin, strains resistant to each have been encountered. The percentage of *R. equi* isolates resistant to either macrolides or rifampin has ranged between 0% and 4% depending on the studies.[231,238] Rifampin should not be used in monotherapy because this increases the chance of resistance developing.[230,239] Rifampin resistance is conferred by mutations in the RNA polymerase β subunit encoded by the *rpoB* gene.[240,241] Progressive development of resistance to both erythromycin and rifampin during treatment is extremely rare, but it has been reported.[215] The molecular mechanisms of macrolide resistance in *R. equi* isolates have not been determined, but *R. equi* isolates resistant to one of the three macrolides listed previously are almost invariably resistant to the other two as well. Therapy of foals developing severe diarrhea during macrolide therapy or therapy of foals infected with resistant isolates is problematic because of the limited range of alternative effective drugs.

Oral doxycycline in combination with rifampin has been used successfully for the treatment of foals with pneumonia caused by *R. equi*. The recommended dose of doxycycline in foals is 10 mg/kg q12h PO. This dose results in serum, pulmonary epithelial lining fluid, and bronchoalveolar cell concentrations above the MIC_{90} of *R. equi* isolates (1 μg/mL) for the entire dosing interval. Doxycyline is bacteriostatic against *R. equi*, but the drug is highly synergistic with rifampin and with macrolides in vitro. Therefore doxycycline could also be combined with a macrolide for the treatment of rifampin-resistant isolates. Chloramphenicol can be administered orally and achieves high concentrations within phagocytic cells in other species. The recommended dosage regimen is 50 mg/kg q6h PO. However, the fact that only 70% of *R. equi* isolates are susceptible to this drug and the potential human health risk make this drug a less attractive alternative. High doses of a TMS combination (30 mg/kg of combination every 8 or 12 hours orally) have been used alone or in combination with rifampin in foals with mild

or early *R. equi* pneumonia or for continued therapy in foals responding well to other antimicrobials.[110] However, TMS is not nearly as effective as the combination macrolide-rifampin.

In an experimental model of *R. equi* infection in immunosuppressed mice, the most effective drugs in monotherapy were found to be, in order of effectiveness, vancomycin, imipenem, and rifampin.[242] Amikacin, erythromycin, ciprofloxacin, or minocycline in monotherapy did not lead to a significant decrease in bacterial counts. The most active drugs in combination were those including vancomycin or rifampin, but these combinations were not significantly different from vancomycin monotherapy.[242] Vancomycin and imipenem should be used in foals only for the treatment of life-threatening *R. equi* infections caused by isolates confirmed to be resistant to all other possible alternatives.

517

518

Nursing care, provision of adequate nutrition and hydration, and maintenance of the foal in a cool and well-ventilated environment are important. Oxygen therapy using humidified oxygen by pharyngeal insufflation in moderately hypoxemic foals, or by percutaneous transtracheal oxygenation in severely hypoxemic animals, is indicated.[243] Judicious use of NSAIDs is of value in reducing fever and improving attitude and appetite in febrile depressed anorectic foals. Nebulization may be helpful in selected animals with tenacious secretions and nonproductive cough. However, most foals with *R. equi* pneumonia do not benefit from nebulization, and the procedure is stressful to some. Similarly, bronchodilators are rarely helpful clinically in foals with pneumonia caused by *R. equi*. In addition to appropriate systemic antimicrobial therapy, foals with *R. equi* septic arthritis or osteomyelitis often require aggressive local therapy such as joint lavage, surgical debridement, and IV or intraosseous regional limb perfusion with antimicrobial agents. The prognosis of foals with abdominal abscesses is poor, although rare patients will respond to long-term antimicrobial therapy. Surgical removal or marsupialization has been attempted in some foals, but abdominal adhesions usually result in the inability to resect the lesion or in chronic intermittent episodes of colic.

31.7.8 Prognosis

Before the introduction of the combination of erythromycin and rifampin as the treatment of choice in the early 1980s, the prognosis of *R. equi*–infected foals was poor, with reported survival rates as low as 20%.[244] Using erythromycin and rifampin, Hillidge reported a successful outcome (as assessed by survival) in 50 of 57 foals (88%) with confirmed *R. equi* pneumonia.[219] Studies in referral centers, more likely to see the most severely affected cases, have revealed survival rates ranging from 59% to 72%.[9,213,229] Recent studies have shed light on the impact of *R. equi* infections on future athletic performance. Ainsworth and colleagues[245] performed radiography, hematologic and BAL analysis, and pulmonary function tests in five horses (6 to 18 months) with prior *R. equi* pneumonia and compared the results with age-matched controls with no history of respiratory disease. There was no significant difference between the two groups. In another study the gas exchange of seven standardbred horses previously diagnosed with *R. equi* pneumonia as foals was not compromised during intense treadmill exercise compared with reference values for healthy fit standardbreds.[246] Bernard and co-workers[247] evaluated the influence of *R. equi* pneumonia on future racing performance. Thirty horses that previously had *R. equi* pneumonia were compared with the affected foals' dams' progeny. There were no significant differences in total earnings, average earning index, and age at the first race between horses that previously had *R. equi* pneumonia and controls or the North American average. These results suggest that horses with previous *R. equi* pneumonia are likely to perform as well as expected if they race, but because only foals registered with the Jockey Club were considered, it does not indicate if they are as likely to race as a control population. More recently, the records of 219 foals diagnosed with *R. equi* pneumonia and treated with erythromycin and rifampin were reviewed.[213] The survival rate was 72%. Of the survivors 54% had at least one racing start, as opposed to

65% for the control population, suggesting that horses contracting *R. equi* pneumonia as foals may be slightly less likely to race as adults. However, as also shown by Bernard and colleagues,[247] the racing performance of foals that raced was not significantly different from that of the U.S. racing population.[213]

31.7.9 Control of *Rhodococcus Equi* Infections on Farms where the Disease Is Endemic

Current approaches for the control of *R. equi* infections on endemic farms depend on (1) decreasing the size of infective challenge, (2) screening for earlier recognition and therapy of affected foals, and (3) passive immunization. Recent advances in the area of chemoprophylaxis and immunoprophylaxis are also discussed.

31.7.9.1 DECREASING THE SIZE OF INFECTIVE CHALLENGE

There seems to be a progressive buildup of infection on horse farms with prolonged use. Thus, endemic farms are often those used for breeding horses for many years, those with heavy concentrations of mares and foals, and those located where summer temperatures are high, where the soil type is sandy, and where dust is extensive. Large numbers of foals kept on bare, dusty, manure-containing paddocks may result in heavy environmental challenge, with clinical disease maintaining the population of environmental virulent bacteria. General recommendations that would be expected to decrease dust formation and inhalation of virulent *R. equi* may help in reducing the incidence of the disease. However, solid evidence demonstrating the efficacy of the following general recommendations in decreasing clinical disease is lacking. Common sense dictates that foals should be housed in well-ventilated, dust-free areas and that dirt paddocks should be avoided. Pneumonic foals should be isolated, because they may contribute the most to contamination of the environment with virulent organisms. When possible, pasture could be rotated to decrease grass destruction, dust formation, and consequent inhalation of *R. equi*. Any sandy or dirt areas should ideally be planted with grass or made “off limits” to foals, or, alternatively, irrigation may be useful in decreasing dust formation and encouraging grass propagation. Because mares and foals tend to congregate around water sources and under shade in hot summers, reduction in the size of mare-foal bands or mobile troughs and shade may reduce the destruction of grass and exposure to barren soil. Dispersal of foals onto grass paddocks will reduce dust formation and therefore the number of inhaled bacteria. Ingestion of low numbers of organisms via grazing on contaminated grass may actually have the beneficial effect of immunizing foals orally.[160,248] Manure should be regularly removed from stalls, pens, and paddocks and composted. The fact that the concentrations of airborne virulent *R. equi* are higher in stables than in paddocks[157] suggests that frequent cleaning and disinfection of stalls may help to decrease contamination and opportunity for infection. Avoiding dirt-floored foaling stalls should be considered, because *R. equi* is a soil saprophyte and epidemiologic evidence suggests that dirt floors may increase the risk of development of *R. equi* pneumonia.[163]

31.7.9.2 SCREENING FOR EARLIER DETECTION OF AFFECTED FOALS

R. equi pneumonia is often not recognized until it is well advanced and therefore difficult to treat. Even severely affected foals may appear to suckle and behave normally to a casual observer. Screening for early recognition of *R. equi*–induced pneumonia before development of clinical signs and appropriately treating infected foals reduce losses and limit the costs associated with long-term therapy of severely affected animals. It is important to emphasize that screening methods are not diagnostic tests. A useful screening test is one in which the probability of disease is high with a positive test result (high positive predictive value) and very low with a negative test result (high negative predictive value). The higher the prevalence of disease at a given farm, the higher the positive predictive value of a given test will be. Therefore, depending on the prevalence of

R. equi infections on a given farm, a positive result of a screening test could be a basis to perform a diagnostic test (low to moderate prevalence) or to initiate therapy (high prevalence). Screening methods can be divided into three categories: physical examination findings, imaging techniques, and laboratory tests (Box 31-1). In one study on a large breeding farm with endemic *R. equi* problems, use of twice-weekly complete physical examinations with auscultation of the lungs was apparently successful in promoting early diagnosis and preventing mortality.[249] However, thoracic auscultation is a fairly insensitive tool, and many foals will not show clinical signs of respiratory disease or develop a fever until lung lesions are well established.

Imaging techniques such as radiography and ultrasonography are relatively specific because they detect lung lesions. As stated in the diagnosis section earlier, radiography offers the advantage of detecting either central or peripheral lesions. However, radiography has several disadvantages that limit its use as a practical screening test. Disadvantages of radiography include cost, need for special equipment, need for more personnel, and exposure of personnel to radiation. In addition, early radiographic lesions can be subtle and less typical of *R. equi* pneumonia than more advanced cases. Ultrasonography of the chest offers several advantages over radiography as a screening test. The entire chest can be scanned in just a few minutes, and when the periphery of the lung is affected ultrasonography is more sensitive than radiography. Biweekly ultrasonographic examination of the chest of all the foals on endemic farms (starting at 3 to 4 weeks of age) has been extremely useful in preventing mortality by promoting early identification of pneumonic foals before development of clinical signs.[250] Using this approach, as many as 50% of foals on a farm were found to have subclinical lung lesions.[250] Many foals with mild lung lesions may recover without therapy. However, it is impossible to discriminate between foals in which the infection will successfully resolve without treatment and foals that will eventually develop clinical signs. Foals with no clinical signs and ultrasonographic lesions consisting of only irregularities of the pleural surface (comet tail artifact) do not require therapy.[250] However, foals with focal areas of consolidation ≥1 cm in diameter or in depth (see Fig. 31-15, *A*) and foals with clinical signs of respiratory disease are usually treated.[251] Ultrasonography also offers the advantage of allowing evaluation of the severity of lung involvement, and follow-up examinations permit a more objective assessment of response to therapy. The duration of therapy is proportional to the initial severity of the lesions.[250]

31.7.9.2.1

Box 31-1 Screening Methods for Earlier Detection of Foals Infected with *R. equi* on Endemic Farms

31.7.9.2.1.1

PHYSICAL EXAMINATION

Daily visual inspection of foals for attitude and respiratory effort

Measuring rectal temperature of each foal twice daily

Biweekly thoracic auscultation by a veterinarian

31.7.9.2.1.2

IMAGING TECHNIQUES

Biweekly thoracic radiography

Biweekly ultrasonography*

31.7.9.2.1.3

LABORATORY TESTS

Biweekly measurement of white blood cell count

Biweekly measurement of fibrinogen concentrations

* Preferred method when the resources or expertise required are available.

Many farms do not have access to the resources or expertise required for periodic ultrasonographic evaluation. Laboratory tests may be more practical on farms where blood can be collected by farm workers. Recent studies have shown that currently available serologic assays and measurement of serum amyloid A are not useful screening tests.[252,253] In contrast, combination of careful daily observation and measurement of WBC counts and plasma fibrinogen concentrations in all foals at 2- to 4-week intervals, although labor intensive, may be a useful alternative to ultrasonography for early identification of *R. equi*–infected foals on endemic farms. In one study 165 foals were monitored during the entire breeding season, and diagnosis of *R. equi* pneumonia was confirmed in pneumonic foals by culture of a tracheobronchial aspirate. Total WBC count was found to be a significantly better screening method than measurement of fibrinogen concentrations.[216] Using a cutoff value of 14,000 cells/μL, sensitivity and specificity for early identification of foals with *R. equi* pneumonia were 88% and 81%, respectively.[216] On a farm where the disease prevalence is 40%, the predictive value of a positive test result (WBC >14,000 cells/μL) would be 75% and the predictive value of a negative test result (WBC <14,000 cells/μL) would be 91%. In contrast, the same cutoff value used on a farm with a disease prevalence of 5% would result in a predictive value of a positive test result of only 20%. This example underscores the fact that such screening methods are valid only when the prevalence of the disease is high. Because increases in WBC counts and fibrinogen concentrations are nonspecific findings, it is advisable to subject foals identified by such screening methods to additional diagnostics (e.g., ultrasonography or TBA) before initiation of therapy to reduce the rate of false-positive results. However, some farms where the prevalence of the disease is particularly high and well documented may elect to initiate therapy based on these screening methods alone.

31.7.9.3

PASSIVE IMMUNIZATION

IV administration of HI plasma obtained from horses vaccinated against *R. equi* using various antigens has consistently proved effective in significantly reducing the severity of *R. equi* pneumonia in foals after experimental challenge.[192,254] However, studies evaluating the efficacy of various HI plasma preparations under field conditions have given equivocal results, with only two of five controlled clinical trials demonstrating a statistically significant reduction in the incidence of *R. equi* pneumonia.[162,220,255–257] In one randomized controlled prospective study involving 165 foals on an endemic farm, the incidence of pneumonia caused by *R. equi* was 19% in the group that had received plasma versus 30% in the control group. Although the decrease in incidence did not quite reach significance ($P = .09$), such a decrease would be relevant to many farm managers.

The ideal time for administration of HI plasma and the minimal effective dose require further research. Administration of HI plasma before infection with *R. equi* is important.[258] However, early administration may result in the decline of passively transferred antibody to a nonprotective level at a time when foals are still susceptible to *R. equi* and environmental challenge is high.[256] Therefore IV administration of 1 L of HI plasma within the first few days of life followed by a second administration at approximately 25 days of age, although expensive, may be the best approach on farms with high morbidity rates. U.S. Department of Agriculture (USDA)–licensed *R. equi* antibody (HI plasma) for the prevention of *R. equi* pneumonia is commercially available in North America (Lake Immunogenics Inc., Ontario, NY; Plasvacc USA, Templeton, Calif.). HI plasma is expected to slightly decrease the incidence of the disease (by 30% to 40%) but will not prevent infection in all foals and should not lull farm owners into a false sense of security and reduce the need for continued vigilance. Whether this strategy is cost-effective will vary from farm to farm. When used for the control of *R. equi* infections on endemic farms, administration of HI plasma should always be combined with screening techniques aimed at early identification and treatment of infected foals (see earlier).

519

520

31.7.9.4

CHEMOPROPHYLAXIS

Another suggested approach for the prevention of *R. equi* infections on endemic farms is the prophylactic administration of antimicrobial agents to all the foals during the time period when they are most susceptible to infection. Azithromycin is an attractive choice for prophylactic administration because of good oral bioavailability, long half-life, and high and sustained concentrations in pulmonary epithelial lining fluid, bronchoalveolar cells, and neutrophils. In a prospective randomized clinical trial, azithromycin was administered at a dose of 10 mg/kg q48h for the first 2 weeks of life. Preliminary data analysis suggests an overall significant benefit, although protection was not absolute.[259] However, there are several potential problems with the mass administration of azithromycin or other antimicrobial agents for the prevention of *R. equi* infections. First, the period of susceptibility to *R. equi* is much longer than 2 weeks. As a result, the ideal time period for antimicrobial prophylaxis remains unknown. Second, administration of azithromycin to foals has occasionally resulted in life-threatening adverse effects such as enterocolitis and possibly hyperthermia. Prophylactic administration to all the foals on a farm will increase the likelihood of occurrence of adverse effects. Finally and most importantly, the long-term effects of this practice on selection of resistant bacterial isolates are unknown. Given the fact that *R. equi* isolates resistant to azithromycin are usually resistant to erythromycin and clarithromycin also, development of resistance could have devastating consequences for the foal crop.

A novel approach that may prove beneficial in the prevention of *R. equi* pneumonia is the administration of gallium maltolate. Gallium is a trivalent semimetal that shares many similarities with ferric iron. Most bacteria require iron for survival. Recent studies have shown that iron acquisition is essential for the survival of *R. equi* and that the organism can acquire and use iron bound to transferrin and lactoferrin.[260] Gallium readily binds to plasma transferrin and lactoferrin.[261] Bacteria acquire gallium and incorporate it into essential iron-dependant enzyme systems, which leads to inactivation of those systems and bacterial death. A recent study has shown that gallium inhibits in vitro growth of *R. equi* and that oral treatment of mice with gallium maltolate may decrease the number of *R. equi* in tissues after experimental infection.[262] Recent pharmacokinetic and safety studies in neonatal foals have indicated that gallium maltolate at a dose of 20 mg/kg results in adequate serum concentrations and that no adverse clinical or clinicopathologic effects were apparent when gallium was administered for 5 days.[263] Larger numbers of foals treated over longer periods of time will be needed to more

fully characterize safety issues. Clinical trials to critically evaluate the prophylactic effectiveness of gallium in foals on endemic farms are awaited.

31.7.9.5 ACTIVE IMMUNIZATION

It would be considerably more convenient to control *R. equi* pneumonia on endemic farms by the active immunization of mares or foals with a protective antigen. Such attempts have so far been unrewarding in foals. The role of antibody in partial protection against *R. equi* infection would suggest that vaccination of mares would be effective at conferring at least some degree of protection. However, in both a field study and an experimental challenge, vaccination of mares did not provide protection against *R. equi* pneumonia despite a significant increase in colostral specific *R. equi* antibody and transfer of passive immunity to foals.[257,264] More recently, a vaccination of a small number of mares with VapA protein antigen associated with a water-based nanoparticle adjuvant led to high anti-VapA IgG concentrations in mares and foals and may have conferred protection against natural challenge compared with nonvaccinated controls.[265] However, a more extensive study on an endemic farm will be necessary to confirm these preliminary findings before widespread vaccination of mares can be recommended.

Because cell-mediated immunity is of paramount importance in protection against *R. equi*, active immunization of foals will likely be required for complete protection. Recent studies in mice indicated that DNA immunization against *vapA* protects against *R. equi* infection and that the IgG subisotype response is consistent with a Th1-based immune response.[266] A similar DNA vaccine containing the *vapA* gene has been shown to induce strong cell-mediated immune responses in adult horses, but responses were poor in foals.[267] Immunization in foals will need to be initiated very early in life, and an effective vaccine will have to overcome the relative immaturity and possible inherent bias of the naive neonatal immune system. The fact that oral administration of live virulent *R. equi* confers almost complete protection against heavy intrabronchial challenge[248,264] and the fact that most foals on endemic farms do not develop disease or develop subclinical disease and eventually clear the infection provide the proof of concept regarding the potential for active immunization in foals. Further work is needed to examine active immunization strategies based on a better understanding of the antigens of importance and the method of administration or adjuvant required to produce the effective Th1 immune response required for protection against *R. equi* pneumonia in neonatal foals.

31.8 PNEUMONIA IN FOALS

DANIELA BEDENICE

Equine pneumonia is a significant cause of morbidity and mortality in both the newborn and the older foal.[268–271] Although the causative agents and the mode of lung infection are generally different for each age-group, foal pneumonia is commonly associated with a compromise in the immunologic protection of the host. The exact immunologic basis of the foal's inherent susceptibility to opportunistic respiratory pathogens needs to be further elucidated.

Failure of passive transfer of immunity (FPT) is a well known risk factor of neonatal infection, including respiratory disease,[271] because not only are affected foals deprived of specific maternal antibody protection, but their neutrophil function is also seriously impaired.[272] Although foals can respond immunologically in utero to bacterial or viral infections, their ability to do so is less than that of adults. Reduced complement values and

defective chemotaxis (directed migration of neutrophils or macrophages) and killing capacity of the neonatal neutrophil contribute to a relatively decreased defense against invading bacteria. Furthermore, an immature ciliary apparatus and the presence of fewer alveolar macrophages in neonates in comparison with adult horses lead to decreased bacterial clearance from the lungs.[273] The number and distribution of the bronchoalveolar cells approach adult levels only at approximately 3 to 6 weeks of age.[274]

It has been suggested that a natural cellular immunodeficiency may also occur in foals at 2 to 4 months of age.[275] Although the exact association between age-related cellular immunodeficiency and the defense against intracellular pathogens such as *P. carinii (Pneumocystis jiroveci)* and *R. equi* of foals still needs to be clarified, $CD4^+$ and $CD8^+$ T lymphocytopenia was documented in a filly with *P. carinii* pneumonia.[276]

520

521

31.8.1 Etiology

31.8.1.1 NEONATAL PNEUMONIA (<1 MONTH OF AGE)

In contrast to the older foal, infectious lung disease in the neonate is usually part of a multiple-organ, systemic infection or sepsis, which may be acquired via the placenta in utero or perinatally through environmental bacteria leading to hematogenous (ascending) infection (e.g., omphalophlebitis). *E. coli, Klebsiella* species, *Actinobacillus equuli, Salmonella* species, and *Streptococcus* species are some of the more common bacteria involved in neonatal foal pneumonia.[277]

Descending lung infections may be caused by inhalation of viral, bacterial, or opportunistic fungal agents. Furthermore, iatrogenic aspiration (oil, medication, oral supplements) or aspiration of gastric reflux, milk, meconium, and contaminated amniotic fluid after placental infection may seed the foal's lung. Meconium aspiration occurs in utero in foals that experience fetal distress (perinatal asphyxia). Although the meconium is commonly sterile at this time, it creates mechanical airway obstruction, surfactant inactivation, and pulmonary inflammation (caused by vasoactive mediators and chemotactic and inflammatory cytokines, including TNF-α, interleukin [IL]-1β, and IL-8).[278] The resulting edema and vasoconstriction may lead to hypoperfusion of the pulmonary parenchyma, with damage to type II pneumocytes and decreased production of surfactant.[279] This type of “secondary surfactant deficiency” may also be induced by other forms of generalized pulmonary inflammation, including diffuse bacterial pneumonia. Neurologic dysfunction, severe inflammation, or structural abnormalities of the upper airways (congenital cysts, dorsal displacement of the soft palate, laryngeal paralysis, pharyngeal weakness, etc.) may predispose to aspiration pneumonia postpartum.

EVA and herpes viral infections (EHV-1 and EHV-4) have been implicated in in utero viral infections leading to lung disase.[280] Although involvement of adenovirus in the pathogenesis of pneumonia has also been reported in a thoroughbred foal, fatal adenoviral pneumonia is primarily associated with combined immunodeficiency (SCID) in Arabian foals.[281,282] In addition, a recent report documents the isolation of influenza A virus from a seven-day-old foal with bronchointerstitial pneumonia.[282]

31.8.1.2 PNEUMONIA IN OLDER FOALS (1 TO 6 MONTHS OF AGE)

S. zooepidemicus and *R. equi* are the most important pathogens associated with pneumonia in older foals, although plurimicrobial infections *(Actinobacillus* species, *B. bronchiseptica, E. coli, Klebsiella pneumoniae, Pasteurella* species, *Pseudomonas* species, *Salmonella* species, and *Staphylococcus* species) are not

uncommon.[283,284] *S. zooepidemicus* was isolated from 87% of uncomplicated lower respiratory tract infections in foals (1 to 8 months old) on selected farms[285] and was documented as the most common cause of pulmonary abscesses in a second study.[286] In contrast, anaerobes appear to be infrequently involved in primary pneumonia of foals.[285] *Corynebacterium pneumonia* due to aerosol infection is a rare cause of diffusely increased interstitial and peribronchial radiographic densities, indicative of pulmonary abscesses in foals.[287]

Although respiratory viruses are often believed to be primary offending agents that lead to secondary bacterial lung invasion, they have limited importance in nursing foals.[285,288] Equine adenoviruses (EAdVs) and EHV-2 are ubiquitous in the general equine population, with little pathogenicity in immunocompetent foals. Although adenoviruses are the most common respiratory pathogens in Arabian foals with severe combined immunodeficiency (SCID), the role of EHV-2 in the respiratory disease complex of foals remains unclear. The latter has been implicated as a predisposing factor for *R. equi* pneumonia.

Because of the complexity of the disease, in-depth discussions of *Rhodococcus* pneumonia and ALI and ARDS are presented elsewhere in Chapter 31.

31.8.1.3

INTERSTITIAL PNEUMONIA

Acute, severe interstitial or bronchointerstitial pneumonia is a sporadic, rapidly progressive disease of foals of 1 to 6 months of age that is characterized by a sudden onset of respiratory distress, tachypnea, fever, high mortality, and histopathologic evidence of severe, diffuse, necrotizing bronchiolitis, alveolar septal necrosis, and neutrophilic alveolitis on necropsy.[289–291] Although no definitive causative agent(s) or factor(s) of this disease have yet been identified, suspected causes include viruses, *P. carinii*, heat stroke, environmental toxins, and bacteria.[289–292] Enteric gram-negative organisms, *R. equi, Pseudomonas aeruginosa*, and *P. carinii* have all been cultured from the lungs of affected foals.

The reported cases are usually sporadic, affecting a single foal within a herd,[289] although rare clusters of cases have also been described.[291] The disease is generally rapidly progressive and may lead to sudden death as a result of fulminant respiratory failure. Severe respiratory distress, hypoxemia, hypercapnia, and respiratory acidosis are the most striking clinicopathologic signs. The hypoxemia of bronchointerstitial pneumonia is relatively resistant to supplemental oxygen therapy, indicating a pulmonary shunt. Thoracic radiographs commonly demonstrate caudodorsally distributed interstitial and bronchointerstitial pulmonary opacities. With advanced disease, the radiographic pattern progresses to include patches of a coalescing alveolar nodular pattern with air bronchograms.[293] As with bacterial pneumonia, many foals demonstrate hyperfibrinogenemia and neutrophilic leukocytosis on hematology.

Therapy is symptomatic, including antiinflammatory therapy, broad-spectrum antibiotics, thermoregulatory control, bronchodilation, and supplemental oxygen. Surviving foals may develop a proliferative epithelial and interstitial response including bronchiolar and alveolar epithelial hyperplasia, type II cell hyperplasia, and hyaline membrane formation.[293]

Chronic pulmonary disease (1 to 3 months' duration) with marked radiographic interstitial opacities was reported in 12 foals, age 3 to 9 months, that were examined at a veterinary teaching hospital.[294] Evaluation failed to yield a consistent pathogen from tracheobronchial aspirates. The authors proposed that chronic

interstitial pneumonia occurring in foals is associated with a good prognosis and considered corticosteroid therapy as a potentially useful treatment.

31.8.1.4 *PNEUMOCYSTIS JIROVECI (CARINII)* INFECTION

Rare opportunistic fungal pathogens of the lung may include *P. carinii* (renamed *P. jiroveci* in humans), *Aspergillus, Candida*, and *Mucor* species. *P. carinii* is a unicellular eukaryote that has been classified as a fungus after DNA studies.[295] It is most commonly seen in humans and animals that suffer from a concurrent immunodeficiency. It was first recovered in Arabian foals with SCID.[296] It has since been recovered from foals of other breeds with no specific history of immunodeficiency, although for the most part no direct testing for immunocompetence was performed in the reported cases. However, one more recently documented case demonstrated a low number of circulating $CD4^+$ and $CD8^+$ lymphocytes in a filly with *P. carinii*.[276]

In several reports the onset of clinical signs in affected foals ranged from a 3-week history of weakness, weight loss, and nasal discharge to acute dyspnea. Half of the reported non-Arabian cases had concurrent infections with *R. equi, Enterobacter cloaca, E. coli*, or *S. zooepidemicus*. A severe interstitial, sometimes miliary and alveolar pattern was seen on radiographs of the lungs. The majority of the reported foals died, and the diagnosis of *P. carinii* was obtained at necropsy.[276,292,296–299] On postmortem examination the lungs were uniformly heavy and consolidated, and a diffuse interstitial pneumonia was found. Trophozoites and cysts were observed in the alveolar epithelial cells, and macrophages within the alveoli. Silver staining and streptavidin-biotin immunolabeling of histologic sections provide a better visualization of the organisms in the pulmonary tissue.[297] A few foals were diagnosed by visualization of the organism on a BAL sample. Two surviving foals responded to trimethoprim-sulfamethoxazole (TMS) therapy.

521 522

31.8.2 Clinical Presentation and Diagnosis of Foal Pneumonia

The clinical manifestation of pneumonia in the newborn foal can be variable and depends on the disease severity and underlying or associated problems. Early in life, localizing clinical signs of respiratory infection may be absent even in the presence of extensive disease. Dyspnea may be seen in severely affected foals and may manifest as an increase in respiratory rate, effort, or thoracoabdominal asynchrony (paradoxic breathing). However, signs of respiratory distress and hypoxemia are frequently vague. Even some severely hypoxemic foals may show only restlessness, considerable resistance, and struggling when being handled or restrained. Abnormal respiratory sounds (crackles or wheezes) may be heard on auscultation of ill foals. However, even normal foals may show crackles on the down lung after having remained in lateral recumbency for a prolonged period of time. Furthermore, foals with no auscultable abnormalities may still have extensive pulmonary disease.[300,301] Similar to other species, cyanosis is a sign of severe hypoxemia in foals. The arterial Pa_{O_2} (partial pressure of oxygen), however, must reach very low levels (35 to 45 mm Hg) before clinical cyanosis is observed. Approximately 5 g/dL of unoxygenated hemoglobin in the capillaries generates the dark-blue color that is appreciated as cyanosis in humans. Therefore severely anemic foals may never appear cyanotic even in the face of profound hypoxemia. Weakness, depression, anorexia, weak or absent suckle reflex, dehydration, and fever may also be noted in newborn foals with respiratory disease. Cough and nasal discharge are usually absent in the early stages of neonatal pulmonary disorders.[277] The older foal, on the other hand, will generally exhibit clinical signs that focus on the respiratory tract, such as abnormal auscultation of the lungs, nasal discharge, cough, fever, tachypnea, and increased respiratory effort.

Thoracic radiographs and arterial blood gas analysis are important in confirming the presence and evaluating the extent and distribution of foal pneumonia. Because radiographic findings may precede or lag behind alteration of respiratory function, repeated diagnostic imaging is recommended. A recent study documented that radiographic abnormalities involving the caudodorsal lung region were most common in neonatal foals admitted to a referral center.[302] Bedenice and colleagues showed that the presence of dyspnea, tachypnea, a fibrinogen concentration >400 mg/dL, systemic inflammatory response syndromes (SIRS), hypoxemia, or FPT in neonatal foals may be a predictor of underlying respiratory disease and should prompt an early radiographic evaluation of the thorax, even in the absence of other localizing clinical signs.[271,302] Thoracic ultrasonography has become a popular diagnostic tool for the assessment of equine lung and pleural disease and is particularly useful in determining the side(s) of the thorax affected, as well as the precise location of the lesion in most cases.[271]

Diagnostic sampling of the respiratory tract is less commonly performed in neonatal foals compared with older foals and adult horses. However, TBA, BAL, protected catheter brush (PCB), or protected aspiration catheter sampling (PAC) is important in stabilized patients, irrespective of age, to direct antimicrobial therapy and evaluate therapeutic efficacy. Lung biopsies are rarely performed and are limited to patients with chronic disease or suspected fungal pneumonia.[301]

31.8.3 Treatment

The treatment goals in dealing with bacterial pneumonia in either age-group are similar and directed at maintaining adequate gas exchange to ensure patient survival, limit progressive pulmonary damage, and ultimately eradicate infection. Long-term goals should aim to maintain optimal pulmonary function and conserve adult athletic performance. Specific treatment strategies for septic pneumonia may include goal-directed antimicrobial therapy, treatment of inflammation independent of antimicrobial therapy, respiratory therapy (oxygen therapy, ventilation, bronchodilation), and cardiovascular support.[300]

Broad-spectrum antimicrobial treatment, with consideration of the drugs' anticipated sensitivity and lung penetration, should be initiated before culture results are available. Third- or fourth-generation cephalosporins (ceftiofur and cefepime, respectively) show good penetration into lung tissues.[303] Alveolar delivery of antibiotics typically occurs via diffusion of a free, nonprotein-bound drug and is usually satisfactory if plasma concentrations and alveolar perfusion are adequate.[304] Aminoglycosides penetrate lung tissue at 10% to 45% of serum levels. However, the acidic environment of infected airways may reduce the drug's activity below levels sufficient to eradicate the offending bacteria in some cases.[305,306] Antibiotic therapy should not be discontinued prematurely in neonatal foals, because pulmonary infection is commonly well established before its diagnosis.[307]

31.8.4 Outcome

The survival of neonatal foals with septic pneumonia is contingent on the underlying disease conditions, a prompt diagnosis, and the cause and severity of lung dysfunction. Few studies have objectively evaluated the outcome of foal pneumonia.[300] One report documented that 65% of foals with radiographic evidence of pulmonary disease were discharged alive from the hospital, in contrast to 86% survival of foals without respiratory illness. The presence of diffuse radiographic infiltrates (caudodorsal, caudoventral, and cranioventral lung involvement) or concurrent alveolar patterns within the caudodorsal and caudoventral lung indicated lower

survival rates.[271] Pneumonia is also one of the greatest causes of morbidity and mortality in foals greater than 1 month of age.[269]

The long-term effect on athletic performance has thus far been evaluated only in older foals that survived *rhodococcus* pneumonia. *R. equi* infection in foals was associated with a decreased chance of racing as adults. However, the performance of foals that went on to race was not significantly different from that of the general U.S. racing population.[308] It remains speculative whether severe equine neonatal pneumonia will most likely limit future peak athletic performance. Human studies have shown that many hosts develop long-lasting or permanent lung changes after recovery from neonatal pneumonia, which may significantly affect the quality of life and susceptibility to later infections. Case-based evaluations in horses have demonstrated that functional and structural pulmonary abnormalities may occur in survivors of severe neonatal pneumonia. However, the clinical significance of this finding currently remains unclear.

31.9 FUNGAL INFECTIONS OF THE EQUINE RESPIRATORY TRACT

ALLISON J. STEWART

31.9.1 Definition and Etiology

Fungi are eukaryotic organisms with a definitive cell wall made up of chitins, glucans, and mannans. Within the fungal cell wall, the plasma membrane contains ergosterol, a cell membrane sterol that is frequently targeted by antifungal agents. There are over 70,000 species of fungi, but only 50 species are known to cause disease in people or animals. Pathogenic fungi can be divided into three groups: multinucleate septate filamentous fungi, nonseptate filamentous fungi, and yeasts. Dimorphic fungi are able to interchange between forms depending on environmental conditions. Examples of dimorphic organisms include *Blastomyces dermatitidis, Histoplasma capsulatum*, and *Coccidioides immitis*, which exist in yeast form in vertebrate host tissue and in hyphal or mycelial form in vitro. In soil and decaying matter, the mycelial form usually is present and is composed of a collection of hyphae. The mycelia produce infective spores that are capable of inoculating vertebrate tissue.

522
523

Fungal infections in horses are relatively uncommon, although geographic prevalence is highly variable. Fungi are ubiquitous, and their constant aerosol exposure to respiratory tissue is inevitable. Upper respiratory and pulmonary disease caused by fungi is frequently acquired by the inhalation route, with the sporular diameter small enough to allow penetration into the distal airways and alveoli. In most samples of stable air, more than 90% of particles visible under a light microscope are spores of fungi or actinomycetes.[309] One study found that if a horse stood quietly in its stable without access to hay, the mean concentration of dust was very low (approximately 12 particles per cubic centimeter [of particles less than 5 mm in diameter]). When the bedding was disturbed during the normal "bedding down" operation, the concentration of respirable dust increased sixfold.[310] Systemic fungal infections and some cases of fungal pneumonia are thought to arise through a compromised GI tract, by inhalation, or via open wounds.

Tissue invasion of pulmonary tissue usually occurs in the immunocompromised host, although on occasion the normal individual may be affected. Important predisposing factors for fungal pneumonia include (1) qualitative and especially quantitative granulocyte abnormalities and (2) the presence of devitalized tissue. In most cases of upper respiratory tract fungal granuloma, there are no obvious predisposing causes.

Primary pathogenic fungi such as *B. dermatitidis, H. capsulatum, C. immitis, Cryptococcus neoformans*, and *Conidiobolus coronatus* usually infect immunologically normal horses. However, in a report of cryptococcosis in

seven horses, five had a history of illness that may have predisposed them to cryptococcosis.[311] A separate group of fungal pathogens tend to infect only those equine patients with abnormal host defenses. Opportunistic fungi including *Aspergillus* species, *Candida* species, *Fusarium* species, *Emmonsia crescens*, and *P. carinii* have caused fungal disease in horses that are immunocompromised or neutropenic; have neoplasia, colitis, enteritis, or bacterial pneumonia; or have been treated with corticosteroids.[312–323] In vitro studies support the critical role of phagocytic cells in host defense against opportunistic fungi.

31.9.2 Clinical Signs

Mycotic granulomas have been found in the nasal passages, paranasal sinuses, nasopharynx, guttural pouch, trachea, bronchioles, lungs, and mediastinum of infected horses. The most common clinical signs of upper respiratory fungal infection include unilateral or bilateral serosanguineous or mucopurulent nasal discharge, as well as inspiratory or expiratory noise. Other clinical signs include coughing, facial deformation, and dyspnea caused by partial blockage of nasal passages by granulomatous masses. Differential diagnoses for fungal granulomas of the respiratory tract include ethmoidal hematoma, squamous cell carcinoma, amyloidosis, and exuberant granulation tissue.

Fungal plaques in the guttural pouch often are located over the arterial blood supply. Horses with guttural pouch mycosis usually have episodic serosanguineous nasal discharge that may progress to potentially fatal epistaxis if there is erosion into an artery. The duration of clinical signs can vary from days to many months. Guttural pouch mycosis is discussed in detail elsewhere.

Pulmonary fungal infections causing granulomas, diffuse pneumonia, or pleuropneumonia can manifest with signs similar to those of bacterial infection. There may be cough, nasal discharge, tachypnea, respiratory distress, hemoptysis, and, if chronic, weight loss. Radiographic appearance of fungal pneumonia may reveal virtually any infiltrative pattern. Although miliary patterns are occasionally seen, the most common initial finding is a patchy bronchopneumonia. Multiple focal sites are common, and lesions tend to be peripheral in distribution. Differential diagnoses include bacterial pneumonia, recurrent airway obstructive disease, silicosis, granulomatous disease complex, or neoplasia.

Systemic infections can have variable clinical signs dependent on the location and extent of the infection. Fungal infections can affect multiple organ systems and body cavities. Weight loss, colic, or diarrhea can often occur with infection within the abdominal cavity.

31.9.3 Diagnostic Sampling

Lesions in the nasal passages, nasopharynx, guttural pouch, trachea, and bronchioles usually can be observed directly during endoscopic examination. Masses in lungs and paranasal sinuses may be observed radiographically. CT or MRI provides detailed imaging of the equine skull and can be used to determine the extent of lesions and bony invasion. An 8- to 20-mm trephine* can be drilled into the nasal or maxillary sinus; a sterile rigid arthroscope or flexible endoscope can then be passed through the trephine to directly view some lesions within the paranasal sinuses.

For nasal and nasopharyngeal lesions, specimens for cytology, histopathology, and culture can be obtained by use of endoscopically guided biopsy instruments; however, these samples tend to be small, superficial, and often nondiagnostic. Mucosal contaminants may overgrow the organism of interest. Larger biopsy samples from the nasal passages or nasopharynx often can be obtained by use of a uterine biopsy instrument† passed nasally with

visual guidance from a flexible endoscope. Excisional biopsy or surgical debulking may be performed through a sinus flap or via laryngotomy.

Fungal pneumonia may be diagnosed from samples obtained by tracheal wash or BAL or via a lung biopsy (Fig. 31-17). Lung biopsy is associated with significant risk if a pulmonary vessel is accidentally biopsied. The biopsy should be performed ideally after radiographic evaluation or with concurrent ultrasound guidance, and the sample should be obtained from the periphery of the lung; however, some horses have experienced fatal hemorrhage associated with biopsy of a vessel only 2 cm from the periphery. The lung is rich in plasminogen, so bleeding complications may be severe. Spring-loaded biopsy needles‡ are safer for lung biopsy than Tru-Cut biopsy instruments.[324] Ultrasound evaluation can be used to monitor for bleeding after the procedure.

523

524

Fig. 31-17 Percutaneous lung biopsy from caudal periphery of lung of a weanling foal.

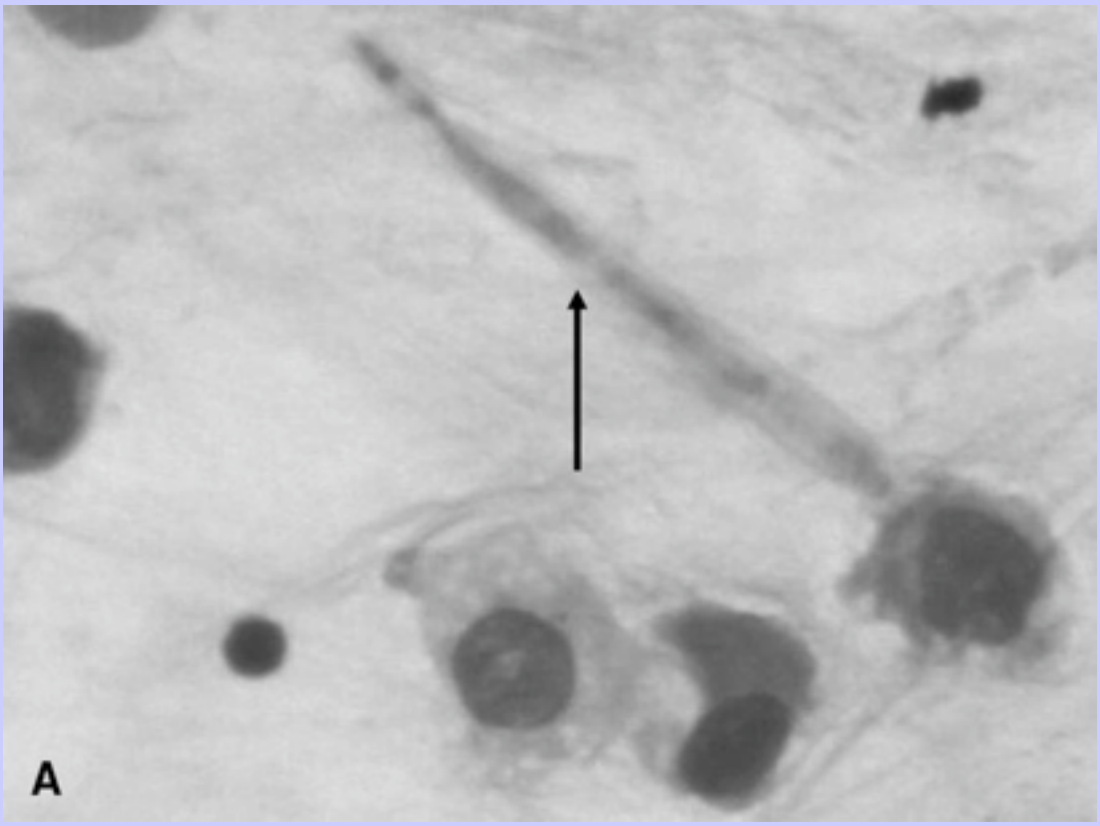
31.9.3.1

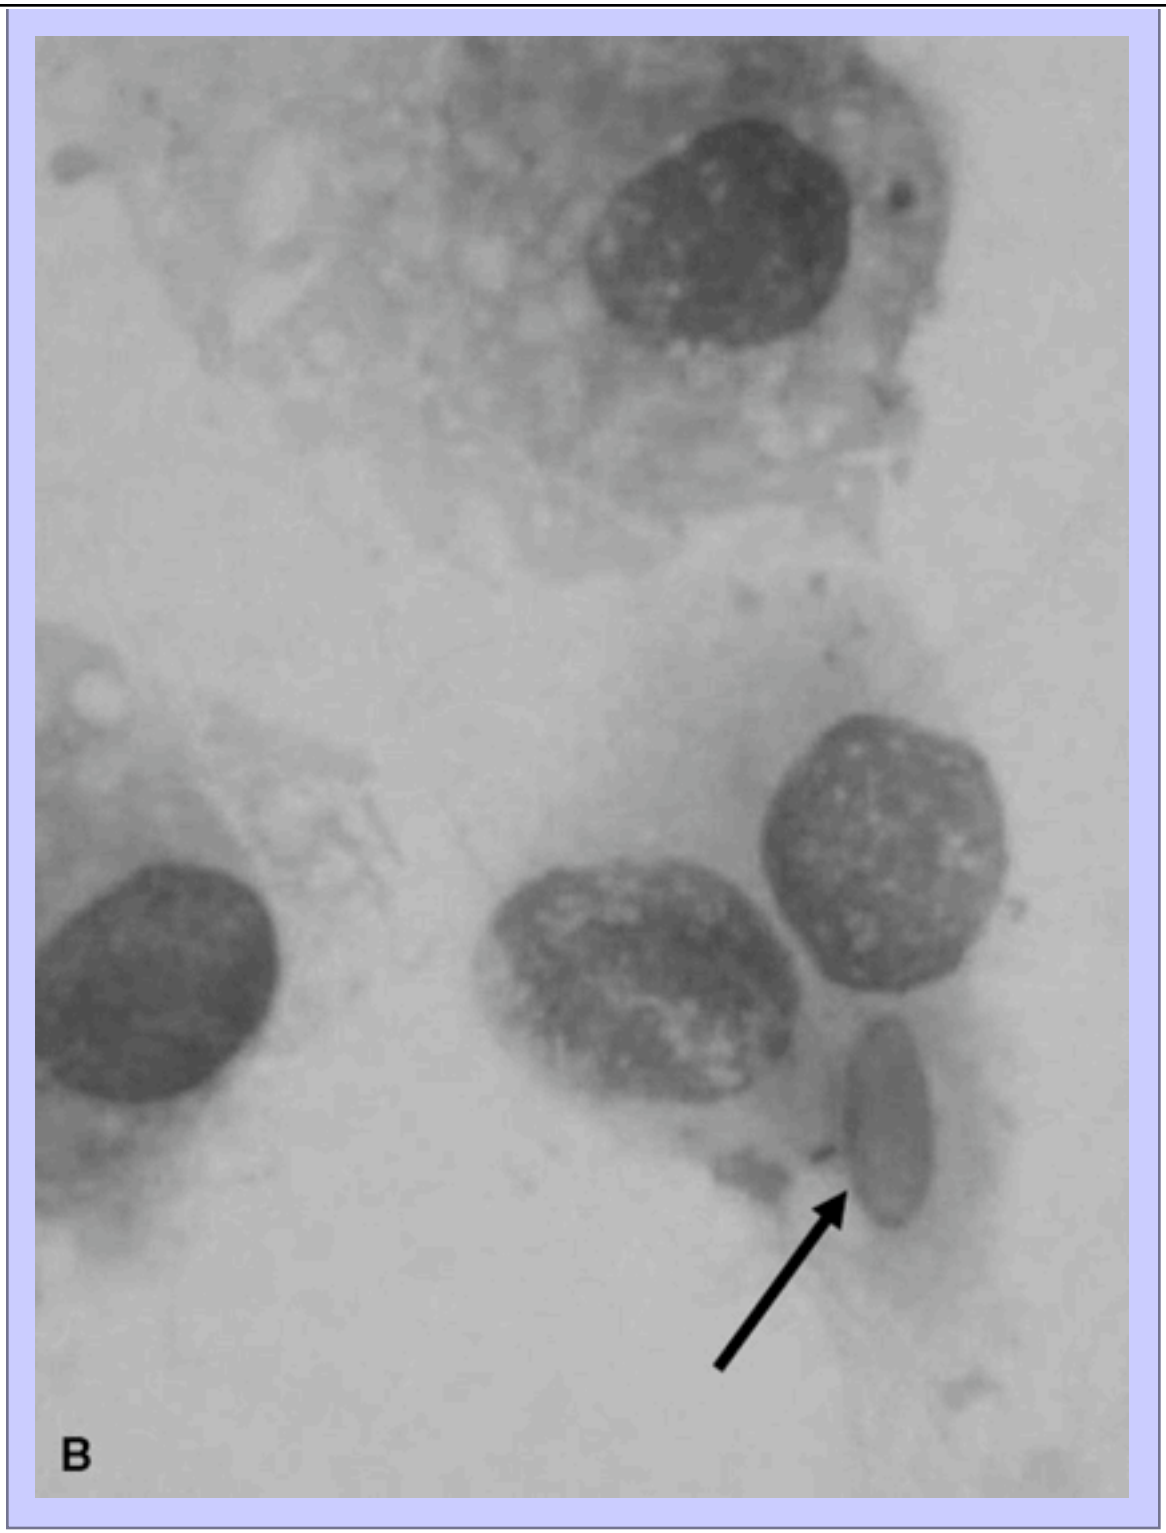
CYTOLOGY

Fungal hyphae may be identified in airway fluid or in impression smears obtained from biopsied masses. Clinicians must be careful in attributing significance to the presence of fungal elements in a TTA. Fungal hyphae are often present either free or in large mononuclear cells in tracheal aspirates from healthy horses.[90] A study of healthy thoroughbred racehorses showed that 70% had fungal elements detected in their tracheal

aspirates.[92] None of the horses from either study had other evidence of fungal pneumonia. Barn fungus such as *Alternaria* species are nonpathogenic and rarely incite an inflammatory response in the host. The organisms often have a blocklike appearance and may be colored (Fig. 31-18, *A* and *B*). A normal predominance of macrophages, lymphocytes, and nondegenerate neutrophils (<5% to 10%) would be expected.

Fig. 31-18 *Alternaria* species from transtracheal wash specimens obtained from healthy horses. **A**, An extracellular spore *(arrow)* with several macrophages, squamous cell (indicative of pharyngeal contamination. **B**, Intracellular spores *(arrow)* within binucleated macrophage. Courtesy Elizabeth Welles, Auburn University, Ala.





To be significant cytologically, large numbers of fungi should be involved in the inflammatory process within the lung. With fungal pneumonia, aspirates may contain predominately neutrophils that often are degenerate and may contain intracellular fungal hyphae. If processing of the sample is delayed, extracellular fungi may be

phagocytized, which confuses the interpretation. Some fungi have characteristic morphologic features that can permit an early presumptive identification (Table 31-5).

* Michelle 8-mm trephine or 14- to 20-mm Galt trephine, Jorgensen Laboratories, Inc., Loveland, Colo.

† Jorgensen Laboratories, Inc., Loveland, Colo.

‡ 4-g × 20-cm biopsy needle, Temno Products Group International, Lyons, Colo., or Magnum biopsy needle.

31.9.3.2

HISTOPATHOLOGY

Hyphae of certain fungi may be poorly visualized when routine hemotoxylin and eosin (H&E) stains are used; therefore special stains such as periodic acid Schiff (PAS), Gridley's fungus, and Grocott-Gomori methenamine-silver nitrate (GMS) can be useful to stain histopathologic specimens. With chronicity, there is often evidence of extensive fibrosis.

31.9.3.3

MICROBIOLOGIC CULTURE

Fungi can be found in tracheal aspirates from healthy horses. Sixteen percent of healthy horses are reported to have fungal growth on the tracheal aspirate bacterial culture plates; therefore results of fungal culture must be interpreted with caution.[91] Some fungi have fastidious growth requirements. They may be outcompeted by contaminant bacteria and may take up to several weeks to grow on culture media. For transport of tissue for microbiologic culture, the sample should be placed in a prepared culture medium* and transported at room temperature. Specific culture media such as Sabouraud's dextrose agar,† inhibitory mold agar, and Mycobiotic agar containing cycloheximide and chloramphenicol are useful.

524

526

Table 31-5 Characteristic Morphologic Features and Availability of Serologic Tests for Fungal Organisms Reported to Cause Fungal Granulomas in Horses (September 2006)

	Cytologic Appearance	Serologic Test	
Agent	**Tissue Form**	**Method**	**Veterinary Laboratory***
Cryptococcus neoformans	Round, thin-walled, yeastlike fungus (51–10 µm) with a large heteropolysaccharide capsule (1–30 µm in diameter) that does not take up common cytologic stains. Capsule is best stained using Mayer's mucicarmine stain. Organisms show narrow-based budding and lack endospores.	Capsular antigen ELISA (antigen) Latex agglutination (antigen)[331]	$30.00 UT $12.50 CU $20.00 CSU $16.00 UGA $18.00 NMDA
Conidiobolus coronatus	Broad, thin-walled highly septate, irregularly branched hyphae (5–13 µm in diameter).[356] Often surrounded by acidophilic staining glycoprotein antigen-antibody complex known as Splendore-Hoeppli material.	Immunodiffusion is highly sensitive and specific; decreasing titer correlated to disease resolution in horses[354,358]	Serologic testing not widely available
Pseudallescheria boydii	Hyaline, nonpigmented, septate, randomly branched hyphae (2–5 µm in diameter) with regular hyphal contours. Asexual form has nonbranching conidiophores with terminal conidia. Sexual form in culture has cleistothecium (large round body) and ascospores.[347]		
Coccidioides immitis	Spherules have a double-contoured wall, are variable in size, but can be large (20–80 µm, up to 200 µm). The mature spherules (sporangia) contain endospores (sporangiospores) 2–5 µm in diameter. In the environment, mycelium are thick-walled with barrel shaped arthroconidia.	AGID (antibody) for IgM and IgG[332,375] CF (antibody)[375,379,385] May have some false-positive results[378]	$15.00 UT $12.00 CSU $8.00 NMDA $12.00 NMDA $12.50 CU

Aspergillus species	Broad (2–4 µm diameter) septate hyphae with parallel sides and acute right angled branching.	*Aspergillus* galactomannan EIA (sandwich immunoassay) Some reactivity to *Penicillium*, *Alternaria*, and *Paecilomyces* AGID (antibody) *Aspergillus fumigatus* only	Platelia *Aspergillus* antigen EIA by MDL $15.00 UT $12.50 CU
Blastomyces dermatitidis	Yeasts are spherical (15–17µm in diameter) with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic. Yeasts are often located within multinucleated giant cells.	AGID (Antibody)[328]	$15.00 UT $12.50 CU
Histoplasma capsulatum	Yeasts (2–4 µm in diameter) have a thin clear halo surrounding a round or crescent- shaped basophilic cytoplasm.	AGID (Antibody)[374]	$15.00 UT $12.00 CSU $12.50 CU
Acremonium strictum	Mononuclear cells contain single, spherical, intracytoplasmic encapsulated spores 3–5 µm in diameter[313]		
Candida species	Ovoid budding yeast cells (2–4 µm in diameter) with thin walls or can occur in chains that produce septate pseudohyphae when blastospores remain attached after budding division. Filamentous, regular, true hyphae also may be visible.		
Pneumocystis carinii	Trophozoite (yeast form), ameboid (2–5 µm in diameter) with filopodia that attach to the surface of type I pneumocytes. Sporangia (cystic form) are encapsulated spores (4–6 µm in diameter) containing eight uninuclete spores (intracytic bodies).[322,323,325,383]

31.9.3.4 MOLECULAR TECHNIQUES

Serologic tests that use immunodiffusion, radioimmunoassays, complement fixation, and ELISA are available to detect circulating antibodies against several fungal organisms (Table 31-6). These titers often decrease with resolution of disease; therefore repeated measurements can be used to help monitor response to treatment. IHC,[318,325–327] fluorescent in situ hybridization,[326] and DNA probes[328] can be used to positively diagnose fungal organisms in histopathogy sections. A panfungal real-time PCR assay‡ can be used to detect a variety of fungal organisms in body fluids and fungal isolates, followed by species-specific real-time PCR assay to positively identify the organism.[313]

‡ University of California Davis, Calif.

31.9.3.5 IMMUNE FUNCTION TESTING

Several fungal infections have been associated with host immunosuppression caused by severe malnutrition, congenital immunodeficiency, or acquired immunodeficiency.[321–323] Blood can be tested for immunoglobulin quantification by radial immunodiffusion§ and lymphocyte subpopulation phenotyping via flow cytometry.‖,[323,329]

§ Cornell University, Ithaca, NY.

‖ Kansas State University, Manhattan, Kans.

31.9.4 Treatment

Treatment of fungal granulomas of the upper respiratory tract may involve surgical options (debulking, laser therapy, or cryotherapy) and/or medical therapy (systemic, topical, or intralesional). Treatment of *Aspergillis* species pneumonia is usually frustrating, as diagnosis is often made late in the course of disease and the horse frequently has severe underlying illness. Successful therapy has been reported for fungal pneumonia with other causes.[313,330–333] Several pharmacokinetic studies on antifungal drugs have been recently performed,[334–337] and as these medications become more affordable, the success rate of therapy is likely to increase. The drug of choice depends on the site of infection, the fungus involved, and the financial resources of the owner. Specific antifungal agents used in horses have been recently reviewed.[338] Therapy may not be attempted because of the severity of the primary disease, expense, or poor prognosis.

Prevention of invasive fungal pneumonia is difficult. It is impossible for the horse to avoid large inhaled inocula, given its environmental conditions. Improving ventilation and minimizing exposure to inspired spores are most beneficial in immunocompromised patients. At present the most important methods of disease prevention are treating predisposing illnesses promptly and effectively and judiciously avoiding overuse of corticosteroids and broad-spectrum antibiotics.

Table 31-6 Pharmacokinetic Studies of Antifungal Drugs Performed in Horses

Drug and Relative Cost	Dosage	Source	Susceptible Organisms, Equine Reports, Comments
Ketoconazole $ = Moderate	30 mg/kg q12h mixed with 0.2 NHCl via nasogastric intubation[333]	LW Tablets (200 mg) (Nizoral, Janssen)	*Scopulariopsis*,[334] *Coccidioides, Cryptococcus, Candida, Malassezia, Histoplasma, Sporthrix, Microsporum, Trichophyton*.
Itraconazole $ = Very expensive	5 mg/kg/day solution PO[336] (bioavailability 60%, compared with 12% for capsules)	Sporonox solution (10 mg/mL oral or injectable solution) Sporanox capsules (100 mg) (Janssen)	*Aspergillus*,[348,369] *Histoplasma, Bastomyces, Coccidioides*,[381] *Cryptococcus, Candida*, Paracoccidia, *Paecilomyces, Scopulariopsis, Sporothrix, Alternaria, Sporotrichum, Prototheca*. Not active against *Fusarium, Mucor, Rhizopus*. Very unstable and lipophilic, therefore compounded substances are not recommended.
Fluconazole $ = Moderate	14 mg/kg PO loading dose followed by 5 mg/kg/day PO[335]	LW Injectable solution (2 mg/mL) (Pfizer, Bedford Labs) Tablets (200 mg) (Pfizer) Generic available Powder (100 g) (Spectrum Chemicals)	*Histoplasma, Bastomyces, Coccidioides*,[332] *Cryptococcus, Mucor, Rhizopus, Candida*,[320] *Conidiobolomycosis*,[360] *Parracoccidia, Paecilomyces, Scopulariopsis, Sporothrix, Alternaria, Sporotrichum, Prototheca*. Minimal activity against *Aspergillus* and *Fusarium*.
Voriconazole $ = Very expensive	4 mg/kg/day PO[336]	Vfend (Pfizer, Bedford Labs) Tablets (200 mg)	Drug of choice for invasive *Aspergillus, Candida, Cryptococcus, Scedosporium apiospermum*, and *Fusarium* species in human patients who are unable to tolerate or are refractory to other therapeutic agents.

LW, Local wholesaler; *PO*, by mouth.

31.9.5 ANTIFUNGAL THERAPEUTICS (Table 31-7)

31.9.5.1 Amphotericin B

Amphotericin B deoxycholate is a polyene antibiotic that combines with ergosterol in the fungal cell membrane, resulting in an increase in cell permeability. IV amphotericin B can cause nephrotoxicity and phlebitis. Other possible side effects include anorexia, anemia, cardiac arrhythmias, hepatic and renal dysfunction, and hypersensitivity reactions.[339] Amphotericin B also been used successfully to treat histoplasmosis and pulmonary aspergillosis and cryptococcosis.[330,331,340] A high dose of oral amphotericin B successfully treated mucormycosis caused by *Absidia corymbifera*.[341] Topical amphotericin B has been successful in treatment of nasopharyngeal *C. coronatus*.[342–345]

31.9.5.2

Azoles

Benzimidazole derivatives in the class azoles, such as miconazole, enilconazole, ketoconazole, itraconazole, fluconazole, and voriconazole, destroy fungi by inhibition of ergosterol biosynthesis in the fungal cell membrane. Azole antifungals inhibit cytochrome P450-dependent 14α–sterol demethylase, which is essential for the formation of ergosterol. Topical 2% miconazole was used in the resolution of four cases of guttural pouch mycosis[346] and as part of successful multimodal therapy against nasopharyngeal *Pseudallescheria boydii*.[347] Enilconazole is not commercially available in the United States but has been used topically in the successful treatment of guttural pouch mycosis.[348–350] Aerosolization of 1.2 mg of enilconazole per kilogram q12h in 125 mL of saline resolved *Scopulariopsis* pneumonia.[333] Ketoconazole is absorbed poorly in the nonacidified form[334] but can be acidified for better absorption (30 mg/kg via NGT q12h mixed with 0.2 NHCl).[333]

526

527

Table 31-7 Treatment of Common Fungal Infections in Humans and Horses

Infection	Recommended Treatment in Humans[386]	Treatments Tried in Horses	Comments
Cryptococcosis	Induction with amphotericin B 0.7–1 mg/kg, plus 5-fluorocytosine 100 mg/kg/day for 2 weeks then consolidation with fluconazole 400 mg/day for >10 weeks.	Daily infusions of amphotericin B (initially 0.35 mg/kg, increasing over 8 days to 0.5 mg/kg in 1 L 5% dextrose in water over 1 hr IV for 1 month) successfully used to treat pulmonary cryptococcosis. Flunixin meglumine (0.25 mg/kg IV) was administered before each treatment.[331]	Reported doses range from 0.3–0.9 mg/kg in saline IV over 1 hr.
Histoplasmosis	Amphotericin B 0.7–1 mg/kg/day for 2 weeks, then itraconazole 200 mg-400 mg/day for 4–18 months.	Successful treatment of histoplasmosis in a filly using amphotericin B (0.3–0.6 mg/kg eod IV infused over 1 hr) with a total cumulative dose of 6.75 mg/kg administered over a 1 month period. After each treatment the filly became lethargic for 18–24 hr. Polyuria and polydipsia occurred during the fourth week, but urine concentrating ability was maintained and azotemia did not occur.[330]	In vitro susceptibility to fluconazole is poor.
Blastomycosis	Amphotericin B 0.7–1 mg/kg/day to 1.5–2.5 g total or to 0.5 g total, then itraconazole 200–400 mg/day		
Aspergillosis(invasive pulmonary)	1. Voriconazole 200–400 mg PO q12h, 3–6 mg/kg IV q12h 2. Amphotericin B 1–1.5 mg/kg/day until desired response, then itraconazole 400 mg/day when disease progression slows		Fluconazole has limited efficacy.

Candidiasis	1. Amphotericin B 0.7–1 mg/kg/day for 2 weeks 2. Fluconazole 6 mg/kg for 2 weeks 3. Caspofungin 70 mg once, then 50 mg/day for 2 weeks 4. Voriconazole	Two foals were treated with intravenous amphotericin B for 8 days (total dose, 2.6 mg/kg) and 29 days (total dose, 10.3 mg/kg), respectively. Fluconazole 5.5 mg/kg PO q24h for 6 weeks and 4 mg/kg PO q24h for 28 days was used to treat two other foals.[320]	Fluconazole is generally considered the drug of choice against *Candida* species, although *Candida krusei* is resistant to fluconazole.
Pneumocystis	1. Trimethoprim-sulfamethoxazole 2. Pentamidine isethionate 3. Trimetrexate	Trimethoprim-sulfamethoxazole (TMS) (25–30 mg/kg POq12h) is the treatment of choice.[384] Dapsone*(3 mg/kg PO daily for 2 months) was used to successfully treat a foal with *Pneumocystis carinii* that developed *Salmonella* enterocolitis after treatment with TMS.[329]	Lacks ergosterol, therefore antifungals are not effective.

eod, Every other day; *IV*, intravenously; *PO*, by mouth.

* Jacobus Pharmaceutical Company, Inc., Princeton, NJ.

Itraconazole (Sporanox solution) is absorbed well orally (bioavailability 60%). A dose of 5 mg/kg PO q24h maintains concentrations above MIC for susceptible yeasts (*Histoplasma* and *Blastomyces* species) and *Aspergillus* species, with no detectable side effects.[336] The use of compounded itraconazole is not recommended. It is very unstable (requires low pH), and owing to its lipophilic nature it is difficult to formulate in aqueous solution.

Oral fluconazole at a loading dose of 14 mg/kg followed by 5 mg/kg every 24 hours yields concentrations in plasma, cerebrospinal fluid (CSF), synovial fluid, aqueous humor, and urine above the MIC reported for several equine fungal pathogens.[335] Fluconazole, however, reportedly has minimal activity against filamentous fungi (*Aspergillus* and *Fusarium* species). Low-dose oral fluconazole (1 mg/kg PO q24h) for at least 10 to 15 days anecdotally has been successful in treatment of fungal keratitis. Compounded fluconazole formulations are very stable. The cost of fluconazole has been markedly reduced since generic products became available.

527

528

Voriconazole, a new broad-spectrum triazole antifungal agent, was approved for use in human medicine in 2002. It is now considered the drug of choice for initial treatment of invasive aspergillosis, candidiasis, cryptococcosis, and serious fungal infections caused by *Scedosporium apiospermum* and *Fusarium* species in patients that are unable to tolerate or are refractory to other therapeutic agents.[351,352] An initial single-dose pharmacokinetic study in horses recommended a dose of 4 mg/kg PO q24h.[337] Multiple dosing studies are still required owing to the potential for drug accumulation.

31.9.6 SYSTEMIC IODIDE THERAPY

The exact mode of action of iodides is unknown; however, they seem to have a beneficial effect on the granulomatous inflammatory process. Iodides have very little, if any, direct in vitro antibiotic effect.[353] Although several successful cases in which iodides were used as primary or adjunctive therapy have been reported, overall efficacy is considered limited at best. Treatment is inexpensive, but toxicity and resistance can occur. Iodide toxicity is characterized by excessive lacrimation, nonproductive cough, increased respiratory secretions, and dermatitis.[354] The recommended dose of 20% sodium iodide is 20 to 40 mg/kg/day IV for 7 to 10 days.[342,345,354,355] Orally administered iodine is available in two forms. Inorganic potassium iodide (10 to 40 mg/kg/day) is available only as a chemical grade and is unstable in the presence of light, heat, and excessive humidity.[345,355] Organic ethylenediamine dihydriodide (EDDI) (0.86 to 1.72 mg of EDDI per kilogram, equivalent to 20 to 40 mg/kg/day of the 4.57% dextrose powdered form*) is commercially available.[355] Administration of iodine in the diet of pregnant mares may cause congenital hypothyroidism in foals and should be avoided.

* The Butler Company, Columbus, Ohio.

31.9.7 ETIOLOGIC AGENTS

31.9.7.1 Conidiobolomycosis

C. coronatus is a saprophytic fungus that causes granulomatous lesions of the upper respiratory tract in horses. Single to multiple granulomatous lesions in the nasal passages, trachea, or soft palate can be observed endoscopically (Fig. 31-19). Histologic appearance of conidiobolomycosis is similar to that of pythiosis and basidiobolomycosis. Hyphae of *C. coronatus* are thin-walled, highly septate, and irregularly branched (see Table 31-5).[356] The lesions typically have large numbers of eosinophils and fewer macrophages, neutrophils, plasma cells, and lymphocytes surrounding hyphae. Definitive diagnosis is based on microbiologic culture, immunodiffusion, or PCR.[357] Detection of serum antibodies by immunodiffusion is considered highly sensitive and specific[354,358] and can be used to monitor response to treatment.[358] A nested PCR *Pythium* assay has also been used to identify *C. coronatus*.[359]

Conidiobolomycosis lesions can be treated with surgical excision, laser therapy, cryotherapy, or long-term administration of iodides or antifungals.[342,354,357] Amphotericin B has been administered intralesionally or topically in combination with dimethyl sulfoxide (DMSO) to treat *C. coronatus*.[342–345] It is important to remember that long-term therapy and reevaluation are essential, as recurrence can occur.[345] Oral fluconazole was successful in treating two pregnant mares with nasal conidiobolomycosis.[360] A vaccine using *C. coronatus* antigen from broth cultures was unsuccessful in treating seven horses with conidiobolomycosis.[357]

31.9.7.2 Cryptococcosis

Cryptococcosis is caused by *C. neoformans* (var. *neoformans* and var. *gattii*) and is a ubiquitous, saprophytic, round, basidiomycetous yeastlike fungus with a large heteropolysaccharide capsule that does not take up common cytologic stains (see Table 31-5, Fig. 31-20). The capsule forms a clear halo when stained with India ink. The capsule is immunosuppressive and antiphagocytic. A relatively high frequency of equine

cryptococcosis occurs in Western Australia.[311] There is an epidemiologic relationship between *C. neoformans* var. *gattii* and the Australian river redgum tree *(Eucalyptus camaldulensis)*, whereas *C. neoformans* var. *neoformans* has historically been associated with bird (particularly pigeon) excreta.[311] Cytologic or histopathologic identification is very reliable for diagnosis because of the characteristic morphology.[361] Serologic testing with latex agglutination to identify cryptococcal capsular antigen is useful with resolution of lesions correlated with declining serum titers.[331]

Fig. 31-19 Endoscopic image of mycotic granulomas caused by *Conidiobolus coronatus* in the nasopharynx of a horse.

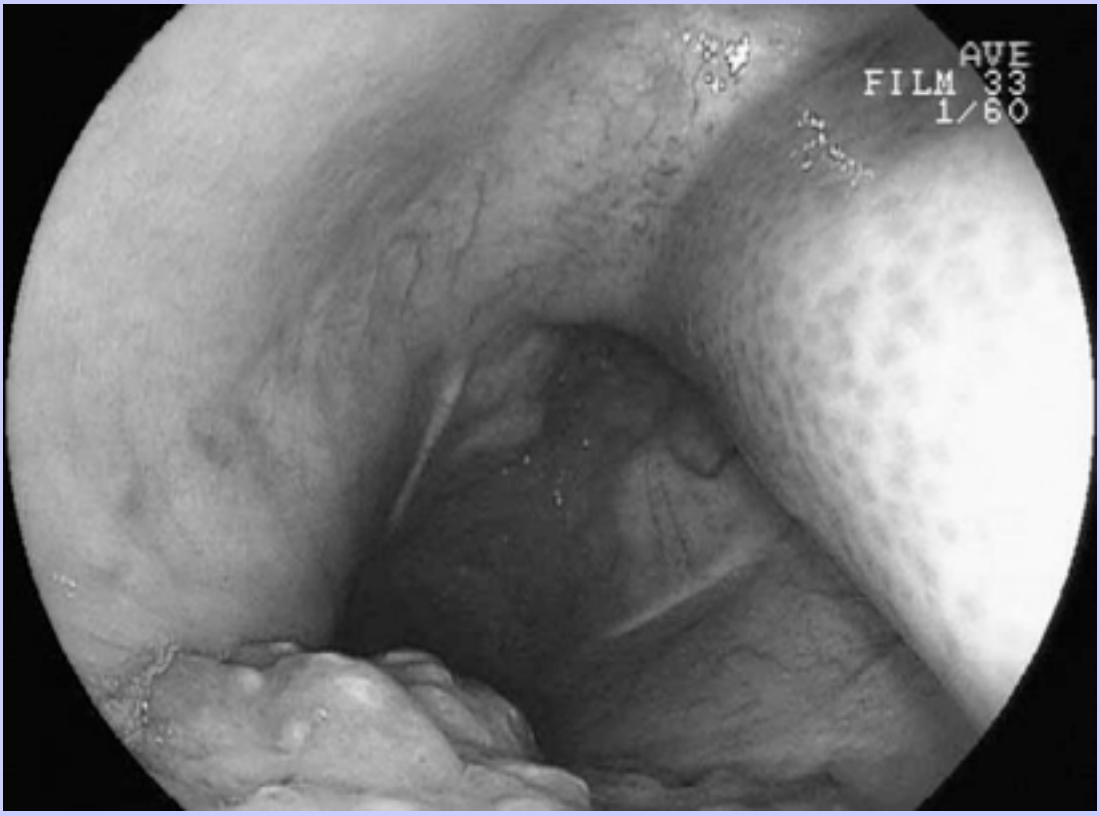

Fig. 31-20 Photomicrographs of an impression smear from a biopsy of a mass in the nasal passage of a horse. The smear is extremely cellular, with abundant neutrophils and macrophages. Round yeast cells with large nonstaining capsules and occasional narrow-based budding consistent with cryptococcal organisms *(arrow)* are shown. (Modified Wright stain ×100.) Courtesy Elizabeth Welles, Auburn University, Auburn, Ala.

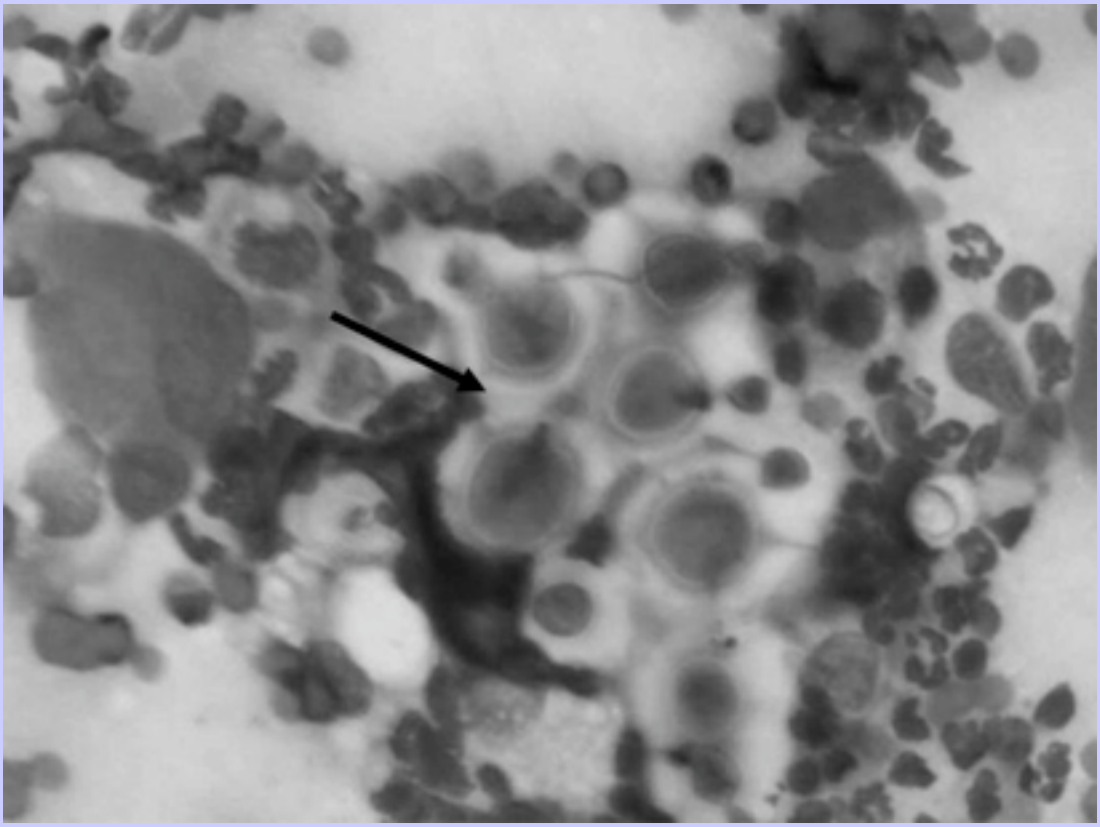
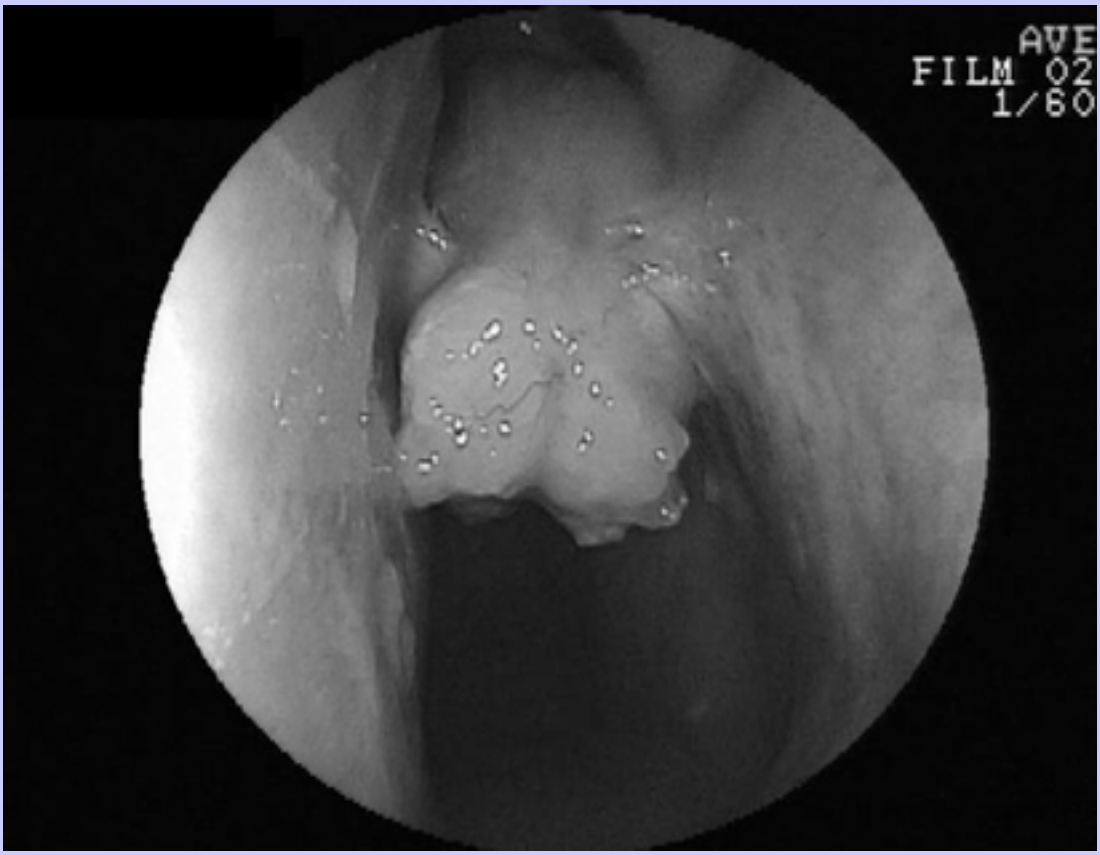


Cryptococcosis in horses is associated primarily with pneumonia, rhinitis (Fig. 31-21), meningitis, and abortion. Successful medical treatment, however, has been reported rarely. Surgical removal of a localized jejunal lesion was successful in one horse.[362] A pony with multiple pulmonary cryptococcomas, from which *Cryptococcus gattii* was cultured from both transtracheal washings and lung mass aspirates, was treated successfully with daily infusions of amphotericin B over 1 month. One year after cessation of treatment, clinical signs had resolved and the cryptococcal antigen titer had decreased from 4096 to 256.[331]

528

529

Fig. 31-21 Endoscopic image of a cryptococcus granuloma in the nasal passages of a horse.



Cryptococcus should be treated with amphotericin B, fluconazole, or voriconazole (see Table 31-7).

31.9.7.3

Pseudallescheriosis

P. boydii is a saprophytic ascomycete. Infection most commonly involves the extremities, and in human patients it is known as Madura foot. Hyphae within tissue cannot be differentiated from *Fusarium* or *Aspergillus* species unless cultured. *P. boydii* cultured from the nasal cavity and sinus of a horse with chronic, malodorous nasal discharge was susceptible in vitro to miconazole, ketoconazole, natamycin, and clotrimazole. After debridement and flushing of the plaque, miconazole cream was infused twice daily for 4 weeks through lavage tubing that had been passed into the nasal passage through a hole drilled in the frontal bone and sinuses. Adjunctive iodide therapy was also administered, and the lesions resolved (Fig. 31-22).[347]

Nasal mycosis caused by *P. boydii* has been reported in two other horses, both of which were euthanized.[363,364] *P. boydii* has also been isolated from the pharynx of 2 of 60 normal donkeys and from horses with chronic uterine infection.[365,366]

31.9.7.4

Aspergillosis

Aspergillus species have broad septate hyphae with parallel sides and acute right-angled branching (see Table 31-5). They have a propensity for vascular invasion. Definitive diagnosis is by culture or staining by IHC or immunofluorescence. *Aspergillus* species are very common in the environment, especially in moldy feed and bedding.[340] They are opportunistic pathogens and often cause disease in horses that are immunosuppressed from debilitating disease such as enterocolitis, septicemia, neoplasia, Cushing's disease, or equine protozoal myeloencephalitis or because of surgery or that have been treated with immunosuppressive drugs[312,314,316–318] (Fig. 31-23).

Infection is by inhalation of an overwhelming number of spores resulting in fungal proliferation and invasion of the small airways, or by translocation of organisms across an inflamed GI tract leading to lesions centered around large blood vessels as a result of hematogenous spread. In two retrospective studies of invasive pulmonary aspergillosis, 41 of 49 cases were associated with enterocolitis.[312,314] *Aspergillus* species pneumonia is almost uniformly fatal, often with no or mild respiratory signs. Antemortem diagnosis of pulmonary aspergillosis is made rarely. In a retrospective study of 30 cases of *Aspergillus* species pneumonia, only two cases were diagnosed or suspected antemortem.[314] TTA or BAL may not be helpful because hyphae and spores are often present extracellularly or within macrophages in aspirates and lavages from healthy animals.[312] False-negative results also can occur. Cytologic examination of a transtracheal wash specimen obtained from the foal shown in Fig. 31-23, *A*, 2 days before euthanasia failed to identify *Aspergillus* species hyphae. Serologic diagnosis occasionally has been useful[367] but is often unreliable because many horses have titers to *Aspergillus* species. Development of a commercially available ELISA is promising.[316,340]

In human medicine 50% to 90% of patients with invasive aspergillosis die despite treatment. Amphotericin B has been the mainstay of treatment for invasive aspergillus for decades but is associated with nephrotoxicity in about 50% of human patients. Nephrotoxicity is reduced using liposomal amphotericin B. Voriconazole, a new azole antifungal, is now considered the drug of choice against human aspergillosis, whereas caspofungin (in the new class of echinocandin antifungals) shows promising results in patients with refractory infections.[368] Oral itraconazole is currently the treatment of choice for aspergillosis in horses owing to a lack of pharmacokinetic analysis and safety testing and the costs associated with the newer antifungal agents.[336] In human medicine itraconazole has shown comparable response rates to amphotericin B.[368] There are limited reports of horses surviving pulmonary aspergillosis.[340]

Treatment of mycotic *aspergillus* rhinitis and sinusitis in horses has been more successful. It is, however, important to rule out concomitant invasive pulmonary aspergillosis. Oral itraconazole,[369] topical natamycin (flushed via an endoscope or indwelling catheter placed into the sinus), and nystatin powder (insufflated up the nostril) have been curative.[370]

31.9.7.5

Blastomycosis

Blastomycosis is caused by inhalation of conidiae of the thermally dimorphic saprophytic fungus *B. dermatitidis. Blastomyces* yeasts can be identified on cytologic examination, often within multinucleated giant cells. They are spheric, with basophilic protoplasm and unstained, uniformly shaped refractile walls. Unilateral, broad-based budding is characteristic (see Table 31-5).

Blastomycosis was reported to cause pyogranulomatous pleuropneumonia, pulmonary abscessation, peritonitis, and abscesses in a 5-year-old horse.[328] *B. dermatitidis* was positively identified from transtracheal wash fluid by use of a DNA probe, and serology was strongly positive. The horse was euthanized without treatment.[328] Disseminated blastomycosis was diagnosed in a miniature horse with SC infections associated with a chronic pectoral wound. The pony had pulmonary consolidation and pleural effusion. Yeasts were observed histologically in many tissues, and *B. dermatitidis* was cultured after 6 weeks.[371]

Treatment with amphotericin B, itraconazole, or fluconazole is recommended (see Table 31-7).

31.9.7.6

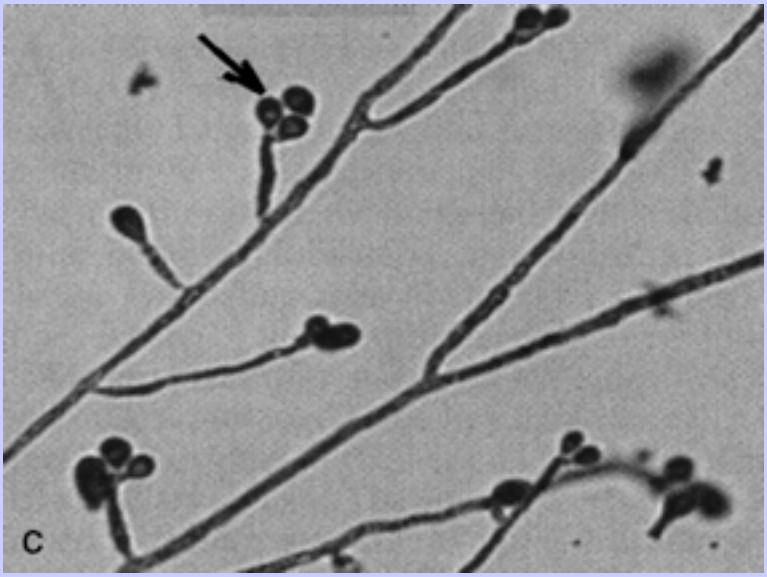
Histoplasmosis

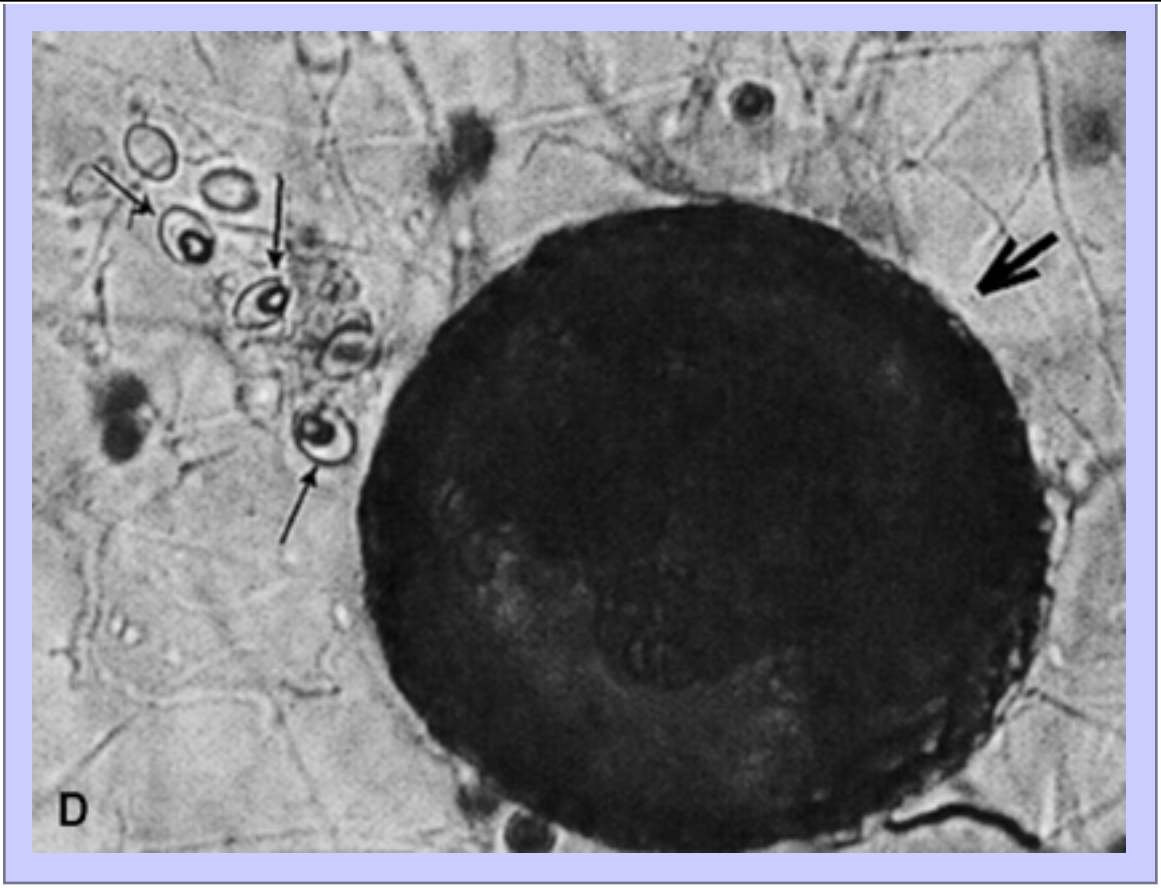
Histoplasmosis is caused by the saprophytic, dimorphic fungus *H. capsulatum*, which is most prevalent in moist soil containing bird or bat waste. Yeast organisms are 2 to 4 µm in diameter, with a thin clear halo surrounding a round or crescent-shaped basophilic cytoplasm (Fig. 31-24). Histoplasmosis has been reported in less than 10 equine cases,[330] and thus horses are considered to be relatively resistant to disease. *H. capsulatum* may occur in an enteric, pulmonary, or disseminated form.[330] *H. capsulatum* was identified in pulmonary granulomas in a horse dying of chronic *Yersinia* colitis[372] and in another horse with intestinal salmonellosis.[373] It has also been associated with abortions and severe granulomatous pneumonia in neonatal foals (Fig. 31-25) and a yearling.[374] Successful treatment with amphotericin B was reported in a filly with pulmonary histoplasmosis diagnosed by cytologic identification of the organism on a tracheal wash smear and from a lung aspirate.[330]

529

530

Courtesy R. Reid Hanson, Auburn University, Auburn, Ala.





Treatment with amphotericin B or itraconazole is recommended (see Table 31-7).

31.9.7.7 Coccidiomycosis

C. immitis is a soil saprophyte that grows in semiarid areas with sandy, alkaline soils.[375] Inhaled arthroconidia enlarge to form nonbudding spherules, which incite an inflammatory reaction in the lungs and lymph nodes.[375] Horses have weight loss, fever, abdominal pain, and signs of respiratory disease (Fig. 31-26). Localized, recurring nasal granulomas also have been reported.[376] Diffuse infections with granulomas in the lungs, liver, kidney, or spleen carry a grave prognosis.[375] Przewalskii horses may be more susceptible.[377]

C. immitis is difficult to culture, and spherules may not be observed histologically from antemortem lung biopsies. However, serology is very useful to diagnose infection, and decreasing titers are associated with clinical improvement.[332,375] Serum antibodies are detected rarely in healthy horses.[378] Antifungal agents successful in treatment of infected horses include itraconazole and fluconazole.[332,379]

31.9.7.8 Scopulariopsis

Scopulariopsis pneumonia was diagnosed by culture of BALF in a 2-year-old quarter horse filly with pleuropneumonia. The infection resolved after multimodal therapy with ketoconazole and aerosolization of enilconazole.[333]

31.9.7.9

Adiaspiromycosis

Adiaspiromycotic miliary fungal pneumonia caused by the saprophytic soil mold *E. crescens* was diagnosed in a horse by percutaneous lung biopsy. Euthanasia was performed without treatment.[319]

Fig. 31-23 One-month-old foal with *Escherichia coli* septicemia and secondary *Aspergillus* pneumonia. **A**, Dyspneic foal being supported with intranasal oxygen. The foal had eight septic joints and severe pneumonia and was subsequently euthanized owing to the guarded prognosis. **B**, Photomicrograph of the pleural surface of the lung *(black arrows)* with extensive superficial and deep fungal growth. *Aspergillus* species characteristically have parallel-sided, regular septate hyphae with acute-angled dichotomous branching. They are seen reasonably well with hemotoxylin and eosin stain. **C**,*Aspergillus* species hyphae within pulmonary parenchyma stained metachromatic with specific fungal stain (Gridley stain). 31.9.7.10

Acremonium Strictum

A diagnosis of interstitial fungal pneumonia caused by *Acremonium strictum* was made based on cytologic evaluation, culture, and PCR testing of BALF in a 10-year-old horse. The horse made an uneventful recovery with supportive treatment, which included 1 month of fluconazole.[313] In general, fluconazole has been shown to have poor activity against *A. strictum* in vitro.[380] The isolate cultured from the horse was found to be resistant to fluconazole based on in vitro sensitivity testing that was performed after the course of treatment. It is therefore uncertain if the fluconazole assisted in disease resolution.[313]

31.9.7.11

Candidiasis

In human medicine, candidemia is the most common fungal infection in burn patients, neutropenic patients with malignancies, patients undergoing complex abdominal surgery, and patients receiving total parenteral nutrition and long-term corticosteroid therapy.[368] In humans, *Candida* species account for 8% to 10% of all

blood culture isolates and rank fourth in the list of most frequently isolated pathogens from blood cultures.[368] The mortality in patients with candidemia is 40% to 75%.[368] Over 60% of isolates are *Candida albicans*.[368] Fluconazole is generally considered the drug of choice against *Candida* species, although *Candida krusei* is resistant to fluconazole. Itraconazole, amphotericin B, caspofungin, and voraconazole are alternative antifungal agents (see Table 31-7).[368]

Systemic candidiasis was diagnosed and successfully treated in four neonatal foals. Each foal had prior sepsis attributable to gram-negative bacteria that had been aggressively treated with numerous antibiotics and parenteral nutrition. *C. albicans* was cultured from a transtracheal wash from one of the foals. Three of the foals had *Candida* glossitis, and one had panophthalmitis and fungal keratitis. Two of the foals were treated with IV amphotericin B, and oral fluconazole was used on the other two foals.[320]

Superficial *Candida* species infections of the mucous membranes (thrush)[381] can occur in isolation or as part of a systemic infection, and further microbiologic culturing of the blood, tracheal wash, urine, or joint fluid may be indicated to rule out systemic infection.[320] *Candida* species glossitis can be treated by rinsing the mouth either with potassium permanganate (0.025% q24h) or nystatin (0.3 g in 10 mL of water q8h).

31.9.7.12 Pneumocystosis

532

P. carinii has been reclassified from a protozoan to a saprophytic fungus based on the DNA sequence of its 16S-like RNA subunit, but some researchers even consider it to be a plant because it lacks ergosterol, the major fungal sterol.[382] It exists as an ameboid yeast or as a cystic sporangia. *P. carinii* cannot be cultured, and diagnosis is based on the cytologic identification of characteristic morphologic features using specimens obtained by BAL rather than tracheal wash. A fluorescent in situ hybridization method with an oligonucleotide probe that targets the 18S ribosomal RNA has been developed recently to detect *P. carinii* in histologic sections.[326] IHC also can be used.[325]

533

Three quarters of human AIDS patients are infected with *P. carinii*, and people undergoing immunosuppressive therapy after organ transplantation are predisposed. *P. carinii* causes diffuse interstitial pneumonia, especially in immunocompromised patients such as Arabian foals with SCID.[321] It also has been diagnosed in immunocompromised adult horses,[322,323] as well as an immunocompetent foal.[325] TMS (25 to 30 mg/kg PO q12h) is the treatment of choice (see Table 31-5).[383,384] Dapsone* (3 mg/kg PO daily for 2 months) was used to successfully treat a foal that developed *Salmonella* enterocolitis after treatment with TMS.[329]

* Jacobus Pharmaceutical Company, Inc., Princeton, NJ.

31.10 *STREPTOCOCCUS EQUI* INFECTION (STRANGLES)

Corinne R. Sweeney

S. equi infections in horses, commonly referred to as *strangles*, was described in early veterinary science literature. Since described by Jordanus Ruffus in 1251, much has been learned about the disease and the organism that causes it.[387,388]

31.10.1 Clinical Signs

Strangles is characterized by sudden onset of fever followed by upper respiratory tract catarrh, as evidenced by mucopurulent nasal discharge (Fig. 31-27) and acute swelling with subsequent abscess formation in submandibular and retropharyngeal lymph nodes. The name *strangles* was coined because affected horses sometimes suffocated as the lymph nodes became enlarged and obstructed the airway. Clinical severity varies greatly depending on the immune status of the animal.

Fever is the first clinical sign and is maintained as lymphadenopathy develops and abscesses mature. Pharyngitis makes swallowing painful, and affected animals may become anorectic or reluctant to eat and stand with the neck extended.

Lymphadenopathy is a major clinical sign. The submandibular and retropharyngeal lymph nodes are about equally involved in *S. equi* infections. They usually become swollen and painful approximately 1 week after infection. Other lymph nodes of the head region (parotid, cranial cervical, and retropharyngeal) are also frequently involved and may abscess (Fig. 31-28). Retropharyngeal lymph nodes may drain into and cause empyema of the guttural pouch (Fig. 31-29). Periorbital abscesses can cause marked swelling of the eyelids. Abscesses of the lymph nodes at the thoracic inlet can cause severe tracheal compression, asphyxia, and death.

31.10.2 Pathogenesis

S. equi enters via the mouth or nose and attaches to cells in the crypt of the lingual and palatine tonsils and to the follicular associated epithelium of the pharyngeal and tubal tonsils. There is no evidence of colonization before penetration. After a few hours the organism is difficult to detect on the mucosal surface but is visible within cells of the epithelium and subepithelial follicles. Translocation occurs in a few hours to the mandibular and suprapharyngeal lymph nodes that drain the pharyngeal and tonsillar region.

Fig. 31-27 Horse with bilateral thick purulent nasal discharge typical of strangles.

Fig. 31-28 Draining submandibular lymph node in a standardbred mare with strangles.

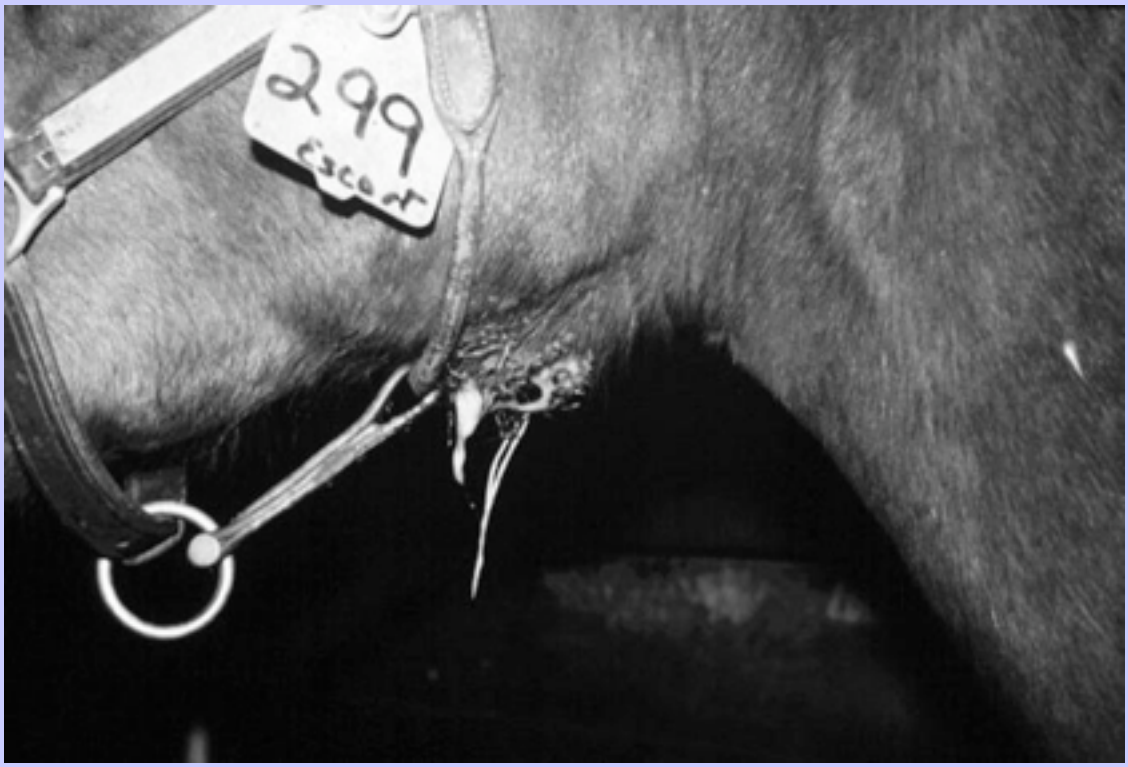

Fig. 31-29 Guttural pouch empyema with marked distention of the guttural pouch in a foal with strangles infection.

Complement-derived chemotactic factors attract large numbers of polymorphonuclear neutrophils (PMNs), although gross evidence of abscessation is not visible for 3 to 5 days after *S. equi* enters the lymph node. Failure of neutrophils to phagocytose and kill the streptococci appears to be a result of a combination of the hyaluronic acid capsule, antiphagocytic SeM protein, Mac protein, and other undetermined antiphagocytic factors released by the organism. 533 534

Although strangles predominantly involves the upper airways including the guttural pouches and associated lymph nodes, metastasis to other locations occasionally occurs. Spread may be hematogenous or via lymphatic channels, which results in abscesses in lymph nodes and other organs of the thorax and abdomen (Fig. 31-30). This form of the disease is known as *bastard strangles*.

Nasal shedding of *S. equi* usually begins 2 to 3 days after onset of fever and persists for 2 to 3 weeks in most animals. Some animals never shed. In others, shedding may persist much longer, should infection persist in the guttural pouch.[389,390] Systemic and mucosal immune responses are evident 2 to 3 weeks after infection and coincide with mucosal clearance.

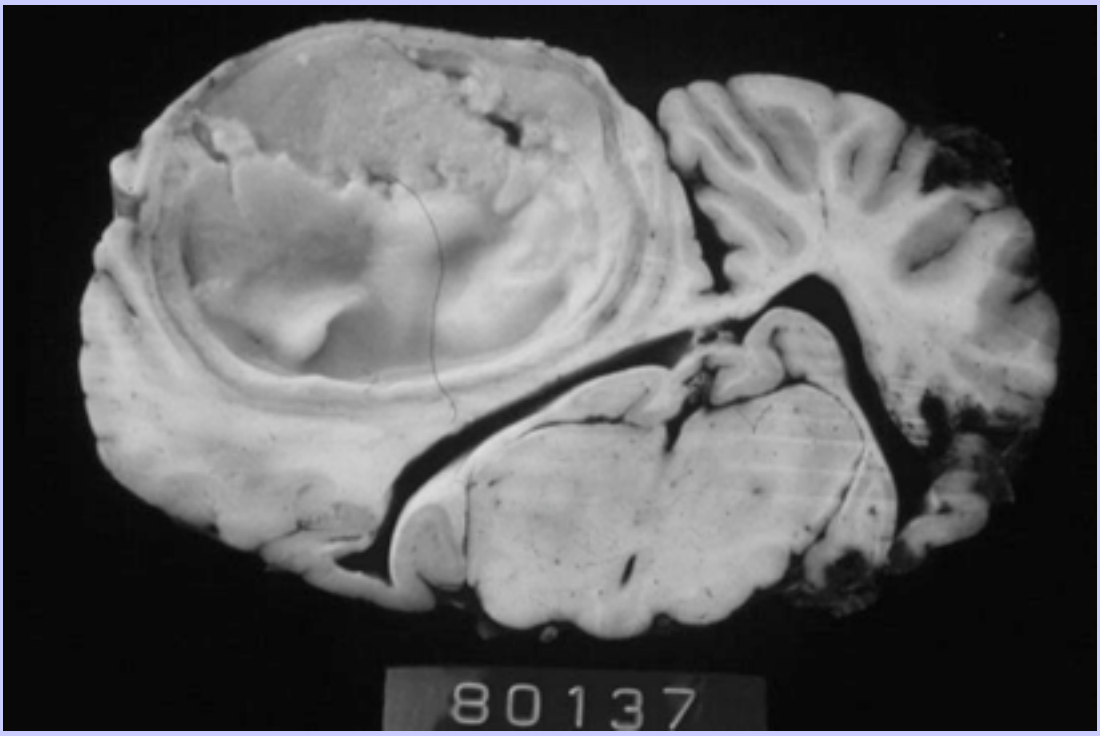
Approximately 75% of horses develop a solid enduring immunity to strangles after recovery from the disease. A small percentage of these horses become susceptible to a second attack of the disease within months, which probably represents a failure to produce or maintain an adequate level of the appropriate mucosal and systemic antibodies. Older horses with residual immunity have limited susceptibility and develop a mild form of strangles often termed *catarrhal strangles*. These animals shed virulent *S. equi* that will produce severe disease in more susceptible, often younger horses. Colostral antibodies ingested during the first 24 hours of life have also been shown to recirculate to the nasopharyngeal mucosa, thus providing an additional source of protection to the foal during its first weeks. Foals that suckle immune mares are usually resistant to *S. equi* infection until weaning.

31.10.3 Epidemiology

31.10.3.1 TRANSMISSION

Purulent discharges from horses with active strangles and those that are recovering are an important and easily recognizable source of new *S. equi* infections among susceptible horses. Transmission of infection occurs when there is either direct or indirect transfer of *S. equi* within these purulent discharges between affected and susceptible horses. Direct transmission refers to horse-to-horse contacts, particularly through normal equine social behavior involving mutual head contact. Indirect transmission occurs through the sharing of contaminated housing, water sources, feed or feeding utensils, twitches, tack, and other less obvious fomites such as the clothing and equipment of handlers, caretakers, farriers, and veterinarians unless appropriate barrier precautions are undertaken to prevent spread of *S. equi*.

Fig. 31-30 "Bastard strangles": brain abscess caused by *Streptococcus equi* in a yearling Arabian colt.



It is increasingly recognized that there may be transmission that originates from outwardly healthy-appearing animals, and in this situation the source of infection may not be readily recognized and clinical signs may appear in in-contact animals without warning. *S. equi* may originate from outwardly healthy horses as follows:

- Horses that are incubating the disease and go on to develop signs themselves
- Horses that are recovering from recent disease but that continue to harbor the organism after full clinical recovery for some weeks
- Horses that are fully recovered from the disease but continue to be potentially infectious for prolonged periods through periodic shedding of *S. equi*

31.10.3.2

ENVIRONMENTAL PERSISTENCE OF *STREPTOCOCCUS EQUI*

Currently there is a lack of definitive field-based proof for prolonged environmental persistence of *S. equi. S. equi* is known to be sensitive to bacteriocins from environmental bacteria and does not readily survive in the presence of other soil-borne flora.

31.10.4 Diagnosis

31.10.4.1 CULTURE

Culture of nasal swabs, nasal washes, or pus aspirated from abscesses remains the gold standard for detection of *S. equi*. Nasal washes are more effective than swabs in detection of small numbers of *S. equi* because a greater surface area within the internal nares is sampled. Culture may, however, be unsuccessful during the incubation and early clinical phases. *S. equi* is normally not present on the mucosa until 24 to 48 hours after the onset of fever, so infection in horses monitored by daily measuring of rectal temperatures during an outbreak may be recognized early and isolated to limit transmission of *S. equi*.

31.10.4.2 POLYMERASE CHAIN REACTION

The PCR is designed to detect DNA sequence of *SeM*, the gene for the antiphagocytic M protein of *S. equi*. However, PCR does not distinguish between dead and live organisms, so a positive test result must be considered presumptive until confirmed by culture. In addition, clinical samples that contain polymerase inhibitors or abundant *S. equi* may give negative PCR results although culture of the same sample confirms the presence of *S. equi*. PCR accompanying culture on a nasal swab or wash may be used in a control program to select animals for guttural pouch endoscopy.[389,391]

31.10.4.3 SEROLOGY

Fifteen or more surface exposed or secreted proteins of *S. equi* elicit strong serum antibody responses during infection and convalescence. The most reactive and best studied of these is SeM, a major virulence factor and protective immunogen. A proprietary ELISA for measuring SeM specific antibody is commercially available (EB1, IDEXX, Lexington, Ky.) and is useful for diagnosing recent (but not necessarily current) *S. equi* infection, determining the need for booster vaccination, and aiding in the diagnosis of purpura hemorrhagica and metastatic abscesses. It does not distinguish between vaccine and infection response. That considerable variation exists in the responses of individual horses should be kept in mind when interpreting results.

31.10.5 Vaccination

Most horses develop a solid immunity during recovery from strangles, which persists in over 75% of animals for 5 years or longer. This indicates that stimulation of a high level of immunity is biologically feasible given appropriate presentation of protective immunogen(s). There is evidence that immunity in horses resistant to reinfection is mediated at the mucosal level and functions to block entry of *S. equi*. However, systemic immunity after parenteral inoculation of avirulent live *S. equi* is also protective. Together, these findings indicate that optimum immunity may require both systemic and mucosal responses.

534

535

It is likely that more effective and safer vaccines will eventually be developed based on genomic sequence information from *S. equi* and *S. zooepidemicus*. Protective immunogens must be identified for systemic and mucosal responses, and the appropriate modes of presentation elucidated by experiment. Because it is likely that different immunogens function at the tonsillar and lymphatic levels, the appropriate combination of these components will also have to be identified in multiple experiments with ponies and horses.

31.10.5.1

USE OF EXTRACT VACCINES

Extract vaccines are given intramuscularly or subcutaneously and elicit serum antibody responses 7 to 10 days later. Naïve horses and foals require a schedule of two or three doses at an interval of 2 weeks. Booster doses are given once annually. Pregnant mares may be boostered a month before expected date of foaling. Horses known to have had strangles within the previous year should not be vaccinated. Horses with signs of strangles should not be vaccinated. During an outbreak, only horses with no known contact with animals with strangles should be promptly vaccinated.

Table 31-8 Aims and Measures Used To Control Transmission of *S. equi* on Affected Premises

Aim		Measure
1.	To prevent the spread of *S. equi* infection to horses on other premises and to new arrivals on the affected premises	Stop all movement of horses on and off the affected premises immediately and until further notice. Horses with strangles and their contacts should be maintained in well-demarcated "dirty" (i.e., *S. equi* positive) quarantine areas. Clustering of cases in groups should allow parts of the premises to be easily allocated as "dirty" and "clean" areas.
2.	To establish whether convalescing horses are infectious *after* clinical recovery	At least three nasopharyngeal swabs or lavages are performed at approximately weekly intervals in all recovered horses and their contacts, and the samples are tested for *S. equi* by culture and PCR assay. Horses that are consistently negative are returned to the "clean" area.
3.	To investigate all outwardly healthy horses in which *S. equi* is detected by either culture or PCR assay	Perform endoscopy of the upper respiratory tract and guttural pouches.
4.	To eliminate *S. equi* infection from the guttural pouches	Remove pathology through a combination of flushing and aspiration with saline, and remove chondroids using endoscopically guided instruments. Perform topical and systemic administration of antimicrobials to eliminate *S. equi* infection.
5.	To prevent indirect cross-infection by *S. equi* from horses in the "dirty" area to those in the "clean" area of the premises	Personnel should use dedicated protective clothing when dealing with infectious animals and should not deal simultaneously with susceptible animals. If this is unavoidable, infectious horses should be dealt with *after* susceptible animals. Strict hygiene measures are introduced, including provision of dedicated clothing and equipment for each area and disinfection facilities for personnel and use of thorough stable cleaning and disinfection methods. When cost is not a factor, consideration should be given to destruction of the dedicated equipment after eradication of the infection. After removal of organic material from stables, all surfaces should be thoroughly soaked in an appropriate liquid disinfectant or steam-treated and allowed to dry. This should be repeated if possible. Manure and waste feed from infectious animals should be composted (disinfected by heat) in an isolated location. Pastures used to hold infectious animals should be rested for 4 weeks. Care should be taken to disinfect water troughs at least once daily during an outbreak. Horse vans should be hosed clean and disinfected after each use.

PCR, Polymerase chain reaction.

31.10.5.2 USE OF ATTENUATED LIVE INTRANASAL VACCINE

Live vaccine should be administered only to healthy nonfebrile animals free of nasal discharges. Vaccine is given in a schedule of two doses at 2- to 3-week intervals. Annual booster doses are recommended. Live vaccine should not be used during an outbreak, except in horses with no known contact with infected or exposed animals. The mode of application should be such that an adequate amount of vaccine reaches the pharyngeal and lingual tonsils.

31.10.6 Control of Outbreaks

A practical disease-control strategy should then be agreed on and implemented. The general aims and measures for such a strategy are outlined in Table 31-8.[387]

31.10.7 Treatment

Appropriate treatment of horses with strangles usually depends on the stage and severity of the disease, and veterinary opinion as to whether or not to use antibiotic treatment remains markedly divided. However, the majority of strangles patients require no treatment other than proper rest, a dry, warm stall, and soft, moist, and palatable food of good quality while the disease is allowed to run its course. Food and water should be easily accessible to the horse.

31.10.7.1 HORSES WITH EARLY CLINICAL SIGNS

During an outbreak, immediate antibiotic therapy for new cases in the early acute phase with fever and depression may be curative and may prevent focal abscessation. Because abscesses have not developed at this early stage, the antibiotics have adequate access to the bacteria. Immediate treatment of horses that show the earliest clinical sign, fever, could be an effective way of controlling strangles outbreaks in racing stables or riding barns, although the disadvantages of treatment should be weighed.

535 536

31.10.7.2 HORSES WITH LYMPH NODE ABSCESSATION

Once an external lymphadenopathy is detected in an otherwise alert and healthy horse, antibiotic therapy is probably contraindicated. Although it provides temporary clinical improvement in fever and lethargy, it only prolongs the inevitable enlargement and eventual rupture of lymph node abscess. Therapy should be directed toward enhancing maturation and drainage of the abscesses. Topical treatments such as Ichthammol or a hot pack may be applied to promote maturation of the lymph node abscess, although objective controlled data supporting the use of these techniques are lacking. Surgical drainage of lymphadenopathies is sometimes indicated if abscesses do not rupture spontaneously; however, it is critical to wait until the abscess has matured and thinned out ventrally. The use of NSAIDs such as phenylbutazone may improve the horse's demeanor by reducing fever, pain, and inflammatory swelling at the site of the abscesses. This may in turn encourage eating and drinking.

Even in the face of detectable lymphadenopathy, if the horse is febrile, depressed, anorectic, and especially manifesting dyspnea as result of partial upper airway obstruction, antibiotic therapy is indicated to decrease abscess size and prevent complete airway obstruction. Rarely, affected horses may require intensive

supportive therapy, including IV fluids, feeding by nasogastric tube, and tracheostomy. An animal requiring a tracheostomy should be given systemic antimicrobial drugs to prevent secondary bacterial infections of the lower respiratory tract.

31.10.7.3 DRUGS OF CHOICE FOR THERAPY

Penicillin is generally considered the drug of choice for the treatment of nonpneumococcal streptococcal disease, with alternative drugs used depending on ease of administration or the site of infection. Other agents for therapy include cephalosporins and macrolides. Although there is evidence that trimethoprim-sulfadiazine did not eliminate *S. zooepidemicus* infection in tissue chambers implanted subcutaneously in ponies, the study did not determine its effectiveness against *S. equi*. Anecdotally, many veterinarians believe that trimethoprim-sulfadiazine is effective in treating horses with strangles.

31.10.8 Complications

The overall complication rate associated with *S. equi* infection is approximately 20%. The occurrence of complications can significantly increase the mortality rate.

A variety of complications can occur as a result of strangles. These can be generally grouped as:

- Those associated with the spread of infection to other locations (bastard strangles)
- Immune-mediated processes, including purpura hemorrhagica and myopathies
- Other complications

31.10.8.1 COMPLICATIONS ASSOCIATED WITH METASTATIC SPREAD OF INFECTION

S. equi may potentially infect any site. The term *bastard strangles* is often used to describe metastatic abscessation. Spread of the organism may occur through several routes, including hematogenous spread, lymphatic migration, or spread via close association with a septic focus or direct aspiration of purulent material.

Common sites of infection include the lung, mesentery, liver, spleen, kidneys, and brain. Respiratory distress may occur owing to tracheal compression resulting from enlargement of the cranial mediastinal lymph nodes. Suppurative bronchopneumonia is one important sequela of strangles.

Another important complication of strangles is extension of infection to the sinuses or guttural pouches. Infection of the guttural pouch is of particular importance, as the guttural pouch is the most common site for prolonged carriage of the organism.[389] Other reported conditions associated with *S. equi* infection include myocarditis, endocarditis, panophthalmitis, periorbital abscesses, ulcerative keratitis, paravertebral abscesses, septic arthritis, and tenosynovitis.

31.10.8.2 IMMUNE-MEDIATED COMPLICATIONS

31.10.8.2.1 Purpura Hemorrhagica

Purpura hemorrhagica is an aseptic necrotizing vasculitis characterized primarily by edema and petechial or ecchymotic hemorrhage. Although the exact pathogenesis of purpura hemorrhagica is not fully understood, it appears to a vasculitis caused by the deposition of immune complexes in blood vessel walls. The risk of developing purpura hemorrhagica after exposure to *S. equi* through infection or vaccination is not known. A preexisting high serum antibody titer to *S. equi* antigens may predispose horses to the development of purpura hemorrhagica.

31.10.8.2.2 Myositis

Both muscle infarctions and rhabdomyolysis with progressive atrophy have been documented in horses after exposure to *S. equi*.

- Muscle infarctions: This syndrome is most likely a manifestation of purpura hemorrhagica. On histopathology, there is acute coagulative necrosis of muscle with infarctions.
- Rhabdomyolysis with progressive atrophy: Significant rhabdomyolysis has been identified in some quarter horses after exposure to *S. equi*.

31.10.8.3 OTHER COMPLICATIONS

Streptococcal antigens have been suggested as a trigger for development of myocarditis and proliferative glomerulonephritis. Agalactia has been reported in broodmares with strangles. Although infection of the mammary glands is possible, the mammary glands are usually normal and the agalactia is thought to be secondary to the fever, anorexia, and lethargy associated with infection.

31.11 ACUTE RESPIRATORY DISTRESS SYNDROME AND ACUTE LUNG INJURY (ACUTE BRONCHOINTERSTITIAL PNEUMONIA)

BETTINA DUNKEL

PAMELA A. WILKINS

31.11.1 Definition and Pathophysiology

ALI and ARDS comprise a syndrome of severe pulmonary dysfunction and respiratory failure caused by physical or chemical injury or an exaggerated pulmonary immune response. In human medicine ALI and ARDS are defined by an acute onset, bilateral pulmonary infiltrates, a ratio of pulmonary arterial oxygen pressure (Pa_{O_2}) to fraction of inspired oxygen (Fi_{O_2}) of <300 for the less severe form, ALI, and <200 for ARDS, and no clinical evidence of left atrial hypertension or a pulmonary arterial occlusion pressure of <18 mm Hg.[392] The definition acknowledges ALI and ARDS as clinically recognized conditions, regardless of the inciting cause of

the respiratory failure.[393] No consensus with regard to a uniformly accepted definition in veterinary medicine has been published as of this writing.

ALI or ARDS arises as a complication after major infectious or noninfectious bodily injury. During infections, such as pneumonia, inflammatory cells and mediators localize and destroy the infectious agent while fibrin generated by a locally confined procoagulant state immobilizes the source of infection and minimizes spread of the pathogens.[394] In ALI and ARDS an imbalance of proinflammatory and antiinflammatory factors combined with activation of the pulmonary endothelium and derangement of the coagulation cascade favors the development of a fulminant, uncontrolled pulmonary inflammatory response and a widespread procoagulant environment in alveoli and the pulmonary microcirculation.[393] The triggering event may be an intrapulmonary (viral or bacterial pneumonia, smoke inhalation, near drowning, or food aspiration) or extrapulmonary (trauma, multiple transfusions, systemic inflammatory response, or sepsis) insult.[393,395]

536
537

Although not temporally distinct and largely overlapping, the pathophysiologic events can be divided into an initial exudative phase, a fibroproliferative phase, and, if the patient survives, a recovery phase.[396] The exudative phase is characterized by uncontrolled released of inflammatory mediators such as IL-1, IL-6, IL-8, and TNF-α and influx of inflammatory cells into the pulmonary tissue. Activated neutrophils and alveolar macrophages marginate in the microcirculation and extravasate into the pulmonary tissue, where they release oxidants, reactive oxygen species, proteases, and cytokines. These in turn attract and activate further inflammatory cells, thereby amplifying and perpetuating the inflammatory cascade. The inflammatory process ultimately damages or destroys the alveolar endothelial and epithelial barrier, causing flooding of the alveoli once the edema safety factors are exhausted. The barrier tends to collapse suddenly, resulting in rapid filling of the alveoli with proteinaceous exudate, leukocytes, and red blood cells and destruction of the surfactant layer.[393] The fast onset of pulmonary edema may correspond with the clinically observed acute onset of respiratory distress. Endotoxin and inflammatory cytokines such as TNF, IL-1, and IL-6 activate the coagulation cascade by tissue factor release while fibrinolysis is inhibited by increased plasminogen activator inhibitor (PAI)–1 activity. The result is formation of thrombi in the pulmonary microvasculature and deposition of intraalveolar fibrin-rich hyaline membranes.[394,396] The fibroproliferative response, which can begin within 24 hours of the onset of ALI and ARDS, is characterized by type I pneumocyte necrosis and proliferation of the more resistant type II pneumocytes in an attempt to restore the epithelial surface.[393,396] Fibroblasts invade pulmonary interstitium, alveolar walls, and deposited collagen. The resultant fibrosis reduces pulmonary compliance and increases the work of breathing, and alveolar obliteration and interstitial thickening lead to poor gas exchange.[396]

The effect on the patient is severe hypoxemia with hypocapnia or hypercapnia caused by ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and decreased pulmonary compliance. Alveolar edema causes hypoxemia by creating areas of a low $\dot{V}/\dot{Q}$ ratio (adequate perfusion but no ventilation), whereas areas with deceased perfusion generate hypoxemia and eventually hypercapnia by increasing dead space ventilation (high $\dot{V}/\dot{Q}$ ratio; adequate ventilation with minimal perfusion).[393] The coexistence of areas with high and low $\dot{V}/\dot{Q}$ ratios adjacent to normal lung tissue makes mechanical ventilation of patients with ALI and ARDS extremely challenging.

The resolution of ALI and ARDS depends on a functional distal lung epithelium. For edema to resolve, endothelial and epithelial leaks must be sealed before active salt and water transport can clear the edema fluid followed by cellular protein clearance.[393] Sodium and chloride ions are actively transported via ion channels (epithelial sodium channel ENaC and cystic fibrosis transmembrane conductance regulator CFTR, a chloride transporter) on the apical surface and Na/K-ATPase on the basolateral membrane of alveolar epithelial cells. Water follows the created osmotic gradient through aquaporin-5 channels located on type I epithelial cells.[393,397]

If damage to the pulmonary epithelium is minor, pulmonary edema can be cleared swiftly, pulmonary function improves rapidly, and chances of survival increase. If large areas of alveolar epithelium are destroyed, repair must occur before the edema can be cleared.[393] Severe damage to the epithelium corresponds with prolonged respiratory failure, slow recovery by gradual regeneration of the respiratory epithelium, and high mortality.[397] Although the mortality of human patients with ALI and ARDS is still high, less than 5% of patients die of refractory hypoxemia. Most patients succumb to their primary disease process and multiorgan failure.[396] Recovering patients may have complete resolution of pulmonary compromise, whereas others suffer from residual functional impairment such as muscle weakness, decreased pulmonary function, restrictive or obstructive changes, and low diffusion capacities.[396]

An ALI-ARDS-like syndrome has been described in 1- to 7-month-old foals and occasionally in neonatal foals.[398–400] In earlier reports the condition was named *acute interstitial* or *bronchointerstitial pneumonia*. Extensive searches for a common pathogen were conducted until with increasing understanding of the pathophysiology it became evident that multiple infectious and noninfectious agents are able to initiate the inflammatory response.[398,400–402] In foals the most common underlying condition appears to be bacterial pneumonia, and in rare cases the underlying condition is viral pneumonia.[398–402] There are no reports of ALI or ARDS in adult horses, although based on few clinical case reports and small studies one can suspect that a similar form of acute pulmonary injury exists. Buergelt and colleagues[398] reported not only on 14 foals with acute respiratory distress, but also on six adult horses. However, the onset of respiratory disease in the adults was more prolonged (11 days to 2 months), and the description better fit the heterogenous group of interstitial pneumonia than ALI and ARDS. Two adult horses with respiratory distress after near drowning met the criteria for ALI,[403,404] and two horses affected by smoke inhalation experienced fulminant pulmonary inflammation and most likely ALI.[405] Acute respiratory distress in ponies after experimentally induced gram-negative sepsis has been reported, and although some of the ponies may have suffered from ALI and ARDS, most animals were agonal, making interpretation of the observed pulmonary changes difficult.[406]

31.11.2 Clinical, Diagnostic, and Postmortem Findings

Clinically it is almost impossible to differentiate foals with ALI and ARDS from foals with severe bacterial, particularly advanced *R. equi*, pneumonia, and in a number of cases ALI or ARDS has been triggered by an underlying bacterial infection. Clinical signs include profound depression, fever, and respiratory distress with tachycardia, tachypnea, nostril flare, and cyanotic mucous membranes. Auscultation of the lungs can reveal a variety of abnormal sounds or even complete silence over nonventilated areas. Laboratory findings include severe hypoxemia with hypocapnia or hypercapnia and, depending on the underlying disease process, leukocytosis or leukopenia and hyperfibrinogenemia. Signs of disseminated intravascular coagulation were present in two foals with ALI and ARDS in one report,[401] and an abnormal coagulation panel may be observed. Transtracheal lavage fluid demonstrates neutrophilic inflammation with or without signs of infection, depending on the underlying cause. Thoracic radiographs demonstrate a diffuse, dense bronchointerstitial pattern often coalescing to a focal or diffuse alveolar pattern with prominent airbronchograms. The initial radiographic appearance of the lungs may worsen dramatically within hours because of rapid progression of pulmonary edema. On the other hand, absorption of the alveolar fluid may result in impressive improvement of the radiographic appearance within days.[401,402] A thoracic sonogram is useful in foals that cannot be safely transported to a radiography unit and reveals multiple coalescing comet-tail artifacts predominately in the caudodorsal lung field.

On gross pathologic examination, the affected lungs are wet and firm and fail to collapse, and airways contain variable amounts of pink, foamy liquid. Histologically necrosis of alveolar and terminal bronchial epithelium is observed, with extensive filling of the alveolar spaces with neutrophils, macrophages, hemorrhage, protein-rich edema fluid, or hyaline membranes. Occasionally, microthrombi can be detected in interstitial capillaries. In more chronic cases diffuse proliferation of cuboidal pneumocytes and fibroblasts and beginning fibrosis may be present.[398,400–402]

31.11.3 Diagnosis

The diagnosis can be established if the onset of the respiratory distress is acute, Pao_2/Fio_2 is <300 (Pao_2 of <63 mm Hg on room air) with little response to O_2 supplementation, the correspondent radiographic or ultrasonographic changes are observed, clinical signs of cardiac disease are absent, and the extent of the respiratory distress cannot solely be attributed to a primary disease process (e.g., almost complete destruction of the pulmonary parenchyma by *R. equi* abscesses). Presence of a primary disease process such as bacterial or viral pneumonia does not rule out the concurrent presence of ALI or ARDS.

31.11.4 Treatment and Prognosis

In human medicine, mechanical ventilation using low tidal volumes (6 mL/kg) and some form of positive end-expiratory pressure is the treatment of choice.[407] Because mechanical ventilation, with the exception of rare circumstances,[408] is possible only in neonatal equine patients, the most important treatment remains intranasal insufflation of humidified oxygen via unilateral or bilateral intranasal cannulas at high flow rates (10 to 30 L/min). Large-bore tubing systems minimize the resistance to airflow, and Fio_2 as high as 70% has been measured at the carina in adult horses using bilateral flow rates of 15 L/min (combined 30 L/min).[409] Alternatively, use of intratracheal O_2 insufflation has been described, achieving results similar to high bilateral intranasal flow rates.[410] Antiinflammatory treatment is also essential; although the use of corticosteroids in human ALI and ARDS is controversial; a recent small study reported reduced mortality and decreased need for ventilation in the group treated with low doses of corticosteroids (2 mg of methylprednisolone per kilogram IV loading dose followed by 2 mg/kg/day IV divided in four treatments).[411] Considering that ventilation is rarely an option and that in two reports all but two foal surviving ALI and ARDS received corticosteroids, anecdotal evidence is in favor of steroid administration. IV prednisolone sodium succinate or methylprednisolone at 1 to 2 mg/kg/day divided in two to four doses may be useful. Antimicrobial treatment, if required, should be directed against the underlying disease process. Bronchoconstriction is not a prominent feature of ALI and ARDS, and bronchodilators are therefore of limited use but may be beneficial in individual cases. As described earlier, clearance of edema fluid from the lungs depends on active transepithelial ion transport, a process that can be stimulated by β_2-agonists such as salmeterol, terbutaline, and epinephrine. There is some evidence in experimental models of ALI that β_2-agonists delivered into the airways reduce pulmonary edema by attenuating pulmonary vascular injury and upregulating fluid clearance from the air spaces.[412] Care should be taken when administering bronchodilators as they can induce sudden worsening of ventilation-perfusion mismatch and can lead to acute decompensation of the severely hypoxic patient. Judicious IV fluid therapy may be necessary in dehydrated patients. The increased permeability of the pulmonary capillaries makes capillary hydrostatic pressure the main determinant of pulmonary edema formation, and overhydration or rapid changes in circulating blood volume should be avoided. On the other hand, suboptimal hydration status decreases cardiac output and worsens oxygen delivery to the

peripheral tissue. Measurement of central venous pressure may aid in determination of the patient's hydration status. If foals are too depressed to nurse or eat, nutritional support is essential.

Several other treatments have been suggested in human medicine, including vasodilators such as inhaled nitric oxide or prostacycline, surfactant to reduce surface tension, and scavengers of reactive oxygen species (tocopherol, ascorbic acid); however, none has been proven to increase survival despite the fact that individual treatments improved pulmonary function.[396] Considering that, in contrast to human medicine, most equine patients die as a direct result of respiratory failure and severe hypoxemia, some of those therapeutic options may benefit the equine patient.

Based on the limited information available, the prognosis for survival and future athletic performance is guarded, with survival rates ranging from 60% to 69% in two clinical reports.[401,402] Nevertheless, survival and successful careers as racehorses have been reported even in severely affected animals.[402]

31.12 INTERSTITIAL PNEUMONIA

PAMELA A. WILKINS

KURT WILLIAMS

FABIO DEL PIERO

Interstitial pneumonia is an uncommon cause of acute or chronic disorders of the lower respiratory tract of horses.[413–419] However, because of the severity of the process, it becomes important to recognize and definitively diagnose this entity as early as possible in its clinical course. The term *interstitial pneumonia* defines a number of diseases that are chronic and progress to pulmonary fibrosis. The course is insidious and morphologically characterized by alveolar structural derangements that lead to loss of functional gas exchange units of the lung and altered mechanical properties of the lung, characterizing the pneumonia as a restrictive lung problem.

31.12.1 Etiology

Multiple agents have been implicated in the genesis of interstitial pneumonia in animals, but fewer than 20 have been confirmed in horses (Box 31-2). Chief among these are infectious agents and ingested toxins. Frequently the causative agent cannot be identified, because of the insidious nature of the process, and the final diagnosis is idiopathic interstitial pneumonia. The lung responds in a rather stereotypic manner to injury, and our limited ability to identify infectious, toxic, and immunologic causes frequently hinders our current ability to make an accurate identification of a specific cause. All efforts should be made to identify a causative agent early in the course of the disease, but the practitioner needs to be aware that treatment frequently will be nonspecific and supportive.

31.12.1.1 Box 31-2 Causes of Interstitial Pneumonia in Horses

Uncertain

Idiopathic or cryptogenic

31.12.2 INFECTIOUS AGENTS

Infectious causes of interstitial pneumonia in horses and foals include viral, bacterial, parasitic, protozoal, and fungal agents. Typically the pneumonia is acute and severe, characterized by severe damage to the lung parenchyma (alveolar region).

Viral agents are frequently implicated or suspected but rarely identified by the usual serologic, histopathologic, and virus isolation methods. The advent of more sensitive and specific techniques, such as in situ PCR and monoclonal antibody IHC, may partially resolve the current diagnostic challenge. Most recently, a novel gamma-EHV, EHV type 5 (EHV-5), has been found associated with a nodular form of interstitial pneumonia of horses characterized by pulmonary interstitial fibrosis, suggesting that these rather unusual cases may have an underlying infectious cause.[420] This disease has been termed *equine multinodular pulmonary fibrosis* by the authors describing the pathology of the disease. Horses affected generally have a history of fever, cough, and weight loss, accompanied by exercise intolerance and finally respiratory distress. They can be acutely affected or have a more chronic progressive problem. Typical radiographs reveal multiple discreet to coalescing nodular densities overlying a diffuse interstitial pattern (Figs. 31-31 and 31-32). Histologic appearance is diagnostic of this disease (Figs. 31-33 and 31-34). EHV-5 has been identified in both BALF and lung biopsy samples from affected patients by both PCR assay and IHC.

In some horses with bronchointerstitial pneumonia of unknown cause, bacterial agents have been isolated from the lung. The usual distribution of bacterial bronchopneumonia in the horse is cranioventral, whereas the distribution in interstitial pneumonia is diffuse. In the latter cases the bacteria are most likely opportunistic pathogens and do not represent the primary causative agent. An exception is *R. equi* pneumonia of foals, which can cause an ARDS in older foals. *R. equi* has been cultured from foals with severe, acute bronchointerstitial pneumonia with a diffuse pulmonary distribution.[416] Interstitial pneumonia associated with *P. carinii* has been described in the foal, and *Mycoplasma* species has been isolated from the respiratory tract of adult horses.[421] The significance of the *Mycoplasma* isolates remains a matter of debate. *P. carinii* pneumonia is thought to occur

primarily in immunocompromised foals as a complication of some other serious disease, such as infectious pneumonia or SCID. It is characterized by plasmacytic lymphocytic interstitial pneumonia with flooding of alveoli with foamy acidophilic material.

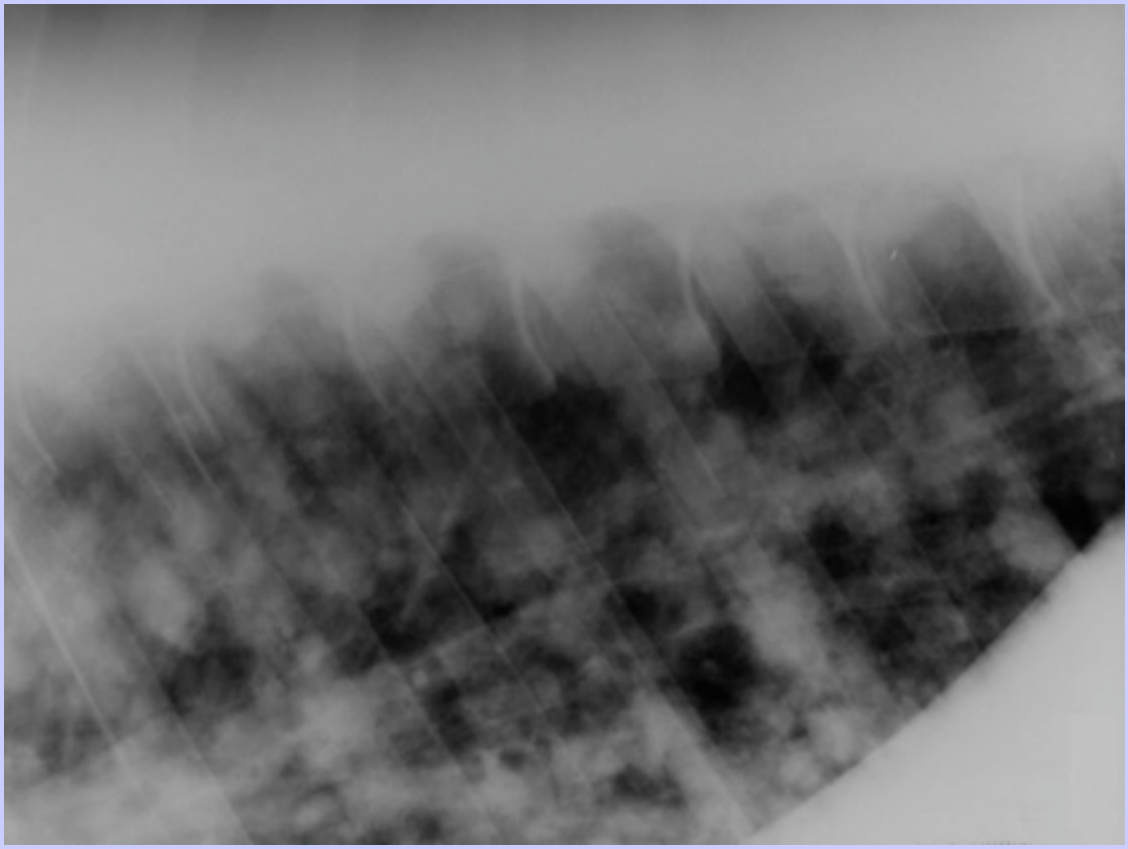

Fig. 31-32 Cut section of lung from horse with equine multinodular pulmonary fibrosis. Note large areas of apparent fibrosis within the pulmonary parenchyma. Courtesy Dr. Perry Habecker, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.

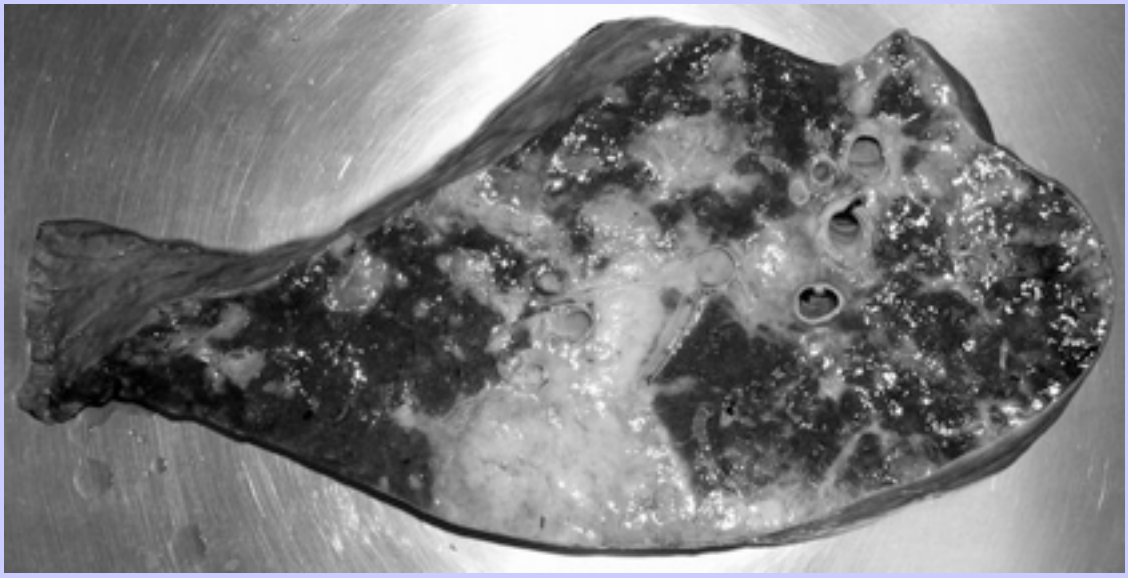

Fig. 31-33 Postmortem histopathologic specimen from a horse with severe equine multinodular pulmonary fibrosis. This is the histologic appearance of one of the fibrotic nodules. The alveoli are constricted within dense neoformed fibrotic tissue. Alveoli have an abnormal cuboidal epithelium (type 2 pneumocytes), and the lumen contains macrophages, sloughed epithelial cells, and neutrophils. Denser and diffuse fibrotic areas present. Courtesy Dr. Fabio Del Piero, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.

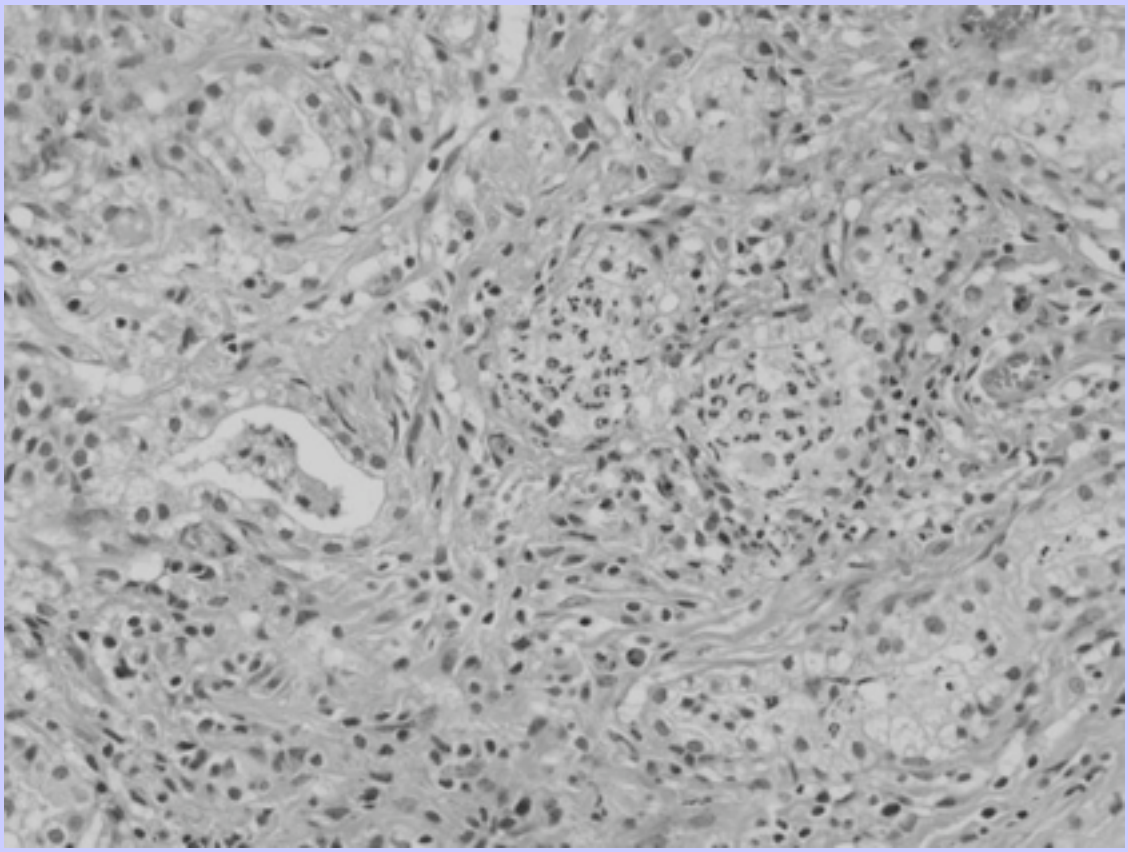

Fig. 31-34 Postmortem histopathologic specimen from a horse with severe equine multinodular pulmonary fibrosis. Note abnormal alveolar cuboidal epithelium, and within the lumen neutrophils and intranuclear amphophilic viral inclusion with chromatic margination within a sloughed epithelial cell or perhaps a macrophage. Courtesy Dr. Fabio Del Piero, University of Pennsylvania, New Bolton Center, Kennett Square, Penn.

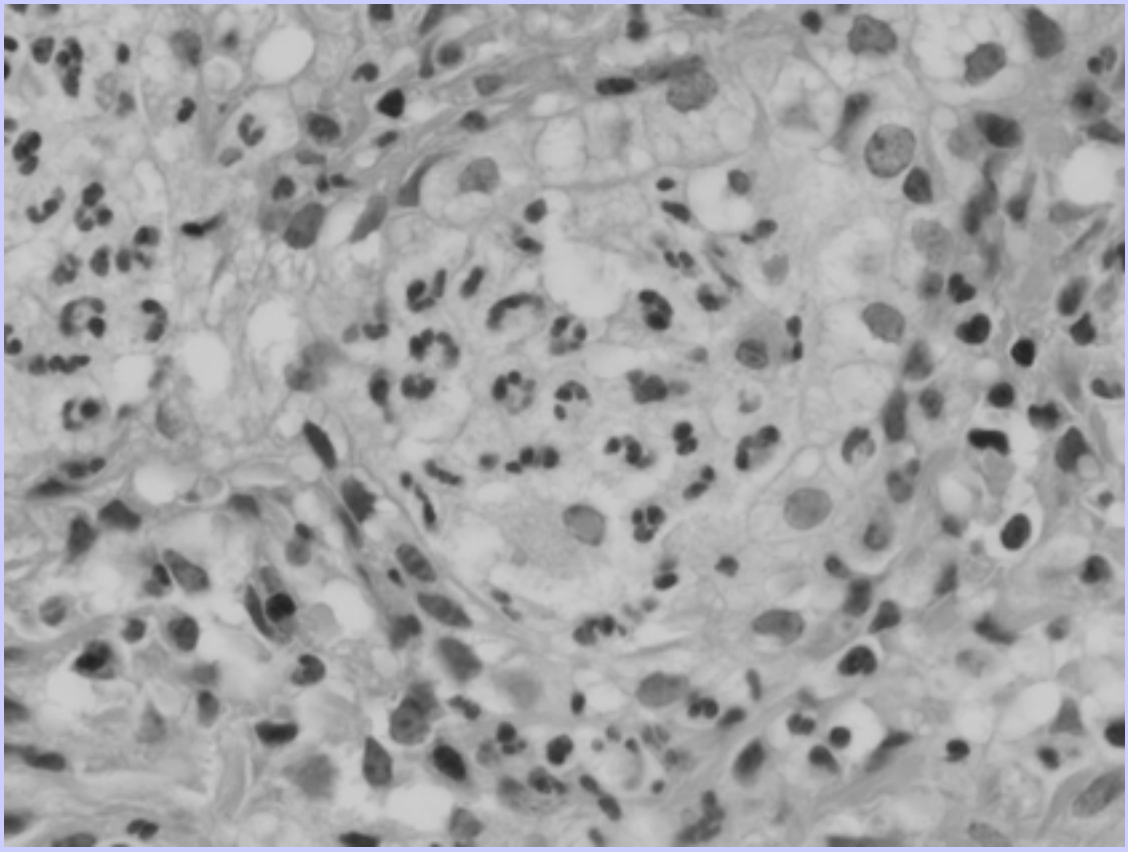

Parasitic pneumonia, an uncommon cause of chronic bronchointerstitial pneumonia, usually occurs in young foals secondary to migration of *Parascaris equorum* larvae through the pulmonary parenchyma.

31.12.3 INGESTED CHEMICALS

Ingested chemicals rank second only to infectious agents as potential causes of interstitial pneumonia in horses. Ingestion of pyrrolizidine alkaloids from a variety of plants (mostly genera *Crotalaria, Trichodesma*, and *Senecio*) can cause interstitial pneumonia in horses.[422] This toxicity is associated with production of a toxic metabolite that is activated in the liver then circulates to the lung. The toxic alkylating agents damage capillary endothelial cells, although the amount of alkaloid required to damage the lung is generally less than that required

for hepatotoxicity. Crofton weed *(Eupatorium adenophorum)*, a poisonous plant found primarily in Australia and Hawaii, produces interstitial pneumonia in horses. Toxicity is associated with ingestion of the flowering plant, but the nature of the toxin is not known. Perilla ketone, derived from the plant *Perilla fructans*, produces acute respiratory distress with a week of ingestion in ponies. The lesions include diffuse alveolitis and type II pneumocyte proliferation with sparing of the bronchioles. Toxicity depends on additional metabolism of the 3-substituted furan by the mixed function oxidase system, which occurs directly in the lung of the horse.

31.12.4 INHALED CHEMICALS

Direct pulmonary injury by inhaled chemicals is an uncommon cause of interstitial pneumonia in horses. In people this type of pneumonia is primarily related to occupational exposure. Smoke inhalation causes acute, diffuse interstitial pneumonia in horses, frequently followed within a few days by opportunistic bacterial pneumonia. Oxygen toxicity can theoretically produce interstitial pneumonia and alveolar type II cell proliferation. This problem is more likely to be seen in neonatal foals mechanically ventilated with increased levels of oxygen ($Fio_2 > 50\%$) for several days, although this may in fact be a form of ventilator-associated lung injury (VALI) associated with mechanical stretch of the airspaces. Damage is thought to be due to production of reactive oxygen metabolites, which attack a lung that may already have been injured by barotrauma resulting from a ventilator-driven increase in airway pressure. Agrichemicals or herbicides, such as paraquat, may cause acute interstitial pneumonia (AIP) in horses and should be considered in horses with a history of possible exposure. Silicosis is a specific chronic granulomatous pneumonia of horses associated with inhalation of silicon dioxide crystals. This syndrome has been described in horses originating from the Carmel Valley region of California. The inhaled particles are ingested by alveolar macrophages and result in lysis of the macrophage, chronic alveolitis, and fibrosis. Multiple granulomas are present, and submicron intracytoplasmic crystalline particles can be identified in macrophages.

31.12.5 HYPERSENSITIVITY REACTIONS

In the most specific sense, *hypersensitivity pneumonitis* refers to pulmonary disease caused by inhalation of organic antigens. Lymphocytic, plasmacytic bronchitis and bronchiolitis, combined with lymphocytic interstitial pneumonia, characterize the disease in horse lung. Granuloma formation and fibrosis can be observed. Chicken dust and fungi have been implicated as causes of severe, chronic bronchointerstitial pneumonia, but the syndrome itself is quite rare.

31.13 ENDOGENOUS METABOLIC AND TOXIC CONDITIONS

Various conditions cause acute pulmonary injury with inflammatory edema or severe alveolar wall damage and serofibrinous exudation similar to that described for AIP. Acute uremia, shock, burns, and trauma can produce an acute pulmonary injury termed *acute lung injury* or *acute respiratory distress syndrome*, depending on severity. Although endotoxin does not directly injure the lung, endotoxemia in the horse initiates inflammatory and metabolic cascades that can lead to pulmonary injury. Activation of these pathways produces vasoactive and chemoattractant molecules that increase vascular permeability, activate complement, produce proinflammatory cytokines, and release neutrophil enzymes that can adversely affect the lungs of horses. Horses as a species are quite sensitive to the negative effects of endotoxemia, and their lungs are particularly sensitive, perhaps because of the presence of intravascular macrophages, which further amplify the inflammatory cascade. Both ALI and ARDS have recently been defined for veterinary patients, although the definition has not been published as of the date of this writing.

31.13.1 Pathophysiology

Interstitial pneumonia progresses through four phases. During the first, the initial insult causes parenchymal injury and alveolitis. This is followed by a proliferative phase characterized by cellular and parenchymal alterations in tissues of the lung. Chronic cases progress to the development of interstitial fibrosis, and the final stage results in end-stage irreparable fibrosis of the lung.

540

541

The structural changes that occur in the lung reduce the number of functional alveoli, adversely affecting ventilatory function of the lung and altering ventilation-perfusion relationships. Reduced lung compliance is associated with the loss of distensible alveoli, the presence of pulmonary edema, and fibrosis. Total and vital lung capacity are decreased in association with the loss of functional gas exchange units and reduced lung compliance. The work of breathing is increased, resulting in exercise intolerance and difficulty in breathing. Pulmonary hypertension and cor pulmonale may be complications of interstitial pneumonia and fibrosis. Although the origin of pulmonary hypertension is unclear, hypoxic vasoconstriction and generation of vasoactive compounds (such as endothelin-1) that alter pulmonary vascular resistance acutely, and vessel anatomy chronically, may play a role.

31.13.2 Clinical Signs

Horses affected with interstitial pneumonia frequently have fever, cough, weight loss, nasal discharge, exercise intolerance, severe dyspnea, cyanosis, and a restrictive breathing pattern. A “heave line” is frequently present; nostril flare and an anxious expression are usual. The history can be acute or chronic. Although affected foals are frequently depressed and anorectic, adults may be bright and alert with a variable appetite. The disease proceeds toward death in many cases, with progressive respiratory compromise, although some patients may also slowly improve with time. More than one foal at a farm may be affected.

31.13.3 Diagnosis

In older horses the primary differential diagnosis of heaves may be excluded by the leukocytosis and hyperfibrinogenemia that commonly occur in horses with interstitial pneumonia and fibrosis but do not occur in horses with heaves. However, these abnormal features are common in horses with infectious bronchopneumonia, and thoracic radiography is of paramount importance in the establishment of a definitive diagnosis. Typically, thoracic radiographs reveal extensive interstitial and bronchointerstitial pulmonary patterns.[423] Nodular infiltrates may be present, either large or miliary, but always diffusely distributed.

Culture of transtracheal or BAL aspirates often yields no significant growth of bacterial or fungal pathogens. Cytologic evaluation of tracheal or BALF shows increased numbers of neutrophils and macrophages. If *P. carinii* is involved, BALF may reveal trophozoites or intracystic bodies with special stains, such as toluidine blue or methenamine silver. Using PCR, EHV-5 has been found in BALF from horses with EMPF.

Histologic examination of a transthoracic lung biopsy specimen is the definitive diagnostic test for chronic interstitial pneumonia and fibrosis and for EMPF. Care must be taken to ensure the biopsy is obtained from a representative area, and we have found ultrasound guidance useful. Clinically important complications from this technique are uncommon but can occur. Biopsy can both define the causative agent and confirm the clinical diagnosis in EMPF when the sample is evaluated for EHV-5.

Additional diagnostic procedures could include arterial blood gas analysis, abdominocentesis and thoracocentesis to rule out metastatic neoplastic disease, PFT, viral isolation, serologic testing for antibody to fungi and chicken serum if hypersensitivity pneumonitis is suspected, and immunohistochemical evaluation of lung tissue for suspected infectious agents. A complete cardiac evaluation should also be conducted, as pulmonary hypertension and cor pulmonale are not uncommon sequelae.

31.13.4 Treatment

Treatment of these cases is often unrewarding. Therapeutic goals are treatment of any underlying or secondary infection; suppression of inflammation; maintenance of tissue oxygen delivery within appropriate limits; relief of any associated bronchoconstriction; and prevention or treatment of complications. Environmental control, with appropriate temperature and humidity control and good ventilation, is beneficial.

Parenteral corticosteroid therapy is the mainstay of treatment, with early and aggressive therapy providing the best long-term outcome, particularly in foals. In one report of 23 foals affected with acute bronchointerstitial pneumonia, 9 of 10 treated with corticosteroids survived, but none of those not receiving steroid treatment lived.

Broad-spectrum antimicrobial treatment should be instituted initially, particularly in foals, as described for the treatment of infectious bronchopneumonia. The choice of antimicrobial agent and duration of therapy should be dictated finally by the culture and sensitivity results from the TTA and by the patient's clinical course. Anecdotally, horses with EMPF have responded to treatment with acyclovir and corticosteroids. The course of therapy is generally prolonged (6 to 12 weeks); clinical and radiographic improvement has been noted in a few cases to date.

Foals, in particular, and adults with severe respiratory distress may benefit from nasal insufflation of humidified oxygen, with flow rates of 10 L/min for foals and 15 L/min in adults. If necessary, as determined by persistent hypoxemia in the face of intranasal insufflation at the rates given, a second nasal canula can be placed in the opposite nostril to increase the Fio_2. Care must be taken to avoid obstruction of the nasal passages. Alternatively, intratracheal or transtracheal insufflation can be considered to further increase Fio_2 and improve oxygenation.

Systemic bronchodilator therapy may or may not be indicated in these cases. If used, bronchodilators may worsen ventilation-perfusion inequalities. Therefore bronchodilator therapy should be accompanied by supplemental oxygen, and the effects should be monitored with serial blood gas measurements and discontinued if hypoxemia worsens. Nebulized or aerosolized bronchodilator therapy may be more judicious, and beneficial effects are evident in some foals with respiratory distress. Aminophylline and theophylline should not be used, owing to their narrow therapeutic range. Furosemide may be appropriate for its bronchodilator effect and its effect on reducing pulmonary artery pressure, particularly if cor pulmonale develops.

31.13.5 Prognosis

The prognosis for horses with interstitial pneumonia is uniformly poor to guarded. Affected foals, treated early and aggressively with corticosteroid and antimicrobial therapy, have the best outlook for life. The disease is usually progressive in adults and eventually results in the demise of the horse, although the occasional horse recovers sufficiently to return to previous performance levels. A fair number of adult horses, with continuous intense management, will live for a period of time but will be severely compromised, which limits their usefulness. Exceptions to the poor prognosis may be seen in cases of *P. carinii* pneumonia in foals if they are treated early and aggressively and possibly also in cases of idiopathic interstitial pneumonia or EMPF in adult

horses that are treated early with corticosteroids and antiviral drugs. A trial of treatment for peracute interstitial disease for 48 hours is warranted, and patients with chronic interstitial pneumonia should be treated for a minimum of 6 weeks before the possibility of recovery is discarded.

542

31.14 EQUINE RESPIRATORY VIRUSES

GABRIELE A. LANDOLT

D. Paul Lunn

Viral respiratory infections in horses are major causes of respiratory disease, resulting in impaired pulmonary function and reduced performance. Although vaccines are available for many of the causative agents, the respiratory viruses have remained a major concern in the horse industry. Infection with equine respiratory viruses can lead to serious respiratory illness with potentially fatal consequences. Yet the incidence and severity of viral respiratory disease may vary from year to year and are dependent on the attack rate, virulence of the circulating virus, infectious dose, management and environmental conditions, and degree of immunity of individual animals in the population.

With the exception of HEV infection, in a group of susceptible horses equine viral respiratory infection generally is characterized by the rapid spread of an acute, febrile respiratory disease accompanied by a dry cough and nasal discharge. Therefore a presumptive diagnosis of viral respiratory disease can often be made based on history and clinical signs. However, to confirm and differentiate among the potential causative agents, laboratory diagnosis is required.

31.14.1 Diagnosis of Equine Respiratory Viruses

The basic approaches for the laboratory diagnosis of equine viral respiratory disease are the isolation of the causative agent (virus isolation), demonstration of the virus or viral product in clinical specimens (detection of virus particles by electron microscopy; detection of viral antigens by immunofluorescence, ELISA, or immunoperoxidase; detection of the viral genome), and the detection of virus-specific antibodies (serology). Because each of these methods has its merits as well as disadvantages (e.g., lack of sensitivity, long turnaround time, high costs), it may be necessary to combine several of them to identify the causative agent accurately and rapidly. The World Organisation for Animal Health (OIE, www.oie.int) publishes the *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals*, which provides an in-depth review of current diagnostic testing strategies.

31.14.1.1 VIRUS ISOLATION

Virus isolation from clinical samples is crucial for epidemiologic investigation and for vaccine production and generally is carried out in cell culture. The notable exception is equine influenza virus, for which embryonated chicken eggs have remained the culture system of choice. As virus shedding in secretions of the respiratory tract is greatest within the first few days after infection, the best results for virus isolation are often achieved by culturing nasopharyngeal swabs collected in the first 24 to 48 hours after onset of clinical disease. The duration of nasal virus shedding is often brief in partially immune animals, so it may prove useful to sample immunologically less protected individuals in a group (e.g., younger horses, poorly vaccinated or unvaccinated animals) to increase the likelihood of demonstrating infectious virus. Nasopharyngeal or nasal passage samples are best collected using polyester-tipped swabs instead of cotton swabs because certain

viruses (e.g., influenza A virus) have been found to adhere to the cotton fibers. The swabs should be placed in a sterile viral transport medium and kept on ice until further analysis.

31.14.1.2 ANTIGEN DETECTION

The most important advantages of diagnostic tests aimed at the detection of viral antigen over traditional virus isolation are the faster turnaround time as well as the ability to detect virions that have lost their infectivity. Immunofluorescence (fluorescent antibody [FA] test) is based on the detection of virus-infected cells employing virus-specific fluorochrome-labeled antibodies. The technique is used to detect viral antigen in a broad range of clinical samples (e.g., frozen sections of tissues, 132 tissue imprints, cells obtained from nasal scrapings or tracheal washes) and has been shown to be highly sensitive. A number of antigen-capture ELISA-based assays have been developed for the detection of equine respiratory viruses.[424–428] Frequently a solid-phase system is used for virus detection. Specific antibody is first adsorbed to the surface of a microtiter plate, and the sample containing the suspected virus is then added. If the virus is present, it binds to the adsorbed antibody. After washing, specific enzyme-labeled antibodies are added. Detection of virus in the sample is achieved by addition of the enzyme substrate, which results in a color reaction. Commercially available ELISA-based test kits (e.g., Flu OIA assay, Biostar, Boulder, Colo.; Directigen Flu-A assay, Becton Dickinson Microbiology Systems, Cockeysville, Md.) have been validated for the rapid, stallside detection of equine influenza virus. Many investigators have found these commercial diagnostic kits to be highly specific and rapid, and their sensitivity approaches that of egg isolation.[429–433] Since the discovery of the PCR the technique has found wide application in diagnostic laboratories. Through the choice of appropriate oligonucleotide primers, a selected region of the viral genome can be amplified. PCR-based assays are extremely sensitive and theoretically can detect a single copy of the target nucleic acid in a sample.[434–436] Yet, owing to the assay's high sensitivity, the greatest challenge facing the diagnostic application of PCR is the production of false-positive results. Nevertheless, PCR-based techniques offer a more sensitive tool for the diagnosis of equine respiratory viruses than conventional techniques such as culture or immunoassays. To increase the diagnostic capacity of PCR, multiplex PCR assays have been developed. By including more than one pair of primers in the reaction mixture, these assays are designed to simultaneously detect a panel of respiratory pathogens. For example, multiplex PCR assays designed to detect nucleic acid of influenza A and B viruses, respiratory syncytial virus (RSV), adenovirus, and parainfluenza virus have been developed for screening of human clinical samples.[437–440] In equine diagnostics, assays capable of simultaneously detecting and differentiating EHV-1 and EHV-4[441–443] as well as EHV-2 and EHV-5[444] have been published. More recently, real-time PCR–based assays have been used for the detection and quantification of equine respiratory pathogens.[445–447] By employing a target-specific fluorescent probe, real-time PCR–based assays eliminate the need to distinguish the target by PCR fragment size on electrophoresis or hybridization with probes post-PCR. The advantages of real-time PCR include high specificity, sensitivity, and a rapid turnaround time.

31.14.1.3 ANTIBODY DETECTION

Detection of virus-specific antibodies has been and continues to be a cornerstone in the diagnosis of equine viral respiratory disease. Detection of specific antibody can provide support that an animal has been exposed to a given antigen. Often, this is used as circumstantial evidence of infectious disease. Commonly used techniques for antibody detection include ELISAs, serum neutralization tests, single radial hemolysis, and hemagglutination inhibition assays. Because most serologic assays are fairly easy to perform and cost-effective and because large numbers of samples can be collected and tested simultaneously, serologic testing is particularly useful for large-scale herd surveillance. Although useful, there are limitations to serologic testing.

For example, the presence of antibody indicates exposure to antigen but does not necessarily indicate active infection or disease. If horses have been vaccinated, a diagnosis of acute infection can often be made only by testing paired samples (acute and convalescent) and by demonstrating at least a fourfold rise in antibody titers over a period of several weeks (seroconversion). Because of the inherent variability of immunoassays, paired samples always should be run by the same laboratory. In addition, antibody is not always detected in the presence of active infection. The most common reason for a negative result despite infection is that insufficient time has passed between infection and measurement of an antibody response. Alternatively, immunocompromised horses may fail to produce a detectable antibody response despite active infection.

542

543

31.14.2 Treatment

The treatment of horses with viral respiratory disease is primarily symptomatic. It is important to ensure that sick animals are kept in a clean, well-ventilated, and stress-free environment. Morbidity caused by pyrexia and myalgia may be reduced by administering NSAIDs. It is important to monitor affected horses for development of complications such as pneumonia and myocarditis, and animals exhibiting signs of respiratory disease after 10 days should be reevaluated to rule out secondary bacterial infections.

Antiviral drugs, such as amantadine, rimantadine, and acyclovir, have been used for prophylaxis and treatment of horses during outbreaks of equine influenza and EHV-1, respectively. Clinical trials with the influenza virus M2 ion channel blockers amantadine and rimantadine have shown that both drugs appear to be equally effective in reducing the severity and duration of clinical illness.[448,449] In addition, oral administration of rimantadine (30 mg/kg q12h) was shown to reduce the virus load in nasal secretion, although the duration of nasal virus shedding was similar to that in the untreated controls.[448] However, the therapeutic and prophylactic benefits of M2 ion blocker antiviral therapy during outbreaks of equine influenza may be limited owing to the potential for the rapid development of drug resistance. In vivo and in vitro studies have demonstrated that drug-resistant influenza virus mutants can develop as early as 1 day after the start of treatment.[450] Subsequent isolation of the drug-resistant virus from susceptible contacts showing signs of clinical disease indicates that acquisition of drug resistance is not associated with attenuation of the virus.[451,452] Finally, treatment of horses with amantadine has also been associated with adverse effects and poor oral bioavailablity.[453]

Acyclovir (9-[2-hydroxyethoxymethyl]guanine), a chain-terminating nucleoside analog, has been shown to be highly efficacious against herpes simples virus and, to some extent, varicella-zoster virus. EHV-1 was also found to be sensitive to inhibition by acyclovir in vitro and in animal models.[454,455] Although there have been no controlled studies reporting on the efficacy of acyclovir in the treatment and prevention of EHV-1 infection in horses, anecdotal reports suggest a potential benefit of acyclovir administration (10 mg/kg PO five times daily) in horses with clinical signs of EHV-1 infection (e.g., myelitis, neonatal infection).[456–458] In humans, acyclovir can be administered by injection, as a topical cream, or as an ingestible capsule. It is interesting to note that evaluation of the pharmacokinetics of a single PO or IV dose of acyclovir in adult horses revealed that intragastric administration of the drug was associated with high variability in serum drug concentrations as well as poor bioavailability.[459]

31.15 EQUINE INFLUENZA VIRUS

Equine influenza is the most frequently diagnosed cause of viral respiratory disease of the horse.[460,461] It is a highly infectious disease that affects horses, donkeys, mules, and zebras. Outbreaks of a disease resembling influenza were reported as early as 1751; however, the causative agent was not isolated until 1956.[462,463]

31.15.1 Etiology

Equine influenza viruses are members of the family Orthomyxoviridae, which contains enveloped viruses with segmented, single-stranded, negative-sense RNA genomes.[464] The Orthomyxoviridae include five genera: influenza A, B, and C viruses, thogotoviruses, and isaviruses.[464] Equine influenza viruses are influenza A viruses. In contrast to influenza B and C viruses, which appear to have a fairly narrow host range, influenza A viruses can infect a wide variety of species (e.g., horses, humans, wild and domestic birds, pigs, sea mammals, dogs, and cats). It has long been recognized that influenza A viruses exhibit partial restriction of their host range,[463] indicating that viruses from one host species occasionally can transmit to infect another host. Undoubtedly, the most prominent examples for direct transmission of influenza A viruses among species are the recent infections of humans and cats with the highly pathogenic avian H5N1 viruses.[465–468] Although horses have often been regarded as isolated or "dead-end" hosts for influenza,[463] events of recent years clearly indicate that the species barrier for viruses jumping either to or from horses is not absolute. For example, the severe influenza epidemic in horses occurring in 1989 in the Jilin and Heilongjiang provinces in the northeast of the People's Republic of China was caused by a virus with avian-like genetic features, suggesting that the virus had spread directly to horses from birds.[469] Another more recent example is the transmission of an equine-lineage virus to dogs in the United States.[470] First isolated from greyhound dogs at a racing kennel in Florida in 2004, the equine-lineage virus spread quickly though a substantial portion of the dog population in the United States over the course of 2 years.

Although the viral and host factors that determine the host range of influenza viruses, and the mechanisms by which species barriers are overcome, are not completely understood, a large body of research highlights the importance of the viral hemagglutinin (HA) glycoprotein in determining host specificity.[463,471,472] HA serves as the viral receptor-binding protein and is embedded, along with the neuraminidase (NA) and the ion channel M2 protein, in a host cell—derived lipid envelope. Mediated by binding of the HA to sialic acid residues on the host cells, the virion envelope and the host cell membrane fuse. This interaction subsequently promotes the release of the viral genome into the cytoplasm of the host cell. NA is responsible for the cleavage of the α-ketosidic linkage between a sialic acid molecule and an adjacent sugar D-galactose or D-galactosamine. Biologically, NA facilitates the mobility of the influenza virus virion by assisting in the release of the budding virus particle from the host cells.[473,474] Both HA and NA are major surface antigens of the influenza virus virion. Partly because of the host immune pressure, these proteins can undergo substantial antigenic variation (antigenic drift), which allows the mutant viruses to escape neutralizing antibodies.

Based on antigenic properties of HA and NA, influenza A viruses are divided into subtypes. To date, 16 HA subtypes (H1 to H16) and nine NA subtypes (N1 to N9) have been described. Although viruses of all 16 HA and nine NA subtypes of influenza A viruses have been isolated from wild waterfowl,[475–477] only a limited number of subtypes have been associated with infection of mammals. For example, in humans, only viruses of H1, N2, H3, N1, and N2 subtypes have circulated widely in the population,[463,478] and only H1, H3, N1, and N2 subtypes have been consistently isolated from pigs.[479–481] In horses, apart from isolated reports of infection with viruses of H1N1, H2N2, and H3N2 viruses (usually associated with human infections),[482] equine influenza infections have been caused by viruses of H7N7 (A/equine/1) and H3N8 (A/equine/2) subtypes.[462,483,484] Although large-scale serologic surveillance indicates that H7N7 viruses may still be circulating at low levels in the equine population of Central Asia[463] and Eastern Europe,[462,485] these viruses have not been isolated from horses since the late 1970s.[433,475,486] In contrast, despite intensive vaccination programs, equine H3N8 viruses continue to

circulate in large parts of the world. Since the 1980s a number of severe, widespread influenza outbreaks in horses have occurred in South Africa,[487] India,[488] the People's Republic of China,[469,489] and most recently the United Kingdom.[490] The causative agent of the South African outbreak was identified as an H3N8 virus, which was most likely introduced by importation of infected horses from the United States or Europe.[433,491]

Since the early to mid 1980s the equine lineage H3N8 viruses have diverged into two distinct evolutionary lineages: European and American. Although the circulation of both lineages initially centered largely on their geographic origin,[492] both lineages now appear to be cocirculating in Europe and, to a considerably lesser extent, in the United States.[433,493,494] Continued genetic divergence appears to have resulted in the formation of three American-like lineages with distinct antigenic characteristics (a South American lineage, a Kentucky lineage, and a Florida lineage).[493] The rate of genetic diversion of equine viruses is small compared with human and swine influenza viruses, but the sustained genetic evolution continues to have considerable impact in terms of immunization.

31.15.2 Epidemiology

Experimentally, horses of all age-groups are susceptible to infection.[495] However, although sporadic infection in foals has been described, there exists only one published report of a widespread outbreak in foals less than 6 months of age.[496] The lower incidence of disease in young foals is most likely a result of the presence of maternally derived antibodies. Influenza-specific serum antibody concentration is a highly accurate correlate to protection against infection and disease, and animals with high concentrations of homologous antibody are almost always protected against experimental challenge.[497,498] After natural infection, ponies were reported to be protected from infection for 8 months, with partial protection persisting for more than 1 year.[499] Although vaccination does not always provide full protection against clinical disease, immunization of horses against influenza has reduced the frequency of disease outbreaks and the frequency and severity of clinical signs when epizootic disease occurs among vaccinated animals.[495,500,501]

Outbreaks of equine influenza occur most often when susceptible animals are congregated and housed in close contact with one another (e.g., horse shows, racetracks, sale barns). Virus transmission occurs through direct contact with infected animals or via droplet or airborne transmission.[502] The virus has been shown to be able to remain infectious for up to 48 hours on dry surfaces (equipment, countertops), but it is capable of surviving for as long as 72 hours in wet environments.[503] Anecdotal evidence suggests that the disease can spread in a matter of hours to days among immunologically naïve animals that are kept in close confinement. Such effective spread is enhanced by a short incubation period (approximately 2 days), high concentrations of virus shed in nasal secretions, an explosive cough, and the practice of housing horses in confined spaces.[503] In partially immune animals, the spread of disease is often considerably slower and outbreaks may last as long as 3 to 4 weeks.[504] After experimental infection, horses typically shed virus for 6 to 7 days.[505–508]

31.15.3 Pathogenesis

Influenza A viruses replicate and induce pathologic changes throughout the entire respiratory tract, with the most significant lesions occurring in the lower airways. After inhalation of the virus, the virion attaches to and enters the respiratory epithelial cells. After replication and release from the host cell, the virus spreads quickly throughout the respiratory tract. Largely through apoptosis,[509–511] influenza virus replication leads to cell death

and subsequent loss of the ciliated respiratory epithelium in the trachea and bronchial tree.[512] Consequently, tracheal mucociliary clearance is impaired, predisposing affected horses to the development of secondary bacterial infections.[483,513,514] In addition, the disruption of the superficial cell layers allows opportunistic bacteria to invade the respiratory epithelium of both the upper and the lower respiratory tract. The combination of reduced airway clearance and erosion of the respiratory epithelium can result in bacterial bronchopneumonia and other complications.[512,515] In uncomplicated cases, regeneration of the respiratory epithelium begins approximately 3 to 5 days after onset of illness,[515] but resolution of the epithelial damage takes a minimum of 3 weeks.[514,516]

31.15.4 Clinical Presentation

Clinical signs of influenza virus infection in horses are often seen 48 hours after exposure to the virus. In vaccinated animals the disease is rarely fatal, but deaths have been reported during some epidemics, particularly in donkeys and rarely in neonatal foals.[462,517] The typical clinical presentation of equine influenza consists of pyrexia, anorexia, lethargy, nasal discharge, and cough. Pyrexia is often the first symptom present, with body temperatures peaking somewhere between 48 to 96 hours after infection. In some cases a second peak of pyrexia may occur around 7 days after infection. Nasal discharge is often serous in the first few days of illness but may become mucopurulent by 72 to 96 hours after infection. Concurrently a dry, hacking cough develops. Coughing typically persists long after pyrexia and nasal discharge have resolved and may still be present 3 weeks postinfection. Most affected animals are anorectic during the initial pyrexia, and weight loss has consistently been documented in experimental infections. In severe infections, lung sounds may become increased in amplitude and adventitial sounds may sometimes be detected. Uncomplicated cases of equine influenza typically resolve within 7 to 14 days postinfection, but complications of equine influenza virus infections can be severe and include secondary bacterial pneumonia, myositis, myocarditis, and limb edema.[484,513,514] It has also been speculated that influenza infection may predispose horses to the development of IAD, RAO, and EIPH.[484,512,513] Furthermore, the effects of influenza virus infection can be significantly exacerbated by even moderate exercise, resulting in increased weight loss and other clinical signs.[518]

Hemographic abnormalities associated with equine influenza infection can include moderate normocytic, normochromic anemia and leukopenia, which may result from both neutropenia and lymphopenia. Monocytosis during early convalescences is a variable finding.

31.15.5 Control

544
545

Vaccination against equine influenza virus infection is the foundation of influenza control. Although a wide variety of vaccine formulations, including modified live and recombinant vaccines, are commercially available, inactivated vaccines are the most common type of vaccine used. Many challenge studies have demonstrated the ability of inactivated vaccines to protect against homologous virus challenge.[497,498,519,520] However, the value of inactivated vaccines is critically dependent on the quality, quantity, and strain of virus used for vaccine preparation.[521]

Based on the finding that the H7N7 viruses have not been isolated from horses since the late 1070s,[486] the inclusion of A/equine/1 virus is no longer thought to be necessary for equine influenza vaccines. In contrast, the divergence of the H3N8 equine viruses in two distinct lineages has made the inclusion of strains representative of both the American and European lineages a desirable feature of vaccines.[433] Sustained genetic evolution of

the A/equine/2 viruses will continue to result in failure of killed vaccines, and therefore inclusion of viral antigens representative of contemporary circulating viruses has to remain a priority.

An intranasal, cold-adapted, modified live virus vaccine (FluAvert I.N., Intervet, Millsboro, Del.) has become available in North America. Whereas studies have demonstrated that the vaccine was able to confer protection for up to 12 months after a single administration, only a 6-month claim is made on the product data sheet.[508,522] Despite the fact that the vaccine contains only one modified live virus strain, which is based on the H3N8 A/Eq/KY/91 isolate, the vaccine appears to protect against both the European and the American lineages.[523] A recombinant canary pox vector-based vaccine (ProteqFlu, Merial) is also available on the veterinary market and has shown excellent performance against recent influenza virus strains.[524]

Because of the presence of maternal antibodies, recommendations for vaccination generally state not to vaccinate foals younger than 6 months of age.[525–527] For inactivated vaccines, initial vaccination should include three doses (even when the data sheet recommends only two initial doses). The timing of the first three doses is critical. The recommended interval between the first and second dose is 3 to 4 weeks. The third dose should be administered when the antibody response to the second dose has waned, which is thought to occur at 3 to 4 months after the administration of the second dose. Regardless of the recommendations provided by the manufacturer, this vaccination regimen is preferred, and contemporary inactivated vaccines are likely to perform well if this approach is taken. After the initial vaccination series, subsequent booster vaccinations should be given at 6-month intervals in high-risk populations. The modified live cold-adapted intranasal vaccine requires only a single initial dose, followed by booster doses at 6-month intervals. If a higher risk of infection is anticipated (e.g., horse show), booster doses may be administered even to well-vaccinated horses 1 to 2 weeks before potential exposure.

31.16 EQUINE HERPES VIRUSES

EHV infection is a common infection of equids throughout the world, with at least nine herpesviruses identified to date and with more likely to be identified in future.[528,529] The most important EHVs are the Alphaherpesvirinae EHV-1 and EHV-4, which both cause respiratory disease. EHV-1 commonly infects horses, donkeys, and mules and occasionally infects domestic cattle, captive camelids, cervids, and zebras; EHV-4 is restricted to horses.[528] Both EHV-2 and EHV-5, which are Gammaherpesvirinae, can be associated with respiratory disease, although their pathogenicity is low.[530] EHV-2 is distributed throughout the world and is a ubiquitous infection of the horse; this increasingly appears to be also the case for EHV-5,[531–533] which previously had been identified only in Australia and New Zealand.[530]

31.16.1 Etiology

Both EHV-1 and EHV-4 are members of the Alphaherpesvirinae subfamily of herpesviruses, in the genus Varicellovirus. These two viruses have very similar antigenic, genetic, and pathogenetic characteristics, although they are quite distinct from the major equine gammaherpesviruses (EHV-2, EHV-3, and EHV-5).[528] Both viruses are easily destroyed by solvents, detergents, disinfectants, and other common veterinary means of decontamination, but under favorable conditions they can persist in the environment for as long as a month, and in refrigerated liquids for much longer.

Both EHV-1 and EHV-4 have a linear double-stranded DNA genome of 145 and 150 kbp encoding 79 and 80 ORFs, respectively,[534–536] which can code for 77 proteins. Amino acid homology of EHV-1 and EHV-4 is 55% to 96%.[534] The gene products of EHV-1 and EHV-4 are classified as immediate early, early, or late (which include the major glycoproteins).[537–540] One genetic factor that has been identified as being associated with the occurrence of EHV myeloencephalopathy (EHM) is a mutation in the DNApol gene.[541] This mutation is present in the large majority, but not all, of the EHM isolates of EHV-1. Infection with viruses with this mutation generated higher levels of viremia in experimental infection,[542] but beyond this there is still a limited understanding of the relationship between the mutation and the pathology that results in EHM.

31.16.2 Epidemiology

EHV-1 infection causes significant suffering in horses and extensive economic losses through frequent outbreaks of a range of diseases including outbreaks of respiratory disease, abortion, neonatal foal death, myeloencephalopathy, and chorioretinopathy.[528] EHV-4 can cause respiratory disease outbreaks, but only sporadic cases of abortion rather than abortion storms. Infections caused by EHV-1 and EHV-4 are particularly common in young performance horses and typically result in establishment of latent infection within the first weeks or months of life,[543] with subsequent viral reactivation causing clinical disease and viral shedding during periods of stress.[528] As more sophisticated methods of detecting latent infection with EHV-1 and EHV-4 are developed,[544] the detectable prevalence of infection continues to rise, with the implication that EHV-free horses are very rare.

31.16.3 Pathogenesis

The pathogenesis of EHV-1 infection has been comprehensively reviewed.[528,545,546] Primary EHV-1 infection occurs at the respiratory epithelium, resulting in erosion of the upper respiratory mucosal surface and viral shedding for 4 to 7 days postinfection; shedding can occur for longer at lower levels, and possibly beyond 14 days. Cell-to-cell spread results in the presence of virus in respiratory tract lymph nodes within 12 to 24 hours postinfection. A lymphocyte-associated viremia is then established and is responsible for the delivery of EHV-1 to the pregnant uterus and other tissues. This viremia can persist for up to 21 days and is a prerequisite for abortion and EHM. In pregnant horses, EHV-1 infection can result in abortion, typically in the last 4 months of pregnancy. There are usually no signs of impending abortion, and the foal is typically expelled in the amniotic membrane having just died from asphyxia owing to placental separation. Some fetuses survive initially but then die as a result of respiratory failure caused by infection of the lungs. The pathology is of infection of endothelial cells of the pregnant uterus causing a vasculitis affecting the small arteriolar branches of the glandular layer of the endometrium at the base of microcotyledons.[528] EHV-1 myeloencephalitis results from widespread vascular injury after damage to the vascular endothelium of the blood-brain barrier resulting from viral infection of the endothelium. Vasculitis develops, with or without local hemorrhage and thromboischemic necrosis, in the brain and spinal cord. It is possible that the immunopathologic response to EHV-1 infection of the vascular endothelium of the CNS may play a part in the cause of the thromboischemic necrosis, thereby contributing to the disease process.

545
546

Latency is established in both the lymphoreticular system and in the trigeminal ganglion,[528] although lymphoid tissues are likely to be the primary home of latent virus.[544] Reactivation of latent virus frequently results in reinfection of the upper respiratory tract and further shedding of virus. Latency and reactivation are critical

features of the epidemiology of EHV-1 infection, allowing the virus to persist for lengthy periods, and in all likelihood as a life-long infection, in the majority of previously infected horses before reactivating and infecting new susceptible horses or resulting in disease in the latently infected horse itself.

Immunity to EHV-1 and EHV-4 has been extensively reviewed.[546] The protective immune response after infection is short lived (3 to 6 months), although this may increase with age and repeated exposure. High titers of virus-neutralizing (VN) antibody before infection can reduce the amount and duration of virus shed from the nasopharynx[547] but fail to prevent infection.[548] The underlying reason for this failure to prevent infection is likely to be related to the rapid intracellular location of EHV-1,[549,550] which permits escape from the effects of VN antibody. However, intracellular virus is susceptible to cytotoxic T lymphocytes (CTLs), which can lyse virus-infected cells. This CTL activity is major histocompatibility complex (MHC) class I restricted and mediated by $CD8^+$ lymphocytes.[551] Ponies with high frequencies of $CD8^+$ CTLs show a reduction in the clinical and virologic outcome of infection[552] and are protected against abortion.[553] Control of EHV-1 infection requires an immune response that not only limits primary infection but also controls reactivation of latent infections.[548] Although circulating and mucosal antibodies each play some role in protection,[547,554] the most important component of a protective immune response to EHV-1 is the CTL response.[553,555,556]

An important aspect of EHV-1 pathogenesis and immunity is the capacity of the virus to evade the immune response.[557] This may be mediated by downregulation of expression of viral proteins in infected cells[558,559] or by downregulation of host MHC-1 expression, thereby reducing antigen presentation to the critical CTL population.[560]

31.16.4 Clinical Presentation

Both EHV-1 and EHV-4 cause respiratory signs, but signs are more severe for EHV-1, as is the likelihood of viremia. Clinical respiratory disease in susceptible horses has an incubation period of 1 to 3 days. Signs include pyrexia, which is typically biphasic, with a first peak at 24 to 48 hours associated with upper respiratory tract infection and a second peak at 4 to 8 days associated with the development of viremia. Depression and anorexia are often mild, and progressive nasal discharge becomes mucopurulent by day 5 to 7. Conjunctivitis, lymphadenopathy of the submandibular lymph nodes, and edema or vasculitis of the distal limbs are variable findings. Respiratory disease, particularly as an outbreak, is uncommon in horses over 2 years of age, presumably because of recurrent exposure to the virus and development of sufficient immunity to suppress clinical signs of disease.

In neonatal foals infected with EHV-1 in utero, foals may be normal at birth but quickly become affected by weakness, lethargy, and profound respiratory distress. Prognosis is poor for survival. The abortion and EHM forms of EHV-1 are discussed elsewhere under the appropriate system.

The clinical signs resulting from infection with EHV-2 remain poorly described and established, although it may be a cause of keratoconjunctivitis and possibly upper respiratory tract disease in foals and weanlings.[530]

31.16.5 Prevention

Because of the ubiquitous nature of EHV-1 and EHV-4 infection, elimination of these pathogens from the population is impossible. Strategies must be used to prevent dissemination of the virus from horses undergoing an active infection. Vaccines are an attractive tool for this, but currently there are no products that can provide

comprehensive protection against infection and its sequelae. Inactivated EHV-1 vaccines are capable of eliciting circulating VN antibody responses, which can limit respiratory disease and nasal viral shedding, and the use of some of these vaccines has been associated with a reduction in the incidence of abortion storms.[546–548,561] Vaccines containing higher antigen loads, and typically those licensed for control of abortion, can generate high titered VN antibody responses and even EHV-1-specific IFN-γ responses.[561] Such vaccines are likely to outperform other inactivated products with lower antigen loads. The one commercially available modified live EHV-1 vaccine (MLV) generates limited EHV-specific cellular immunity[562] and has been demonstrated to reduce respiratory disease and viral shedding.[563] The use of current commercial vaccines of proven efficacy is recommended at 6-month intervals for control of respiratory disease and shedding of EHV-1 and EHV-4. Generally, vaccines effective against EHV-1 will cross-protect against EHV-4. There is no evidence that any commercial or experimental vaccine can prevent the occurrence of EHM.

No attempts are made to control infection caused by EHV-2 or EHV-5 with vaccination. However, the proposal that concurrent EHV-2 infection may play a role in the cause of *R. equi* pneumonia has led some clinicians to attempt vaccination of foals with killed EHV-2 vaccines.[564]

Biosecurity measures after detection of outbreaks of EHV-1 and EHV-4 should include isolation of affected and in-contact horses for 21 to 28 days. The virus is thought to spread primarily through contact, with a limited aerosol spread compared with influenza virus. Extensive codes of practice have been described for control of spread of EHV-1 in breeding facilities, both in publications[528] and in online resources (www.hblb.org.uk).

31.17 EQUINE ARTERITIS VIRUS

EVA is a contagious disease of horses caused by equine arteritis virus (EAV).[565] The disease was probably recognized for two centuries before the isolation of EAV in 1953.[565] Although the vast majority of EAV infections are inapparent or subclinical, occasional outbreaks occur that result in respiratory disease in adults, abortion, and fatal pneumonia in foals. These disease outbreaks have significant costs in terms of animal suffering and economic loss, and the virus now appears to occur worldwide, infecting horses, donkeys, and mules.

546

547

31.17.1 Etiology

EAV is an enveloped RNA virus and is the prototype virus of the genus Arterivirus, family Arteriviridae, order Nidovirales.[566] The genome has only nine ORFs, encoding five structural proteins, a viral replicase, and two known nonstructural membrane glycoproteins. The GL envelope glycoprotein expresses the major neutralization determinants of the virus.[567] Only one serotype has been identified, which is the Bucyrus strain derived from the 1953 disease outbreak of abortion and respiratory disease in standardbreds that first led to the definition of EVA as a clinical viral disease of horses and the identification of EAV as the causative agent.[565] Although there is only one serotype, there are extensive variations in antigenic and pathogenic properties in different isolates of the virus, which are accompanied by differences in structural protein genes. The virus is readily inactivated by lipid solvents and disinfectants, although it can survive for years at subfreezing temperatures.

31.17.2 Epidemiology

EAV is spread by the respiratory and venereal routes, and the persistently infected carrier stallion is central to its persistence and epidemiology.[565] Outbreaks of EVA frequently follow the importation of carrier stallions, and

this has been identified as an increasingly important factor in the spread of this infection throughout the world in recent years. Similarly, virus can be transported and transmitted through infected semen.

Stallions infected by the respiratory route can become carriers in 30% to 50% of cases, shedding for months to years, although some of these horses do spontaneously clear the infection. The carrier state is testosterone dependent, as castration resolves infection. In the carrier stallion the virus spontaneously generates diverse populations of viral variants, which are found in the semen of infected stallions.[568] When one of these variants is transmitted to a mare through breeding, or occasionally through semen-contaminated fomites, a new outbreak can occur if the population is susceptible.[565] Transmission by the venereal route is associated with infection rates in mares as high as 85% to 100%.[566] In this circumstance subsequent spread of the virus is by aerosol and the respiratory route, with large quantities of virus shed for 7 to 16 days.[566] During these outbreaks the EAV strain remains stable with minimal genetic change.[565] Seroprevalence varies among breeds and among countries and geographic regions; up to 85% of standardbreds but <5% of thoroughbreds are infected in the United States.[569] Because there is no variation in breed susceptibility to EVA, this difference is probably a consequence of the number of actively shedding carrier stallions in different breeds. The virulence of strains in specific breeds can vary, however, and the strains shed by standardbreds are typically highly attenuated, causing minimal disease.[565]

The immune response to infection is strong, leading to protective immunity with a duration of several years.[566] Foals born to immunized mares are protected by colostral antibodies for 2 to 6 months.

31.17.3 Pathogenesis

Both venereal and inhalation transmission of the virus occurs in EVA. After respiratory infection the virus invades the respiratory epithelium and infects bronchial and alveolar macrophages, reaching bronchial and other regional lymph nodes by 48 hours postinfection.[566] A leukocyte-associated viremia then leads to general distribution of the virus and further replication in the adrenals, thyroid, liver, and testes. The virus localizes to the endothelium and medial myocytes of blood vessels by 6 to 8 days postinfection, with endothelial damage, lymphocytic infiltration, and damage to the elastica interna of arterioles in the respiratory tract and throughout the body. This results in both hemorrhage and edema in affected organs and tissues, which is most severe approximately 10 days postinfection. Virus is eliminated by 28 days postinfection, except in carrier stallions, in which it persists particularly in the ampulla of the vas deferens.[566]

31.17.4 Clinical Presentation

The great majority of infected horses are asymptomatic. When disease does occur, the clinical signs of EVA can vary from fever and leukopenia to severe disease and death. The incubation period is 3 to 7 days. Each individual may show some of the following signs. Typically the affected animals are pyrexic, with temperatures reaching 40.5° C (105° F) for 1 to 5 days. Anorexia, depression, serous nasal discharge, lacrimation, and coughing may also occur. Edema of the limbs, palpebra, and scrotum has been reported.[566]

Abortion occurs in the acute or early convalescent phases of infection and can be the only sign of infection. Abortion can occur at 2 to 10 months of gestation, with abortion rates of 10% to 70%. Comingling of mares recently bred by an infected stallion with pregnant mares is a common scenario leading to abortion.

Neonatal foals infected with EAV show severe respiratory signs and high mortality. In foals that survive more than 24 hours, a fever and leukopenia or thrombocytopenia are present. Interstitial pneumonia, lymphocytic

arteritis or periarteritis, renal tubular necrosis, and fibrinoid necrosis of the tunic media are seen on pathologic examination. Old, debilitated, or immunosuppressed horse can be similarly predisposed to severe EVA.[565]

31.17.5 Prevention

Both a modified live and a killed vaccine against EVA have been developed in recent years.[565,566] The modified live vaccine provides complete or partial protection against the clinical signs of EVA, but viral replication still occurs after challenge. The duration of vaccinal protection appears to be as long as 2 years, although annual revaccination of breeding stallions is recommended before the start of the breeding season. The modified live vaccine has been used successfully to limit outbreaks of infe ction in race courses after initial diagnosis.[566]

The most important steps in EVA control are the identification of carrier stallions, the prevention of the development of the carrier status in future stallions through vaccination of all colts with breeding potential in the first year of life, and annual revaccination thereafter.[566] Mares being bred to carrier stallions should be vaccinated against EVA. Fresh and frozen semen from carrier stallions is also infective, and EAV-negative mares receiving infected semen should be vaccinated. Extensive codes of practice have been produced by both the USDA (www.aphis.usda.gov) and the Horserace Betting Levy Board (www.hblb.org.uk) to assist in control of EVA.

31.18 EQUINE RHINITIS VIRUS

31.18.1 Etiology

Equine rhinitis viruses (formerly equine rhinoviruses) are a known cause of clinical and subclinical respiratory infections in horses worldwide. The viruses are classified as members of the family Picornaviridae, which includes small (“pico”), nonenveloped, single-stranded RNA viruses. Among the equine rhinitis viruses, at least two serotypes have been isolated from horses: equine rhinitis A virus (ERAV) (formerly equine rhinovirus 1 [ERV-1]) and equine rhinitis B virus (ERBV) (formerly equine rhinovirus 2 [ERV-2]).[570,571]

547

548

Considerable uncertainty has surrounded the classification of the equine rhinitis viruses. Because the illness caused by these viruses resembles the common cold brought about by rhinoviruses in humans, they initially were included in the genus Rhinovirus. However, subsequent studies demonstrated that ERAV differed from other members of the Rhinovirus genus as well as from ERBV.[571–574] For example, whereas rhinoviruses generally demonstrate a narrow host cell range in vitro and in vivo, ERAV is able to infect and replicate in a broad range of cell types and host species. For instance, intranasal inoculation of a human volunteer with ERAV resulted in pharyngitis, lymphadenitis, fever, and viremia.[575] Furthermore, the presence of systemic signs and viremia during ERAV infection, the occurrence of persistent infections, and the physical properties of the virus are all more reminiscent of foot-and-mouth disease virus (FMDV). Based on these characteristics, along with similarities in protein sequences, ERAV was placed alongside FMDV in the Aphthovirus genus of the picornavirus family. Subsequently, ERBV has been reclassified as the sole member of the new genus Erbovirus.

31.18.1.1 EPIDEMIOLOGY

First isolated from horses in the United Kingdom,[576] ERAV infection occurs worldwide and is a recognized cause of acute respiratory disease.[570,577–579] The incidence of neutralizing antibody to ERAV varies

according to the age of the horses, and most horses appear to become infected during their second year of life. In a study by Studdert and Gleeson, only 16% of horses between the ages of 6 and 12 months were seropositive.[573] However, studies conducted in older horses found that a high percentage of 5-year-old horses have antibodies to equine rhinitis virus.[577,580] As with many other respiratory pathogens, young horses entering a large population and in frequent contact with other horses are most susceptible to infection.[577] In addition, there appears to be a seasonal distribution, with most of the ERAV infections occurring in late winter and spring.[581,582] Stress (e.g., transportation and training) and concurrent disease resulting in immunosuppression may predispose to infection.[583] The virus is fairly resistant to inactivation and is thought to survive in the environment for a considerable amount of time. As for human rhinoviruses, virus spread occurs most likely through direct and indirect contact (fomites).[584]

In contrast to ERAV, the prevalence and clinical significance of ERBV are less defined. A recent study found that 24% of 258 horse sera tested were seropositive for ERBV, indicating that this virus may also be prevalent in the horse population.[585] In fact, the results of a recent study suggest that ERBV may play an important role as a causative agent of clinical respiratory disease.[586] However, although ERBV was recovered from a large number of horses with acute respiratory disease, only a small percentage of animals demonstrated a concurrent rise in antibody titers for paired sera.

31.18.2 Clinical Presentation

Although ERAV is generally considered a respiratory pathogen, the clinical signs associated with infection may be quite variable. After experimental infection with ERAV, horses may develop pyrexia, anorexia, nasal discharge, pharyngitis, and lymphadenitis involving at least the submandibular and pharyngeal lymph nodes.[587] On rare occasions laryngitis or mild bronchitis can develop.[580] Based on serologic studies, subclinical ERAV infection may also occur and may be important in the dissemination of the disease.[573,581,584,587,588]

An important distinction of ERAV compared with other members of the genus Rhinovirus (e.g., human or bovine rhinoviruses) is the finding that horses infected with ERAV may develop viremia. On average, viremia lasts 4 to 5 days and the disappearance of virus from the blood coincides with the appearance of neutralizing antibodies.[587] Although the relationship between antibody levels and protection against disease has not been established, immunity is thought to be solid, and antibodies persist for a long time.[584]

Infection with ERAV may be accompanied by long-term urinary and fecal shedding as well as viral persistence.[587] The recognition of the potential for ERAV persistence has important implications for disease diagnosis. Highly sensitive diagnostic methods (e.g., IFA or RT-PCR) may be able to detect persistent ERAV in horses suffering from respiratory disease, which may not be associated with the observed illness. This notion is underlined by the recent finding that the ERAV genome was detected by RT-PCR in nasopharyngeal swab samples obtained from two clinically healthy horses 1 year after acute ERAV infection.[571]

31.18.3 Control

There is currently no vaccine available to control ERAV infection. A recent study by Warner and co-workers demonstrated that the capsid protein VP1 participates directly in viral receptor binding.[589] VP1 is a major surface antigen and therefore may serve as a potential target for vaccines.

31.19 EQUINE ADENOVIRUS

31.19.1 Etiology

Adenoviruses (family Adenoviridae) are a group of nonenveloped, icosahedral DNA viruses. Whereas most vertebrate species harbor an adenovirus, the viruses are highly species-specific. In humans, adenoviruses are extremely prevalent and represent a significant cause of acute respiratory, ocular, and GI disease. Infections of immunocompetent individuals usually stay localized and often take a mild or subclinical course.[590] Similarly, equine adenoviruses have been isolated from clinically healthy adult horses[591] and foals.[592,593] Equine adenovirus (EAdV)–1 has been implicated as the cause of acute respiratory tract disease[594,595] and conjunctivitis, as well as a progressive, fatal pneumonia in Arabian foals with SCID.[596–598] A second serotype, EAdV-2, has been incriminated as a cause of intestinal infection[599,600] and diarrhea in immunocompetent foals.[601,602]

31.19.2 Epidemiology

First isolated in 1969 from a foal with respiratory disease,[603] EAdVs have a worldwide distribution.[604] Although serologic evidence from Australia, the United Kingdom, the United States, the Netherlands, and Nigeria indicates that adenovirus infection occurs at a high frequency in the general horse population,[605–608] the role of EadV in respiratory disease in adult horses remains unclear. In this regard it is interesting that a number of studies found no apparent association between clinically apparent respiratory disease in young adult horses and infection with adenovirus, as diagnosed by subsequent seroconverison.[588,609,610]

In contrast, fatal and nonfatal adenovirus pneumonia has been well documented in foals, particularly of the Arabian breed. Fatal respiratory disease is predominantly seen in foals with SCID. Other foals may develop respiratory disease but usually do not succumb to it.

In general, adenovirus transmission is thought to occur via direct contact with secretions from infected animals or indirectly via fomites or infected premises. In adult horses the virus can persist in the upper respiratory tract, and these animals can act as a reservoir host for the virus. Adenoviruses are highly stable and have been found to remain infectious at 4° C for up to 1 year.

548 549

31.19.3 Clinical Presentation

The clinical signs recorded after experimental intranasal infection of a thoroughbred yearling were confined to a serous nasal discharge that lasted from 4 to 12 days postinoculation. Peak levels of serum antibodies were found at 13 days after inoculation and dropped by approximately 2 months after experimental infection.[611]

In foals, clinical signs generally occur at 10 to 35 days of age.[612] After experimental inoculation at 24 hours of age, clinical signs appeared 3 to 5 days after infection and consisted of intermittent pyrexia, nasal and ocular discharge, tachypnea, and cough. All foals recovered by day 10 postinoculation. The majority of foals developed a mild and transient lymphopenia that was followed by lymphocytosis. Typically, about 25% of infected foals also develop diarrhea.[612] Gross pulmonary lesions found in animals euthanized at 14 to 21 days postinoculation included atelectasis involving up to 25% of the pulmonary parenchyma and suppurative bronchopneumonia.

Histologically, swelling and hyperplasia of the airway epithelium, as well as intranuclear inclusion bodies in the respiratory epithelial cells, were consistent findings up to 11 days postinfection.[613]

Foals with SCID show a progressive decline in health despite intensive therapy. At necropsy, conjunctivitis, rhinitis, tracheitis, and bronchopneumonia are present. Intranuclear inclusion bodies are readily demonstrated in the respiratory epithelial cells. Areas of interstitial pneumonia surround affected bronchi. Acute pancreatitis characterized by inclusion bodies in acinus and ductal cells, as well as adenoviral sialoadenitis involving the labial and parotid salivary gland, can often be demonstrated.[600,614]

31.19.4 Control

No vaccine is available to control adenovirus infection in horses. However, except in immunocompromised animals, the virus appears to be of little clinical importance.

31.20 HENDRA VIRUS

In August 1994, two horses died suddenly on a property in Mackay, Queensland, Australia. Ten days after the death of the second horse, the owner was admitted to the hospital with meningitis. One month after the incident in Mackay, 13 horses housed at a stable in Hendra, Queensland, died or were euthanized owing to severe respiratory illness. Subsequently the trainer and one of the stable workers developed an influenza-like illness, to which the trainer succumbed 6 days later. Potential diagnoses included African horse sickness and equine influenza, although they were exotic to Australia. Yet, during postmortem examination, a novel paramyxo-like virus was isolated from tissues of the affected horses and the trainer.[615] The virus, first referred to as *equine morbillivirus*, was subsequently named *Hendra virus*.

31.20.1 Etiology

HeV is a member of the genus Henipavirus (which also contains Nipah and Menangle viruses) within the Paramyxoviridae virus family. Paramyxoviruses, like orthomyxoviruses (see discussion of equine influenza), are enveloped viruses that contain a negative-sense, single-stranded RNA genome. HeV has unique morphologic characteristics that are useful for diagnostic purposes.[616] Electron microscopy reveals pleomorphic enveloped particles that contain a helical nucleocapsid that is characteristic for paramyxoviruses. The envelope is covered with spikes of 10 and 18 nm length, which gives the particle a unique “double-fringed” appearance.[617] Owing to the fact that HeV contains a host cell—derived lipid envelope, inactivation of the virus is possible using compounds that disrupt the lipid envelope (e.g., lysol, sodium dodecyl sulphate [SDS], acetone, methanol).[618]

31.20.2 Epidemiology

HeV is able to cause natural disease in humans and horses[615] and experimentally induced disease in cats, guinea pigs, and mice.[619,620] The virus naturally infects bats of the suborder Megachiroptera, in which infection does not seem to cause clinical disease.[621,622] These bats are considered to be the natural reservoir of HeV, yet the method of transmission from bats to horses is unknown. Although the virus transmits readily between bats, it does not appear to spread easily between horses or from horses to humans. This notion is highlighted by the finding that no disease spread occurred to other nearby stables during the outbreaks in 1994.[623] In addition, not all horses on the premises became infected, and horses placed in uncleaned stalls that previously contained

animals that succumbed to the disease did not become infected. Under experimental conditions, transmission did not occur between infected and in-contact horses.[624] However, natural transmission among mammalian species can occur but seems to require very close contact.[619] Despite the fact that intermammalian transmission of HeV appears to be relatively rare, the virus has the potential to cause lethal zoonotic infection and therefore poses a serious public health and occupational safety risk for veterinarians.

31.20.3 Pathogenesis

Experimentally, horses can be infected after parenteral and oronasal challenge.[615,624] Infection is characterized by the systemic distribution of the agent. After experimental infection of horses and cats, virus was isolated from the buccal cavity, blood, brain, spleen, lungs, bronchial lymph nodes, kidneys, and urine.[619,620,624] Based on the finding that virus is shed in the urine of experimentally infected animals, it has been speculated that consumption of food contaminated by urine of infected horses may serve as a method of transmission under natural conditions. However, although virus was present in the urine of horses that had died of natural HeV infection, investigators failed to recover HeV from the floors of the stalls in which the animals had been housed.[624]

31.20.4 Clinical Presentation

In horses, HeV infection is characterized by an acute, febrile respiratory illness that is sometimes accompanied by facial swelling, ataxia, head pressing, and recumbency. Frothy nasal discharge and tachycardia are considered to be indicators of imminent death. The course of disease in infected horses is short, with animals dying within 36 hours after onset of clinical signs. Experimentally the incubation period is 6 to 12 days. Although only one of eight experimentally infected horses recovered, seven infected horses survived during the field outbreak at Hendra. However, two of these horses subsequently developed neurologic signs, which consisted of tonic spasms of the muscles of the neck and hind limbs.[625]

At necropsy the most significant lesions are the severely congested, firm, and fluid-filled lungs. In some cases fibrin tags are present on the pleural surface. Histologically, HeV infection is associated with interstitial pneumonia with proteinaceous alveolar edema and hemorrhage. Possibly the most remarkable histologic finding is the presence of syncytial giant cells in the endothelium of pulmonary blood vessels. If examined under the electron microscope, these giant cells contain cytoplasmic inclusion bodies containing the characteristic nucleocapsid structure of paramyxoviruses.[618]

549

550

As only three cases of human HeV infection have been reported, the disease syndrome associated with infection is poorly defined. One patient developed severe, fatal respiratory illness, and a second patient developed a self-limiting influenza-like illness.[626] The third patient succumbed to severe HeV encephalitis more than a year after initial infection.[627]

31.20.5 Control

To date, no vaccine or antiviral therapy is available to control HeV infection. The outbreak in Australia was controlled by a stamping-out program involving slaughter of all known infected horses, quarantine of premises, control of animal movement in defined zones, and serologic surveillance.

31.21 EQUINE LUNGWORM

JULIE ROSS

The nematode *Dictyocaulus arnfieldi* can affect donkeys, horses, ponies, and zebras and is found throughout the world.[628] Donkeys are believed to be the natural hosts of *D. arnfieldi*, with a reported prevalence of infection of 51% to 73%.[629,630] Clinical signs of *D. arnfieldi* infection are rarely seen in donkeys, and individual animals have been found to maintain patent, nonclinical infection for over 5 years in the absence of effective anthelmintic treatment.[631] Horses (and ponies) are abnormal *D. arnfieldi* hosts. The prevalence of *D. arnfieldi* infection in horses is difficult to establish, as infection is usually nonpatent owing to retardation of larval maturation in the lungs.[632] Clayton and colleagues[629] found that 5.88% of horses living in contact with donkeys had patent *D. arnfieldi* infection. A study of thoroughbred horses in Kentucky by Lyons and co-workers[633] found *D. arnfieldi* to be present in the lungs of 11% of horses at postmortem examination (on individual farms, a prevalence of up to 83% was found). In horses with documented parasite infection, only 30% had patent *D. arnfieldi* infection (documented via a modified Baermann's technique). Most parasites identified in the pulmonary tissues were larval stage 5 (L5), with few sexually mature adults being found. A study of 5437 live equids revealed a prevalence of patent *D. arnfieldi* infection of 2% and 0% in horses and ponies, respectively.[634] In contrast, patent *D. arnfieldi* infection was identified in 68% of donkeys and 30% of mules. These studies highlight the difficulty of identifying *D. arnfieldi* infection in horses and ponies. Patent *D. arnfieldi* infection can be more easily established in pony foals than in adults. Necropsy examination of these foals revealed no evidence of retardation of larval development, with sexually mature adult parasites frequently being identified.[629]

D. arnfieldi has a direct life-cycle. L1 hatches shortly after eggs are passed in the feces, and the larvae undergo two molts before they enter a free-living, infective stage (L3). The development of L3 can occur in 4 days. *Pilobolus* fungi may play a role in the dissemination of *D. arnfieldi* larvae from feces.[635] L3 is ingested by the host and penetrates the intestinal mucosa before passing to the mesenteric lymph nodes, where molting occurs. L4 organisms travel, via lymph and blood, to the lungs and break out of the capillaries into the alveoli. Molting from L4 to L5 occurs in the bronchioles, and maturation to the adult form occurs in the small bronchi.[628] Eggs are laid in the bronchi and then transported via the mucociliary clearance apparatus to the pharynx, where they are swallowed and eventually passed in the manure. The prepatent period of *D. arnfieldi* is 2 to 4 months.[635] Clinical disease can be seen as early as 12 days after ingestion of infective larvae.[628] The parasite has a limited survival time in the environment (49 days in warm soil) and cannot overwinter on pasture.[632] Fecal larval production in donkeys increases through the spring and summer months,[636] and environmental conditions favor development of patent infections in late summer and autumn.

Transmission from donkeys to horses is thought to be the main source of infection in horses, but horse-to-horse transmission does occur, thus clinical disease cannot be ruled out based on lack of contact with donkeys.[634,629] In one study 67% of farms on which horses with patent *D. arnfieldi* infection were stabled had no history of occupancy by donkeys.[634]

Clinical disease associated with *D. arnfieldi* was identified in 2.6% of horses presented to a referral clinic for evaluation of suspected pulmonary disease.[637] The average age of the population identified as being infected with *D. arnfieldi* was 5 years. Clinical signs of *D. arnfieldi* infection in horses have been described. One study identified coughing in 100% of cases, with nasal discharge (42.9%), abnormal tracheal auscultation (42.9%), dyspnea

(33.3%), and abnormal thoracic auscultation (28.5%) being identified less frequently.[637] Other clinical signs that have been described include paroxysmal coughing, increased expiratory effort, and audible wheezes and crackles on auscultation.[632] Many reports of lungworm infection describe a chronic disease process; however, in a study involving seven *D. arnfieldi* cases, three cases were of acute onset. It is possible that these animals had concomitant bacterial or viral disease or that the initial lungworm challenge resulted in acute clinical signs.[637] Although clinical disease is rare in donkeys, *D. arnfieldi* infection has been associated with increased susceptibility to respiratory viruses (e.g., influenza).[637]

As discussed earlier, identification of *D. arnfieldi* infection using a modified Baermann's technique frequently results in false-negative results.[629] Clinical signs of nonpyrexic, chronic respiratory disease, possibly with a history of contact with donkeys, may be suggestive of *D. arnfieldi* infection if other causes of respiratory disease have been ruled out. Dixon and colleagues[637] associated a marked increased in eosinophil ratio in BALF and tracheal secretions with *D. arnfieldi* infection if there was concurrent evidence of lungworm larvae in the airways or respiratory secretions or if the eosinophilic nature of the respiratory secretions resolved with appropriate anthelmintic treatment. Respiratory secretion eosinophilia may be a useful indicator of lungworm infection; however, this finding can also be seen in eosinophilic pulmonary disease[637,638] and during transient migration of *P. equorum*.[628] Clinical disease with *P. equorum* is most commonly seen in young horses and ponies. Tracheobronchial aspirates and BALF obtained from normal horses are expected to contain few (<3%) eosinophils[639]; however, significant respiratory secretion eosinophilia has been identified in horses with no apparent respiratory disease.[640] Eosinophilia in respiratory secretions is therefore suggestive of but not pathognomic for *D. arnfieldi* infection. Repeat evaluation of respiratory secretions after *D. arnfieldi* treatment should reveal a marked improvement in eosinophilia ratio in lungworm cases.[640] *D. arnfieldi* larvae have been identified during microscopic examination of centrifugated respiratory mucus before fixing and staining have been performed, and it is suggested that such evaluation is an important diagnostic tool.[632] Peripheral eosinophilia has not been definitively correlated with lungworm infection.[641] At necropsy, a modified Baermann's technique can be applied to diced lung tissue to aid in the identification of larvae.

550

551

Treatment for *D. arnfieldi* infection includes effective anthelmintic treatment, removal from contact with donkeys, and moving horses and ponies to a pasture not grazed by donkeys since the previous autumn. Effective anthelmintics include moxidectin,[642] ivermectin (active against mature and immature parasite stages),[629,643] and mebendazole (16–20 mg/kg for 5 days).[644] Fenbendazole has been shown to improve clinical signs of presumed *D. arnfieldi* infection; however, suppression of fecal shedding was maintained for less than 4 weeks with doses up to 30 mg/kg.[641] Treatment with 200 µg of ivermectin per kilogram, along with a pasture change after treatment, resulted in complete improvement in six of seven *D. arnfieldi* cases and partial improvement in one case.[645] Treatment of donkeys should be instituted to decrease transmission to horses and ponies and potentially to decrease the donkey's susceptibility to other respiratory diseases.[636]

Necropsy findings in donkeys and horses with *D. arnfieldi* infection are similar.[646,647] Gross findings include circumscribed areas of raised pulmonary tissue (3 to 5 cm), more commonly found in the caudal lung lobes. Sectioning of these areas reveals overinflated pulmonary tissue surrounding small bronchi that are packed with mature *D. arnfieldi*. Small airways in these areas tend to be occluded with exudate. Histologic examination of the pulmonary tissue reveals diffuse eosinophilia throughout the pulmonary tissues, especially around the airways. A marked inflammatory reaction is found around parasitized bronchi, with heavy lymphoid cell infiltration of epithelium, lamina propria, and peribronchial tissue. Epithelium becomes hyperplastic, and mucus-secreting cells

increase in size and number. Little cellular or mucoid reaction is seen in bronchial lumen around adult parasites; however, free larvae in bronchial lumen result in intense mucopurulent reaction. Bronchioles in affected areas of the lung usually show evidence of bronchiolitis, with free mucus present in the lumen of bronchioles and hyperplastic, columnar epithelium. Bronchioles are most commonly surrounded by discrete lymphoid nodules. Pulmonary pathology in donkeys tends to be very localized with much of the lung appearing normal on histologic examination.[646]

Prevention of *D. arnfieldi* infection in horses and ponies involves effective anthelmintic treatment and pasturing horses and ponies separately from donkeys or treating donkeys with appropriate anthelmintic treatment to avoid patent infection. Anthelmintic treatment is especially important in the spring. Regular removal of manure from pasture can also help to decrease the parasite load in the environment.

31.22 THORACIC TRAUMA

JANE E. AXON

Thoracic trauma results from blunt or penetrating injuries to the chest wall. Trauma can result in thoracic wounds, hemothorax, pneumothorax, fractured ribs, and diaphragmatic hernia, and a combination can occur in the same horse. Prompt assessment and implementation of emergency procedures in the injured horse with respiratory distress in the field is vital to optimize the horse's chances for survival.[648]

Clinical signs associated with injury to the thorax can vary from mild musculoskeletal pain and a stiff gait to severe respiratory distress and hypovolemic shock. Signs of respiratory distress include anxiety, tachypnea, nostril flaring, cyanotic mucous membranes, tachycardia, and an altered respiratory pattern. Auscultation and percussion of the thorax may assist with locating and identifying the lesions. Percussion and palpation will need to be performed carefully in horses in pain. Palpation of SC emphysema in the absence of an external wound may be associated with a lacerated lung or tracheal trauma and in a dyspneic horse should raise the suspicion of a concurrent pneumothorax.[649] The injured horse may also have weak pulses, pale mucous membranes, and tachycardia resulting from acute hemorrhage from lacerated intercostal or pulmonary parenchymal vessels. Evaluation of the abdomen should also be undertaken. On expiration the cranial portion of the diaphragm extends to the sixth rib; therefore an abdominocentesis should be performed on a horse with a wound caudal to the sixth rib or with a deep penetrating wound to assess abdominal involvement.[648] Further evaluation of the injured horse will include thoracic radiographs, ultrasonographic examination, and exploration of the wound. Arterial blood gas analysis will assist in determining the extent of hypoventilation.

Open thoracic wounds should be covered immediately to prevent additional air from entering the chest cavity.[649] Plastic food wrap wrapped around the thorax or a gauze roll or towel sutured in place can be used. A tension pneumothorax, which may occur with sucking thoracic or axillary wounds, can be alleviated by inserting a trocar into the dorsal pleural space so pleural and atmospheric pressures can equilibrate and a less compromising pneumothorax is created.[648] Intranasal oxygen therapy and removal of air from the thorax may be necessary to improve alveolar ventilation and oxygenation in a horse with pneumothorax before further evaluation. Circulatory support may be necessary until hemorrhage has stabilized.[648] Sedatives and tranquilizers should be used judiciously because most cause respiratory depression; however, they may have to be used if the horse's anxiety precludes instituting treatment.

31.22.1 Hemothorax

Thoracic trauma resulting from lacerations to pleural or pulmonary vessels or rupture of large thoracic vessels may result in hemothorax. Other causes of hemothorax include rupture of lung parenchymal bullae, vessel erosion by severe lung abscessation or neoplasia, hemangiosarcoma, spontaneous hemorrhage at maximal excursion, and coagulopathy.[650,651] Iatrogenic causes include tube thoracostomy and lung biopsy. Hemothorax can be unilateral or bilateral depending on the cause and whether the mediastinum is complete.

Diagnosis is based on clinical signs, radiographic and ultrasonographic findings, and laboratory evaluation of the fluid obtained from thoracocentesis.[650] The horse may be dyspneic and tachycardic, depending on the volume of blood loss into the pleural cavity. On auscultation there is a decrease in normal breath sounds ventrally, and heart sounds are often muffled and radiate over a wider area.[650] Percussion reveals a change from the normal resonance of aerated lung to dullness over the hemothorax.[650] Thoracic radiographs show opacity of ventral lung fields, with an associated horizontal fluid line and a loss of diaphragmatic and cardiac silhouettes.[652] Ultrasonography shows fluid within the pleural cavity with a characteristic hypoechoic to echogenic smoke swirling pattern.[653] Fluid collected by thoracocentesis should be submitted for cell count, packed cell volume, and total protein. A cytologic evaluation should also be performed to determine whether there is evidence of infection or neoplasia, and the sample should be cultured if an infection is suspected. A clotting profile and platelet count should be performed if a coagulopathy is suspected. Hematology and biochemistry should also be performed, as the horse may develop anemia and hypoproteinemia associated with the blood loss.

551

552

Treatment is aimed at stabilizing cardiopulmonary function and treating the underlying cause. Horses with hemothorax from nonpenetrating thoracic trauma or a noninfectious cause can be managed conservatively with intranasal oxygen insufflation, analgesics, IV fluids, or whole blood transfusion if the blood loss is severe. If the horse is not hypoxemic or in respiratory distress, rest alone and close monitoring may suffice. Even if respiratory distress is evident, a tube thoracostomy and drainage of blood may not be necessary.[651] Drainage of the thorax is not recommended in horses with a coagulopathy unless severe respiratory distress is present.[651] If there is a penetrating wound or evidence of infection, drainage should be attempted by ultrasound-guided ventral placement of chest drains. This, however, should not be undertaken until the hemorrhage has stopped and the circulating blood volume has been restored.[654] All horses, even without evidence of infection, should have broad-spectrum antimicrobial coverage, as blood is an excellent medium for bacterial growth.[650]

The prognosis for horses with uncomplicated trauma and hemothorax is good. If the hemothorax is the result of a penetrating wound, the prognosis is poor.

31.22.2 Pneumothorax

Traumatic causes of pneumothorax include puncture or laceration of the trachea, ruptured esophagus, penetration of foreign objects into the thoracic cavity, external wounds resulting in SC emphysema and pneumomediastinum, and direct penetrating or blunt trauma to the lung parenchyma.[650,655–657] Pleuropneumonia is also an important cause of pneumothorax; in one study 17 of 40 horses had pneumothorax resulting from pleuropneumonia.[655] Air can escape into the pleural cavity through slow leaks from necrotic lung or through formation of bronchopleural fistulas. Additional causes of pneumothorax include ruptured

emphysematous lung bullae, maximal exercise, and iatrogenic causes such as tube thoracostomy, lung biopsy, mechanical ventilation, and transtracheal aspiration.[650,651]

Pneumothorax can be described as *closed*, in which air from the lung is trapped in the pleural space, or *open*, in which there is free communication between the pleural space and external environment and air is sucked into the pleural space with inspiration. A tension pneumothorax occurs when air accumulates in the thorax until intrapleural pressure exceeds atmospheric pressure. This is often seen with a sucking pleurocutaneous wound as air moves into the chest cavity with inspiration and, owing to a valve effect of the wound, cannot escape during expiration.[649] Intrapleural pressure may increase to such an extent that the thorax becomes fixed in maximal extension. This leads to severe cardiopulmonary effects with decreased venous return to the heart because of vena cava compression and hypoxemia.[658,658a] Pneumothorax is usually bilateral because of the incomplete mediastinum of horses; however, it may be unilateral if the fenestrations in the mediastinum are blocked as a result of inflammation or a collapsed lung.

Diagnosis is based on clinical signs, aspiration of air from the pleural cavity, and radiographic and ultrasonographic findings.[650] Clinical signs that can be associated with pneumothorax are dyspnea, tachypnea, cyanosis, and evidence of trauma.[650] Characteristic findings on auscultation are a decrease or lack of normal breath sounds dorsally and tympany and hyperresonance on percussion; however, these clinical signs can vary and are not reliable.[655] Concurrent SC emphysema may complicate interpretation. However, if a horse with SC emphysema is dyspneic or distressed, pneumothorax should be suspected unless the emphysema is causing airway compression.[650] Thoracic radiographs show lack of pulmonary vasculature in the dorsal aspect of the caudal lung fields and ventral displacement of the dorsal lung margin (Fig. 31-35). On ultrasonographic examination there are parallel horizontal lines of air artifact reverberation without the pattern of pleura and "comet tail" artifacts. The dorsal air image also moves ventrally with inspiration over underlying collapsed lung or pleural fluid, creating a "curtain" image.[653] SC emphysema in tissue and fascial planes may prevent accurate sonographic imaging. Aspiration of air from the thorax is also diagnostic, as is the associated improvement in clinical signs.

Treatment is aimed at improving alveolar ventilation by correcting the pneumothorax, if the horse is showing signs of respiratory distress, and treating the underlying cause. Treatment of simple pneumothorax requires rest and close observation while gradual reabsorption of air occurs. If hypoxemia (Pa_{O_2} < 80 mm Hg, percent oxygen saturation [$\%O_2$sat] < 90%) or dyspnea is present, nasal insufflation of oxygen (15 L/min) should be administered.[654] An open sucking wound should be occluded. Air is removed from the pleural space by inserting a teat cannula or thoracostomy tube, with a suction device attached, into the dorsal thoracic cavity. If a suction machine is not available, repeated aspiration with a 60-ml syringe through a three-way stopcock valve and or tubing attached to the teat cannula and run into a container of water can be used.[649] The latter acts as a simple water trap, allowing air to be expelled during inspiration while preventing air movement back into the chest with expiration.[649] If the pneumothorax reoccurs or continues, tubes should be left in place to allow constant air removal. A Heimlich chest drainage valve* provides continual drainage and if correctly placed is effective for long periods. In long-standing cases, gradual reexpansion of the lungs is recommended to avoid reexpansion pulmonary edema.[650] Prophylactic broad-spectrum antimicrobial therapy is recommended as long as the tube is in place. If the cause of pneumothorax requires correction under general anesthesia, ventilation should be improved before induction by removing air from the pleural cavity and correcting lung atelectasis.

The prognosis for horses with pneumothorax is good, providing infections can be successfully treated and air leaks are sealed. Pneumothorax associated with pleuropneumonia and parenchymal lesions resulting in air leakage carry a poor prognosis and with an esophageal rupture carry a very poor prognosis.[650,655]

* Heimlich chest drainage valve, Bard-Parker, Division of Becton-Dickson Co., Rutherford, NJ.

31.22.3 Rib Fractures

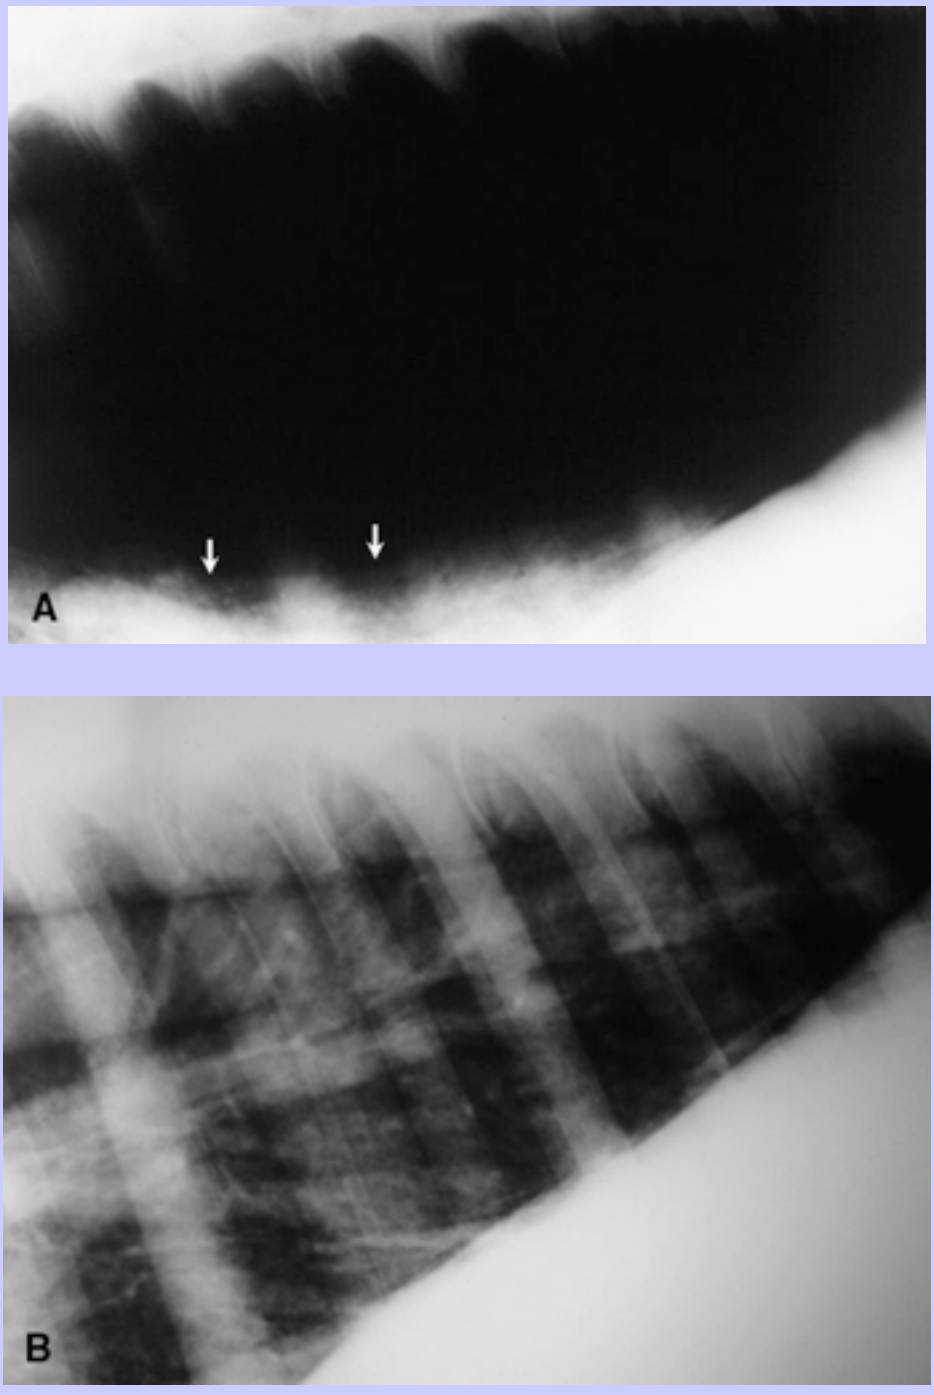
Fractured ribs are most often a result of an accident or kick; however, in neonates fractured ribs are commonly associated with birth trauma.

31.22.3.1 ADULTS

Fractured ribs can be detected either through exploration of the wound or by eliciting a pain reaction on palpation over the affected area. Crepitus associated with a closed fracture is often not detected. Shallow breaths and guarded thoracic movements may be seen as a result of pain from the fracture. Soft-tissue swelling and SC emphysema may also be present. Fractured ribs in adults usually heal without fixation; however, if pain and excessive movement of rib ends are present, surgical correction may be warranted. Stabilization of a flail thorax is usually not necessary unless there is respiratory compromise.[649] NSAIDs, circumferential bandaging, and intercostal nerve blocks assist with providing pain relief. Open fractures should be explored and debrided, and soft tissue repaired.[649] The horse should be closely monitored for respiratory distress or hemorrhage, as a closed pneumothorax or hemothorax may result if a fractured rib end lacerates underlying lung parenchyma or vessels.[648]

552
553

Fig. 31-35 **A**, Lateral radiographic view of the caudal dorsal portion of the thorax of a horse with bilateral pneumothorax. The dorsal borders of the lung margin are *arrowed*. **B**, Same view after thoracocentesis and resolution of the pneumothorax.



31.22.3.2 FOALS

Blunt thoracic trauma during parturition resulting in costochondral dislocation or rib fracture is more common in foals from primiparous mares and dystocias.[658a] The majority of fractures are subclinical; however, sudden death, hemothorax, hemopericardium, lacerated myocardium, pneumothorax, diaphragmatic hernia, and severe respiratory distress can occur.[658a,659] The incidence of fractured ribs in newborn foals on one farm was 21% (55 of 263), and none had clinical signs associated with the fracture after a 6-month period.[658a] However, in other reports rib fractures accounted for 13% of life-threatening fractures in foals less than 7 days of age, and in a necropsy study 19 of 67 foals with fractured ribs (28%) died as a direct result of rib fracture.[659,660] The most common site of injury is the cranioventral half of the thorax at the costochondral junction or adjacent dorsal area.[659] Clinical signs are variable and include pain on rib palpation, “clicking” or crepitation on auscultation, edema localized over or ventral to the fractured ribs, and signs of pain including grunting or groaning when the patient is manipulated or lying on the affected side. Palpation of crepitus over the fractured site is not a consistent finding. If the foal is systemically stable, asymmetry of the thoracic cage can be evaluated if the foal is positioned in dorsal recumbency.[658a] In severe cases involving multiple consecutive ribs, the foal can be in respiratory distress with a flail thorax. Foals may also exhibit respiratory distress with pneumothorax. Pale mucous membranes can be indicative of internal hemorrhage and abdominal hemorrhage, and diaphragmatic hernia should be considered if the diaphragm has been lacerated. Radiographs for detection of fractured ribs in neonates is not reliable.[659,661] Ultrasonographic examination is more reliable and also assists in evaluating the adjacent structures and presence of hemothorax or pneumothorax (Fig. 31-36). Conservative treatment with box rest and supportive care is successful in the majority of uncomplicated rib fractures; however, surgical repair has been performed in patients with multiple rib fractures or those with potential for severe internal injury.[661,662] Specific treatments based on the internal injuries should also be implemented.

31.22.4 Diaphragmatic Hernia

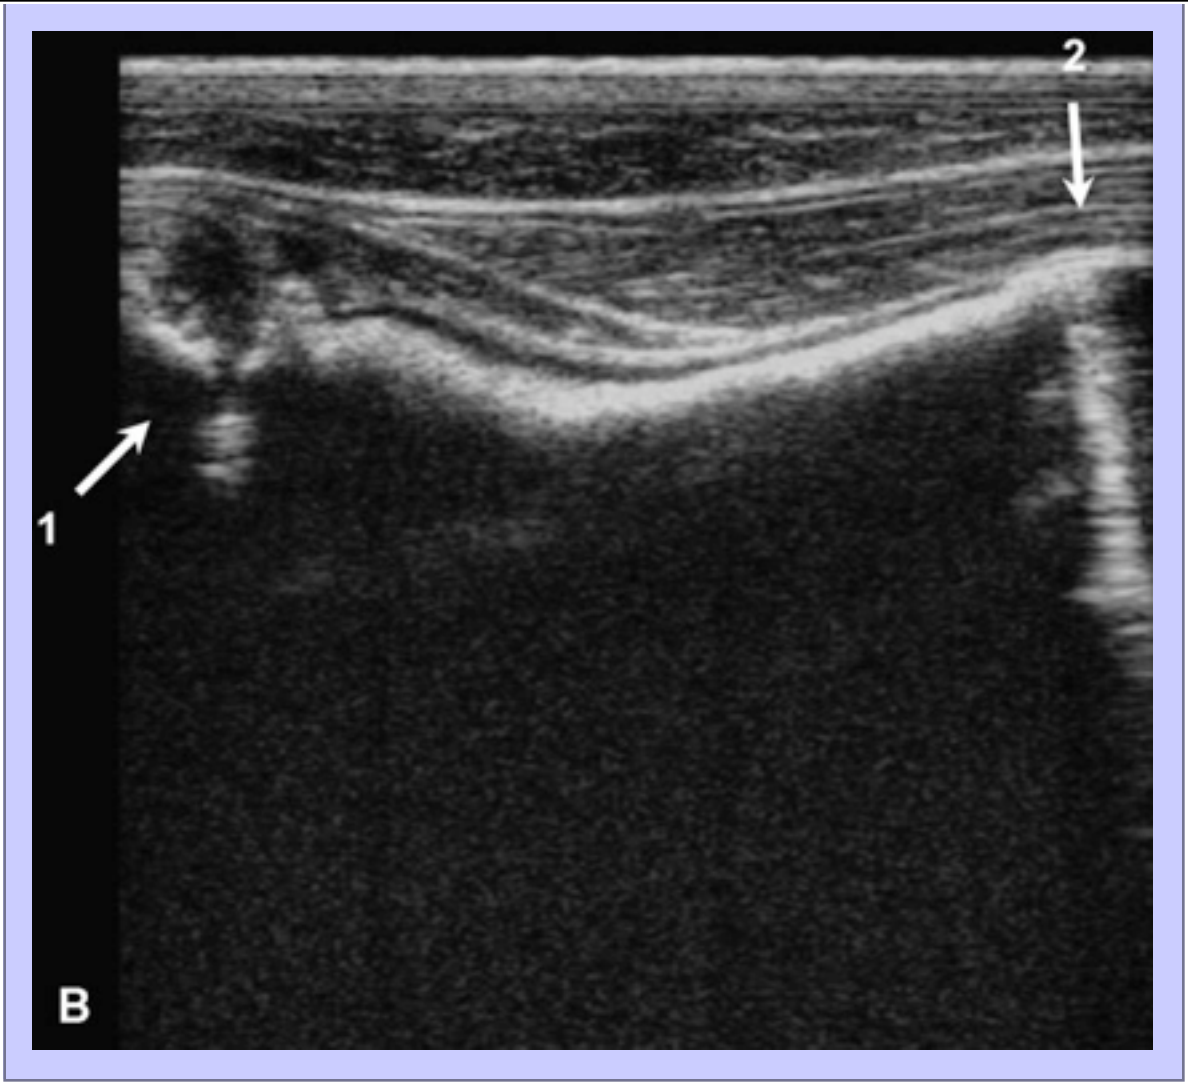
Diaphragmatic hernias occur sporadically in horses.[663,664] Occurrence is usually associated with a history of trauma or sudden increase in abdominal pressure and exertion, as may be experienced by stallions during breeding or mares during parturition.[664] In one study, 48% of 50 horses diagnosed with diaphragmatic hernia had a history of recent trauma.[663] In some cases no history of injury or predisposing cause can be identified.[664] Congenital diaphragmatic hernia can occur owing to incomplete fusion of any of the four embryonic components of the diaphragm or as a result of abdominal compression during parturition.[665] A congenital peritoneopericardial hernia has been reported.[666] Congenital hernias are typically located in the most ventral portion of the diaphragm, whereas diaphragmatic defects from trauma are usually located at the junction of muscular and tendinous portions of the diaphragm.[665] The size and position of the defect are important in determining whether herniation of abdominal viscera occurs.[664,667] Any segment of intestine can be involved, although small intestine is the most frequent.[665]

Clinical signs usually relate to intestinal obstruction or respiratory compromise; however, less specific signs of exercise intolerance and weight loss have been reported.[664] A diaphragmatic hernia may also initially be clinically silent if there is minimal pulmonary or bowel compromise. GI-related clinical signs are variable and depend on the segment and amount of intestine herniated and whether it is simply displaced, incarcerated, or

strangulated.[664] Frequently reported clinical signs are colic, moderate to severe tachypnea, and endotoxic shock. Respiratory signs of tachypnea can be attributed to pain at the site of injury or GI tract, shock, and lung compression and decreased ventilation.[664,667,668] Acute tearing of the diaphragm may be associated with hemorrhage into both thoracic and abdominal cavities.

Diagnosis can be challenging, and thoracic radiographs showing abdominal organs within the thoracic cavity are considered most diagnostic.[664,667] Ultrasonographic examination may show abdominal organs in the thoracic cavity; however, viscera may not be seen if covered by aerated lung or located away from the thoracic wall.[653] Rectal examination often suggests a relative lack of normal abdominal viscera. Auscultation of the thorax may reveal GI sounds, but it is usually not possible to differentiate from sounds referred from the abdomen. There may also be an absence of breath sounds ventrally and associated dullness on percussion, although these findings are not reliable. Abdominal paracentesis is usually normal and can be misleading because the compromised intestine is in the thorax, and therefore thoracocentesis may be more representative.[664] Thoracoscopy may also assist visualization of the hernia; however, partial deflation of the lungs is necessary to visualize the diaphragm, which may further compromise the patient.[658,667]

Fig. 31-36 **A**, Fractured rib *(arrow)*. Sagittal view. Left is dorsal. **B**, Healing fractured rib *(1)* and costochondral junction *(2)*. Sagittal view. Left is dorsal.



Surgical repair of diaphragmatic hernias has been reported but is fraught with complications associated with anesthesia, resection of devitalized bowel, anatomic location, and repair of the defect and possible fractured rib repair.[664] In chronic cases with few or no clinical signs, repair does not appear to be necessary, although complications associated with herniated viscera may eventually occur.[665,669]

31.23 PULMONARY EDEMA

PAMELA A. WILKINS

Pulmonary edema rarely occurs as a primary event in the horse and, when present, is usually secondary to some other pathologic process. Extravascular fluid accumulates within the lung after events that alter hydrostatic and colloid osmotic interstitial and vascular forces, change the surface area and pore size of the blood gas barrier, or diminish lymphatics drainage.[670] Pulmonary edema can be classified as cardiogenic or noncardiogenic. Pulmonary capillary pressure can be increased by any increase in left atrial or pulmonary artery pressure. In the horse this can occur secondary to acute renal failure, left ventricular failure, or very high cardiac output conditions, such as

extreme exercise. Increases in microvascular permeability may occur with sepsis, disseminated intravascular coagulation, hypoxic acidosis, or primary pulmonary pathology, resulting in the release of mediators of inflammation that increase vascular endothelial or alveolar epithelial permeability. Pulmonary edema associated with airway obstruction has been termed *negative-pressure pulmonary edema* (NPPE) and has been reported in horses.[671,672] NPPE occurs secondary to inspiratory efforts against a closed glottis that result in a precipitous fall in intrathoracic pressure. The large decrease in intrathoracic pressure increases the transmural pressure gradient for all intrathoracic vascular structures, favoring movement of water into the extravascular space.

Diagnosis is based on clinical examination, a history of predisposing causes, and radiographs. Horses have a shallow rapid respiratory pattern and may be dyspneic. Arterial blood gas analysis may reveal hypoxemia and hypercapnia. Fine crackles or wheezes may be audible on auscultation. Patients with volume overload (associated with renal failure or, rarely, too-rapid fluid administration) or primary cardiac problems may have an increased central venous pressure with pronounced venous distention. Fluid (clear or slightly yellow or pink-tinged) may drip from the nostrils and can increase in volume without necessarily becoming frothy. Progression to this stage warrants a very grave prognosis. Radiographic findings are nonspecific but include peribronchial and perivascular cuffing, increased prominence of vessels, and a hazy reticular interstitial pattern. Underlying pulmonary disease may obscure signs of edema, and radiographs of sufficiently high quality to show relatively subtle changes may not be obtainable in mature horses. Noncardiogenic pulmonary edema (capillary leak) is a component of the definition for ALI and ARDS.

31.23.1 Treatment

554

555

Treatment consists of correcting the cause, reversing hypoxemia, decreasing plasma volume and left atrial pressure, and increasing plasma colloid osmotic pressure. Intranasal oxygen and even mechanical ventilation may be needed in severe cases. Improvement in oxygenation can be monitored by sequential arterial blood gas analysis or by using transcutaneous oxygen saturation monitoring equipment applied to the nasal mucosa, tongue, or other available nonpigmented mucous membrane. In cases of NPPE, maintaining an adequate, low-resistance airway is very important to prevent further damage, and tracheostomy may be necessary. IV fluid therapy should be guided by the patient's needs and monitored by serial measurement of central venous pressure if necessary. Furosemide may be given intravenously or intramuscularly at a dose of 1 to 2 mg/kg and repeated in 1 hour. If helpful, the dose can be titrated for each patient. At a dose of 1 mg/kg, approximately 8 L of urine is produced in approximately 1 hour.[673] A few studies have been conducted on the effects of furosemide on pulmonary hemodynamics in the horse.[674–677] The effects in horses with pulmonary edema have not been reported. Colloid solutions should be administered cautiously or in conjunction with use of diuretics because they can initially increase vascular pressure. Plasma may be safer than other colloid preparations such as dextrans or hetastarch. Colloid solutions may be of little benefit in raising intravascular osmotic pressure in patients with increased microvascular permeability.

Antiprostaglandin drugs (flunixin meglumine, phenylbutazone) and antihistamines may help. Bronchodilators may be of benefit. The use of corticosteroids remains controversial; if they are used, antimicrobial coverage is advisable because pulmonary edema has been shown to impair pulmonary bacterial defense mechanisms.

31.24 SMOKE INHALATION

PEGGY S. MARSH

Smoke inhalation injury is typically associated with exposure to fires, and there are often concurrent problems in other body systems from thermal injury. Extensive or severe burns can magnify the severity of the injuries. Thermal injury along with smoke inhalation leads to both local and diffuse lesions. Massive tissue edema may occur; it can be a challenge to manage and can create organ dysfunction. To further complicate the problem, severely affected patients may develop a wide variety of problems including life-threatening sepsis and/or hypermetabolism. Depending on the severity of the lesions, smoke and fire injuries often lead to systemic inflammatory response syndrome and in some cases multiple organ system failure.

Insult to the respiratory system by smoke inhalation depends on the fuels that burned, the completeness of combustion, and the generated heat intensity. In general, lesions are initiated by three mechanisms. The first is direct thermal injury, which can be limited to the upper respiratory tract by laryngeal reflexes and efficient heat exchange within the nasal passages. Toxic chemicals in the smoke can cause damage, both directly and indirectly, through inflammatory mediators. Carbon monoxide intoxication is commonly associated with human injuries from smoke and is a product of incomplete combustion.[678] Finally, with combustion there is consumption of oxygen, and the resulting low PAO_2 can lead to pulmonary vasoconstriction as well as generalized hypoxia.

Three phases of pulmonary dysfunction have been described in the horse.[679,680] The first stage is acute pulmonary insufficiency caused by several mechanisms. Carbon monoxide may be present in sufficiently high concentration to cause toxicity within a short time after exposure. Carbon monoxide combines with hemoglobin to form carboxyhemoglobin. Hemoglobin has a 200- to 250-times greater affinity for carbon monoxide as compared with its affinity for oxygen.[678] High levels of circulating carboxyhemoglobin result in a shift of the oxyhemoglobin dissociation curve to the left, thereby decreasing oxygen release at the tissue level and leading to tissue hypoxia. Other processes occurring during this acute phase include progressive edema and necrosis in the upper respiratory tract, leading to airway obstruction, bronchoconstriction in the lower respiratory tract from the irritating effects of noxious products, and altered pulmonary blood flow.[681]

These insults produce the second stage: formation of pulmonary edema, lower airway obstruction, and pulmonary parenchymal lesions. Within 48 to 72 hours after exposure, driven by pulmonary macrophages, neutrophils are called into the area of insult. They release cytokines, proteolytic enzymes, and oxygen-derived free radicals. Expression of the inflammatory cascade in excess of balance causes microvascular damage, leading to increased extravascular lung water. Local insult also results in the release of tissue factor initiating the coagulation cascade to produce fibrin. Debris from the inflammatory cascade along with fibrin and material directly deposited from smoke inhalation create pseudomembranous casts, which may obstruct the small airways. Widespread plugging of the airways may significantly increase airway pressure, causing barotrauma and alveolar damage.[681] Bronchopneumonia is the last stage and occurs as a result of the impaired host immune system, both locally and systemically. This phase may occur up to 1 to 2 weeks after the initial injury.

As the saying goes, “Where there's smoke, there's fire”; commonly horses with smoke inhalation injury will also have burn injury. A complete description of this process in horses has been reported.[682] Thermal injury causes a local response that includes microvascular insult and direct tissue coagulation leading to inflammation, local edema, and finally necrosis. Extensive local injuries will drive a systemic response. Initially there is a decrease in systemic organ blood flow. This is followed by the formation of generalized edema. The pathophysiology of edema formation is complex and involves protein shifts, endothelial damage, and alteration of the interstitial architecture, all leading to a net accumulation of fluid in the interstitial spaces.[683] Over time major thermal injury is characterized by high cardiac output, increased oxygen consumption, and protein and fat wasting, all of which may create a hypermetabolic state.[684,685] Loss of skin as a barrier, release of inflammatory mediators, and

hypermetabolism play a role in the development of immunosuppression. Other features noted with burn injury in the horse include acute hemolysis, renal failure, laminitis, and myositis.[686]

Horses exposed to fire with smoke will have a variety of clinical signs depending on the duration and type of exposure and the length of time from the insult. The extent of damage to the skin may be very difficult to ascertain initially. Acutely, within the first 6 hours, signs of carbon monoxide toxicity and shock may occur. The patient shows signs of severe hypoxemia and may be depressed, disoriented, irritable, ataxic, or even moribund and comatose. As edema and necrosis progress in the upper respiratory tract, dyspnea and stridor may develop. Auscultation of the thorax may reveal decreased air movement, crackles, or wheezes, but these may not become apparent for 12 to 24 hours. If edema of the airways is sufficiently severe, airflow may be severely restricted. Edema fluid may be visible at the nostrils and, later, may be replaced by inflammatory exudate. Concurrent edema formation may be occurring systemically. Hypoxia and generalized edema may lead to dysfunction of distant organs such as the kidneys and muscles. Signs of infection may be difficult to ascertain from other signs. All that may be noticed is a fever and a worsening of respiratory signs after initial improvement.

555

556

Diagnosis is typically based on history and physical examination. A normal initial examination does not rule out exposure because the onset of clinical signs may be delayed several days. Within a short time after exposure, carboxyhemoglobin concentration in venous blood can be measured. A level above 10% is consistent with carbon monoxide toxicity.[679] Various diagnostic tests are useful in determining the extent of respiratory injury. These include endoscopy of the upper respiratory tract and tracheobronchial tree, thoracic radiographs, blood gas analysis, hematology, and cytologic evaluation of tracheal aspirates. Any or all of these tests can be performed on a serial basis as prognostic aids. Diagnostic tools for other organ injury include blood pressure monitoring, measurement of central venous pressure, serial hematologic and serum chemistry analyses, and monitoring of urine production.

Treatment depends on stage of injury. Initially, oxygen support is of benefit. It is a treatment for CO toxicity and helps reduce hypoxemia.[687] Humidified oxygen can be supplied by nasal insufflation or via transtracheal catheter. Upper respiratory tract obstruction may necessitate a tracheostomy. Attention should be paid to keeping the airways clear, and nebulization may be useful, especially when pseudomembranous casts are suspected. Bronchodilators may be useful in counteracting reflex bronchoconstriction. Decreasing inflammation and pulmonary edema may necessitate the use of diuretics and NSAIDs. Use of corticosteroids is controversial because of potential for immunosuppression and laminitis.[679] Novel therapies may include use of hyperbaric oxygen chambers and inhalation treatment with medication to inhibit inflammatory mediators, coagulation factors, or oxidative stress.[688]

Secondary complications require attention. Cardiovascular compromise and burn-induced edema may necessitate the judicious use of IV fluids. To prevent infection, strict hygiene, meticulous nursing care, and optimal nutritional support should be provided.[682,688] Prophylactic antimicrobial use is not recommended in human patients. Documented infection should be treated with appropriate antimicrobial agents based on results of culture and sensitivity patterns.[682]

31.25 RECURRENT AIRWAY OBSTRUCTION

DOROTHY M. AINSWORTH

31.25.1 Definition and Etiology

RAO is an inflammatory condition of the lower respiratory tract of mature horses that is characterized by excessive mucus production, neutrophil accumulation, bronchial hyperreactivity, and (in most cases) reversible

bronchospasm. Because the equine disease differs substantially in its etiopathogenesis from chronic obstructive pulmonary disease (COPD) of humans, it is recommended that the equine disorder no longer be called COPD. The preferred name is RAO or "heaves."[689]

RAO typically develops in adult horses residing in the northern hemisphere, for example in the Northeast and Midwest regions of the United States as well as in Great Britain and Switzerland, where the climate is wet and cool and horses are stabled and fed hay. RAO rarely occurs in horses maintained in warm dry climates such as those found in California or in Australia.[690] In North America the prevalence of RAO diagnosed at veterinary teaching hospitals has been positively correlated with rainfall, minimum temperatures, and total pollen and mold counts occurring 1 to 3 months previously.[691] These findings suggest that environmental conditions are integral to the development of the disease in susceptible horses.

RAO is considered to be a hypersensitivity to inhaled molds and organic dusts contained in the feeds hay and straw. In this regard, RAO is similar to occupational asthma that develops in human workers exposed to organic dusts.[692] Identifying the *specific* causative agents within the hay dust that induce the disease has been a challenge, as stable dust contains over 50 species of molds, large numbers of forage mites, endotoxin, and other inorganic components.[693] Inhalation of aqueous extracts of *Aspergillus fumigatus, Faenia rectivirgula (Micropolyspora faeni)*, or *Thermoactinomyces vulgaris* partially but not fully induces RAO in susceptible horses.[694–696] Similarly, inhalation of endotoxin, a component of hay dust, has been found to produce airway neutrophilia but not all of the changes in pulmonary function that are characteristic of RAO.[697,698] To fully induce RAO in susceptible horses requires inhalation of hay dust particulates either by natural challenge (stabling and feeding hay) or by nebulization of a hay dust solution.[699–702]

31.25.1.1 ROLE OF THE INNATE IMMUNE SYSTEM

After inhalation of the organic dust, it appears that both adaptive and innate immunologic responses contribute to the pulmonary inflammation. Within hours of hay dust exposure, neutrophilia and excessive mucus production are evident endoscopically and cytologically.[703,704] Pulmonary macrophages isolated from affected horses at this time exhibit an upregulation in the gene expression of TNF-α, IL-1β and IL-8.[705] The transcription of these proinflammatory genes may reflect involvement of TLR2 and/or TLR4 signaling pathways (stimulated by fungal wall components and endotoxin) with subsequent nuclear factor (NF)–κB activation and gene transcription.[706–708] However, the importance of these pathways needs to be confirmed because many different mediators activate NF-κB and enhance gene expression. The initial upregulation of these proinflammatory genes is transient, with mRNA levels returning to preexposure levels 24 hours after hay dust challenge.[705] With continuous hay dust exposure, both the protein and the gene expression levels of IL-8 in the airway cells and bronchial epithelium, as well as the gene expression levels of IL-1β and TNF-α in the bronchoalveolar lavage fluid (BALF) cells are upregulated in chronically affected horses.[709–712] However, this gene upregulation may reflect contributions from both macrophages and extravasated neutrophils accumulating in the airways. In addition to IL-8, IL-1β, and TNF-α, another chemokine that has the potential to propagate the airway neutrophilia is IL-17.[712,713] Secreted by lymphocytes and neutrophils, IL-17 promotes maturation, chemotaxis, and activation of neutrophils. In horses continuously exposed to hay dust for periods exceeding 2 weeks, IL-17 also upregulates the gene expression of IL-8 in the airway epithelium.[712]

31.25.1.2

ROLE OF THE ADAPTIVE IMMUNE SYSTEM

The role of the adaptive immune system in the development of RAO is currently controversial. Data that support the hypothesis that RAO is an IgE-mediated (T-helper 2 [Th2]) disorder include the findings of elevated allergen-specific IgE concentrations in the serum[714] and in the BALF of RAO-susceptible or affected horses[715,716] and increased *numbers* of IL-4 and IL-5 (mRNA positive) BALF cells—detected by in situ hybridization techniques—in RAO-affected horses.[717,718] Although Th2 disorders are typically characterized by eosinophilic infiltrates, it has been hypothesized that IL-4 activates its receptor on neutrophils to inhibit neutrophil apoptosis, to increase protein synthesis, and to upregulate the expression of the IL-9 receptor.[719] It has been further hypothesized that activation of the IL-9 neutrophil receptor then enhances IL-8 production and neutrophil influx.[719,720] Although the gene expressions of IL-4 and IL-9 receptors are indeed upregulated in peripheral blood neutrophils isolated from RAO-prone and RAO-affected horses, the existence of this pathway, linking the Th2 limb with the development of neutrophilia, requires additional investigation and confirmation.

556

557

In contrast, other data suggest that RAO is not simply a Th2 immune response. For example, Van der Haegen and colleagues were unable to demonstrate a significant difference in IgE-protein—positive cells in the lung tissue samples of RAO-affected as compared with control horses.[721] Second, cytokine profiles of BAL cells[710,711] or of pulmonary $CD4^+$ and $CD8^+$ cells[722] isolated from RAO-affected horses during the first 24 or 48 hours after hay dust exposure fail to demonstrate an upregulation of IL-4, IL-5, or IL-13. Furthermore, chronic (3 week) hay dust exposure is associated with an increase in the gene expression of IFN-γ in the BALF cells,[710,711] although in one trial but not in the second trial of the same chronically affected horses the gene expression of IL-4 was upregulated.[710] Fourth, GATA-3, the transcription factor required for IL-4 gene expression, is not upregulated in the bronchial cells of RAO-affected horses.[723] Nevertheless, in evaluation of these studies caution should be exercised in categorizing RAO as a Th1 immune disorder. This is because (1) concomitant increases in the gene expression of t-bet, the transcriptional factor for IFN-γ expression in $CD4^+$ cells, is not upregulated concurrently with IFN-γ,[711] and (2) multiple signaling pathways may stimulate the production of IFN-γ. In other species, TLR stimulation leads to the production of proinflammatory factors including IL-12 and subsequent IFN-γ synthesis.[724,725]

31.25.1.3

OTHER INFLAMMATORY MEDIATORS

With the accumulation of intraluminal neutrophils and peribronchiolar lymphocytes and with the activation of alveolar macrophages, it is not surprising that numerous other inflammatory mediators are released and may contribute to the inflammatory response of RAO. For example, histamine that is released by degranulated mast cells increases vascular permeability and produces bronchoconstriction. Although histamine concentrations in the BALF increase in RAO-susceptible horses after exposure to dusty hay, histamine-1 receptor antagonists provide little therapeutic relief for affected horses. This finding suggests that histamine may not be the predominant mediator responsible for the airway inflammatory response.[726] The potential role of prostaglandins, with their bronchoconstrictive ($PGF_{2\alpha}$, PGD_2, TXA_2) and/or bronchodilatory capabilities (PGE_2, PGI_2), have also been examined. In RAO-affected horses, increases in BALF PGE_2 and PGF[727,728] and in serum TXB_2 (a metabolite of TXA_2) are found.[729] However, although administration of a cyclooxygenase inhibitor prevents the increase in the serum TXB_2 in RAO-affected horses, it does not inhibit

the development of airway hyperresponsiveness or bronchospasm in susceptible horses. This finding suggests that the eicosanoids are not the major contributor to the disease.[729] The contribution of lipoxygenase metabolites to the airway disease has also been investigated in RAO-affected horses. In humans, leukotrienes have multiple actions: LTB_4, LTC_4, and LTD_4 are bronchoconstrictors; LTC_4 and LTD_4 are mucus secretagogues; and LTB_4 (through its action on NF-κB) is a chemotactin, promoting the upregulation of adhesion molecules and cytokines that facilitate neutrophil extravasation.[730] In horses, inhalation of LTB_4 or LTD_4 induces airway neutrophilia and bronchoconstriction, respectively, in normal and RAO-affected horses.[731] BALF cells isolated from RAO-affected horses during the first 48 hours of hay dust exposure and stimulated ex vivo produce increased concentrations of LTB_4 and LTC_4.[730] However, actual BALF concentrations of LTB_4 and LTC_4 are not elevated in chronically affected horses.[728] Furthermore, pretreatment of RAO-susceptible horses with either a 5-lipoxygenase inhibitor or a leukotriene receptor antagonist before hay dust exposure does not prevent the development of airway neutrophilia or alterations in lung mechanics.[732,733] Treatment of clinically affected horses with a leukotriene receptor antagonist also fails to improve pulmonary function test results, clinical scores, or arterial blood gas tensions.[734]

There is some evidence that reactive oxygen species, derived from pulmonary macrophages and granulocytes, contribute to the inflammatory process of RAO.[735] An "oxidant stress" has been proposed to develop, based on the findings of increased levels of oxidized glutathione; increased glutathione redox ratios (the ratio of oxidized glutathione to total glutathione); and decreased ascorbic acid concentrations in the pulmonary epithelial lining fluid of RAO-affected horses.[735,736] Changes in these indices of oxidant stress are also correlated with lung dysfunction parameters—total lung resistance, dynamic lung compliance, and arterial oxygen tensions—in RAO-susceptible and affected horses.[737] Reactive oxygen species are well recognized for their microbicidal activities. They also function as messengers in intracellular signaling pathways, upregulating proinflammatory gene expression by activating NF-κB.[738] Thus it is possible that reactive oxygen species generated during the inflammatory process of RAO also contribute to the NF-κB activation that has been detected in bronchial epithelial cells and in BALF cells of RAO-affected horses.[739,740]

Proteases derived from airway phagocytes, lymphocytes, and epithelial cells may also propagate the inflammatory reaction of RAO. Although many matrix metalloproteinases (MMPs) with gelatinolytic and collagenolytic activities have been identified in the respiratory tract secretions of RAO-affected horses,[741,742] the gelatinase MMP-9 is markedly increased in BALF and in tracheal epithelial lining fluid of diseased horses.[743] It has been suggested that the degradative effect of MMP-9 on the basement membrane and on the extracellular matrix components facilitates the extravascular movement of neutrophils into the airways. In vitro, tetracycline derivates effectively inhibit MMP activity detected in tracheal epithelial lining fluid,[744] but the efficacy of these compounds in ameliorating or preventing the inflammatory response of RAO-susceptible horses exposed to hay dust remains to be determined.

31.26 SUMMER PASTURE–ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE

31.26.1 Definition and Etiology

In the southeastern United States a condition clinically similar to RAO called *summer pasture–associated obstructive pulmonary disease* (SPAOPD) develops in mature horses that are kept outdoors. Clinical signs

typically manifest during the late spring, summer, and early autumn.[745] It is interesting to note that this disorder has also been reported to occur in horses in the United Kingdom.[746,747] Horses with SPAOPD exhibit airway neutrophilia, excessive mucus production, and accentuated breathing efforts,[748] although the inciting environmental factors and the immunopathogenesis of this disorder have yet to be determined.

Because of its similarity to RAO, investigators have sought to determine if SPAOPD reflects a Th2 or Th1 immune response to inhaled molds or antigens by examining BALF antibody isotypes and BAL cell cytokine profiles. Seaborn and colleagues found that neither the total nor the antigen-specific IgE and IgG titers to *Aspergillus* species, *Cladosporium herbarum, Penicillium* species, *F. rectivirgula, Saccharomonospora viridis, Thermoactinomyces thalpophilus*, and the forage mite *Lepidoglyphus destructor* in the tracheal lavage fluid were increased in SPAOPD-affected horses relative to controls.[749] During the winter months, when the horses are free of clinical signs, *A. fumigatus*–specific IgG titers in the SPAOPD group exceeded those in controls, but it could not be determined if this increase reflected ongoing production or decreased consumption.

557

558

Cytokine profiles of BALF cells isolated from SPAOPD-susceptible and affected horses have also been examined. When horses are symptomatic, the mRNA copy numbers of *both* IL-4 and IFN-γ in BALF cells are increased relative to controls.[750] This difference is not apparent when horses are asymptomatic, although the copy number of IL-4 in the SPAOPD-prone horses does not decrease during the asymptomatic periods either.[750]

31.26.2 Epidemiology

RAO occurs in both ponies and horses, but no gender or breed predisposition has been identified.[751,752] The prevalence of RAO is dependent on the geographic region examined. Bracher reported that 60% to 80% of Swiss horses older than 8 years of age suffer from some degree of this disease. In North America and in Europe the prevalence of RAO is estimated to range from 12% to 50%.[751]

To assess the genetics of RAO, Marti and colleagues examined families of horses affected with the disease. In one family 67% of the offspring born to an affected dam and an affected sire developed RAO in contrast to the 17% of affected offspring born to unaffected parents.[753] In an analysis of half-siblings, Marti also showed that stallions with chronic airway disease produced more affected offspring than did healthy stallions. Marti concluded that the clinical manifestations of RAO are the result of the interactions of genetic and environmental factors. There are currently no genetic markers that can be used to identify horses or ponies that are prone to developing RAO.

Although it has been clearly demonstrated that hay particulates are integral to the development of the disease, the role of a prior viral (or bacterial) infection in inducing susceptibility to hay dust hypersensitivity has not been established. Furthermore, even though horses with IAD share many of the clinical features of RAO,[754] the relationship of IAD to the development of RAO is unknown.[689]

31.26.3 Clinical Signs and Differential Diagnosis

The severity of clinical signs in RAO-affected horses is variable and is exacerbated by stabling; exposure to dusts, hay, and ammonia fumes; and hot humid weather. In a study of 148 cases of RAO presented for evaluation to a veterinary referral hospital in the United Kingdom, the chief complaints (median duration of which was 7 months) included coughing (84% of cases), bilateral nasal discharge (54%), exercise intolerance (51%), and postexercise breathing difficulty (23%).[755] In a review of 16 cases presented to a veterinary teaching hospital in

western Canada, the most common historical complaint (88% of the cases) was coughing,[756] whereas the predominant clinical complaints in 65 cases presented to a veterinary teaching hospital in the northeastern United States were abnormal breathing effort (68%), nasal discharge (50%), and a spontaneous cough (46%).[757]

On physical examination, mildly affected horses are typically afebrile and exhibit a bright demeanor. In such cases horses exhibit a normal or slightly accentuated (abdominal) breathing effort, respiratory rate, and heart rate. A nasal discharge may not be evident in all cases, but the horse may be observed to swallow excessively because of expectorated exudate. When the horse is exercised, a thick white nasal discharge and a cough become apparent. The frequency of coughing also increases when horses are stabled, and it often exceeds 10 to 15 coughs per hour.[758] Physical examination of more severely affected horses reveals tachypnea (respiratory rates exceed 40 breaths/min), nostril flaring, and a markedly accentuated expiratory effort (heave). The thoracic expiratory component may precede that of the abdominal compartment, producing a "double effort."[759] Abdominal pressure swings may be large enough to cause the anus to protrude with expiration. Paroxysmal coughing, bilateral nasal discharge, anxious facial expression, flatulence during coughing, reluctance to move, inappetence, and weight loss occur in severely affected horses.[760]

Although RAO is a diffuse lung disease, auscultation of mild cases may not reveal abnormal lung sounds unless a rebreathing bag is used to induce a hyperpnea. In one survey thoracic auscultation was abnormal in 47% of the cases, whereas tracheal auscultation was abnormal in 63% of the cases (755). In the latter, abnormal lung sounds and "mucous clicks" (tracheal exudate) were detected by tracheal auscultation. In mildly affected horses, only regional areas of adventitious lung sounds—crackles or high-pitched expiratory wheezes—may be detected. In contrast, in severely affected horses wheezes and mucous clicks may be heard at the horse's nostrils without the use of a stethoscope. Depending on the severity of the disease, thoracic percussion may be normal or may reveal expansion of the caudal lung fields beyond the normal line of pleural reflection.

Researchers have developed a clinical scoring system to categorize the severity of RAO. In one system the total clinical score is based on the magnitude of nostril flaring, ranging from 1 to 4, and the abdominal breathing effort, ranging from 1 to 4.[761] RAO in horses with a clinical score of 3 or 4, 5 or 6, or 7 or 8 was diagnosed as mild, moderate, or severe, respectively. In moderately to severely affected horses, there is a very good correlation between the clinical signs and alterations in pulmonary resistance or dynamic compliance.[762] For mildly affected horses (total scores of 3 or 4), the physical examination findings underestimate the severity of changes in the pulmonary function test results. Naylor and colleagues also developed a clinical scoring system based on the respiratory rate (graded 0 to 2), the respiratory effort (0 to 2), and lung auscultation findings (0 to 2) in affected horses. Although those investigators did not measure pulmonary function test results, they found that the clinical score was more closely correlated with histopathologic changes obtained by lung biopsy (and in particular the presence of peribronchiolar neutrophil and/or mast cell infiltration) than with the degree of BALF neutrophilia.[756]

Rarely, horses with longstanding RAO develop cor pulmonale. Clinically these horses have jugular distention, pulsation, ventral edema, and tachycardia in addition to the clinical signs of RAO.[760–763]

31.26.4 Laboratory Aids and Diagnostic Tests

The diagnosis of RAO is based on the history, the clinical signs, and the response to therapy. It may be difficult to arrive at a definitive diagnosis in asymptomatic horses or in horses that are exhibiting mild signs at the time of the examination, thus necessitating the use of additional diagnostic tests such as cytologic analysis of lower

respiratory tract secretions. During periods of clinical remission, BALF cell populations obtained from RAO-susceptible horses consist predominantly of mononuclear cells (90% macrophages and lymphocytes), and the cell differential counts do not differ from those found in healthy horses.[764] However, when horses develop RAO, aspirates of tracheal and bronchoalveolar fluid contain increased numbers of nondegenerative neutrophils (>25%). For example, in the BALF the percentage of neutrophils may be as great as 90%, far exceeding the normal 5% to 15% found in healthy horses that are stabled and fed hay. In most cases the percentage of eosinophils or mast cells is not increased in affected horses. Therefore cytologic analysis of respiratory secretions in RAO-affected horses reflects a suppurative nonseptic inflammation, distinguishing this disorder from lungworm infections (pulmonary eosinophilia) or pneumonia (degenerative neutrophils, intracellular bacteria). Rarely an infectious bronchitis may complicate a case of RAO; microbial cultures yield low growth of the bacterial isolate, but the predominant cell type in the tracheal secretions is a nondegenerative neutrophil.

558

559

Endoscopic examination of the respiratory tract of RAO-affected horses demonstrates excessive amounts of tracheobronchial secretions that originate from most of the bronchial segments. Distal airways are edematous and inflamed, and airways easily collapse during expiration. Expectorated secretions from the lower respiratory tract coat the pharynx, larynx, and other structures of the upper respiratory tract.

In general, the CBC, serum biochemistry profile, and serum fibrinogen concentrations are normal in RAO-affected horses.[757] In severely stressed horses, a mature neutrophilia and lymphopenia may be evident on the leukogram. Arterial blood gas analyses are normal in approximately 25% of the cases,[765] but others demonstrate hypoxemia (Pa_{O_2} < 85 mm Hg) in the absence of arterial hypercapnia. In affected horses that are exercised, at a given work effort the arterial oxygen tensions are reduced compared with blood gas values obtained from the same horses during clinical remission.[766] Prognostic value of arterial blood gases in RAO-affected horses has not been examined.

Radiographs are usually of limited value in diagnosing RAO because the accentuated bronchointerstitial pattern typically found in the diseased horses can be detected in healthy aged horses. Radiographs can be helpful in ruling out thoracic neoplastic or infectious disorders in horses that have clinical signs resembling RAO (cough, nasal discharge, abnormal breathing effort). In severely affected horses with RAO that repeatedly fail to respond to bronchodilators and glucocorticoids, radiographs should be taken to determine if bronchiectasis (dilation or deformation of the bronchi or bronchioles) exists.[767] Bronchiectasis is a relatively uncommon complication of RAO but causes irreversible airway obstruction as a result of collapse of the affected airways.

Ultrasound evaluation of RAO-affected horses confirms a shift of the caudal lung border caused by alveolar hyperinflation.[768] However, gas in the large colon (left side) or in the cecum (right side) may preclude complete imaging of the most caudal extent of the lung fields at the sixteenth intercostal space. Thoracic ultrasonography of RAO-affected horses may demonstrate small hypoechoic areas of irregularity on the lung surface, but, in general, ultrasonography is not useful in detecting airway inflammation. In horses with cor pulmonale, ultrasonography confirms the presence of pulmonary hypertension and right ventricular hypertrophy.[769]

Lung biopsies, although not typically performed to diagnose RAO-affected horses, demonstrate bronchiolar goblet cell metaplasia, bronchiolar luminal exudate, peribronchiolar lymphoplasmacytic cell infiltration, and accumulations of neutrophils within the airways.[756] The potential disadvantages of performing a lung biopsy include the risk of inducing hemorrhage (hemothorax, epistaxis) and the chance of obtaining a nonrepresentative (nonaffected) tissue sample.

Intradermal skin testing of RAO-affected horses has been performed by many investigators, but unfortunately the results (and conclusions) are variable. Evans and colleagues found that in RAO-affected horses the total number of positive intradermal skin tests evaluated at 0.5, 4 to 6, and 24 hours after allergen injection exceeded that in control horses. Positive responses were detected for two pollens (English plantain, goldenrod), three molds (*Rhizopus* species, *Monilia* species, and *Alternaria tenuis*), and one insect extract (*Tabanus* species). However, this difference in skin reactivity, which involved only 3% of the possible extract reactions, did not permit discrimination between a diseased horse and a healthy horse.[770] Similarly, in a retrospective study of cases examined at a veterinary teaching hospital over a 10-year period, Jose-Cunilleras and colleagues found that the percentage of RAO-affected horses that had positive skin reactions exceeded that of the control horses at all time points examined (0.5, 4, and 24 hours).[771] In contrast, others have failed to find a significant difference between RAO-affected and control horses in either the number of positive skin responses or in the titers developed at the early (0.5, 4 hours) or late (24 hours) phases to a variety of molds.[772–774] Recently Wong and colleagues evaluated the skin responses of RAO-prone (asymptomatic) and control horses to intradermal injections of histamine and a mixture of *Aspergillus* species. They found that compared with the controls the RAO-affected horses had a heightened response to histamine (evaluated at 0.5 hours postinjection) and a delayed resolution of the skin wheal (after 24 hours) to the *Aspergillus* antigens.[775] Thus, positive skin tests and serum precipitins to fungal and thermophilic actinomycete antigens are found in many normal as well as RAO-affected horses, reflecting a level of exposure of the horse rather than a susceptibility to heaves. In general, skin testing does not allow identification of RAO-affected horses or the specific inhaled particulate that is inciting the pulmonary inflammation.[776]

Similarly, serum allergy tests such as the radioallergosorbent test (RAST) or the IgE-based ELISA, which aim to identify the allergen that is inciting the hypersensitivity, are also of limited value in the diagnosis of RAO. Lorch and colleagues compared the results of two different ELISAs (one based on the human FcεRIα chain, the other based on a polyclonal antiserum to equine IgE) and a RAST test with intradermal skin test responses in RAO-affected horses. They concluded that based on the poor performance of all three tests, none should be used as a screening test for allergen hypersensitivity.[777]

Conventional pulmonary function tests, which require measurements of pleural pressure (obtained via an intrathoracic esophageal balloon catheter system) and airflow (detected by a flow meter attached to a sealed face mask worn by the horse) are typically reserved for experimental investigations and are not routinely performed on clinical patients. The characteristic alterations in the pulmonary function test results of horses with RAO are a decrease in dynamic lung compliance or lung distensibility (C_{dyn}); an increase in pulmonary resistance (R_L); an increase in maximum pleural pressure changes (ΔP_{plmax}); and an increase in peak inspiratory and expiratory flow rates.[778] (In general, C_{dyn} reflects peripheral airway function, whereas R_L reflects central airway function.) RAO-affected horses also exhibit bronchial hyperreactivity. The dose of aerosolized histamine required to reduce C_{dyn} to 65% of its baseline value is much less in diseased horses than in controls.[779] These alterations in lung function that develop in affected horses are repeatable on reexposure to hay dust.[780,781] During periods of clinical remission the pulmonary function test results return to normal and are not significantly different from those of healthy age-matched horses. However, an inability to detect a difference in R_L or C_{dyn} between healthy horses and RAO-susceptible horses during periods of disease remission may reflect a relative lack of sensitivity of these tests.[782] For example, some researchers have found that in RAO-susceptible horses during periods of clinical remission, some degree of bronchial hyperreactivity and airflow obstruction remains.[783,784]

31.26.5 Pathophysiology

The changes in respiratory mechanics and the development of clinical signs are consequences of the influx of inflammatory cells (mechanisms discussed earlier), the contraction of smooth muscle in the airways, and the production and accumulation of mucus. Bronchoconstriction probably results from the cumulative effects of (1) released inflammatory mediators—histamine, serotonin, eicosanoids, leukotrienes—and (2) activation of muscarinic receptors on the smooth muscle by released acetylcholine.[785] In addition to their direct effects on smooth muscle tension, histamine and serotonin also augment the release of acetylcholine from parasympathetic nerves.[786] Based on in vitro muscle bath studies, there is also evidence that RAO-affected horses lack inhibitory nonadrenergic-noncholinergic innervation (iNANC) of the peripheral (but not central) airways, further contributing to the development of bronchospasm.[787] The magnitude of airway narrowing that occurs in response to smooth muscle contraction is a function not only of the thickness of the smooth muscle layer but also of the width of the mucosal layer between the muscle and airway lumen. Thus thickening of the airway by peribronchial infiltrates and by epithelial metaplasia amplifies the airway narrowing induced by bronchospasm.[788]

As noted earlier, excessive mucus is evident endoscopically and cytologically in RAO-affected horses. Mucus consists of a liquid sol layer, which surrounds the ciliated epithelium, and an overlying viscous gel layer, which contains water, electrolytes, lysozymes, cells, and the mucin glycoproteins. In RAO-affected horses the excessive mucus formation may be the result of an upregulation of a mucin-producing gene, MUC5AC, responding to released elastases, reactive oxygen species, and other inflammatory mediators.[789] Increased viscosity of the mucus[790] may be a consequence of alterations in the side chain glycoproteins[791] and/or formation of mucin aggregates from DNA and actin released by airway neutrophils. Delayed clearance of the mucus from the lower respiratory tract contributes to the accumulation of the exudate and may reflect an impairment of the mucociliary apparatus as a result of epithelial cell destruction.[792,793]

Narrowed and/or obstructed airways increase R_L and fail to participate in efficient gas exchange.[778] Low ventilation-perfusion lung regions contribute to a widening of the aveolar arterial oxygen-difference ($AaDO_2$) gradient and the development of arterial hypoxemia.[794,795] High ventilation-perfusion regions (dead space) also increase in affected horses, but normal arterial $PaCO_2$ levels are maintained by increases in the total minute ventilation.[796] Changes in minute ventilation are due to an increase in breathing frequency, as tidal volume changes little with the disease. In general, there are no significant changes in cardiac output, heart rate, and mean systemic arterial pressure, but pulmonary artery systolic and mean pressures and pulmonary vascular resistances are significantly increased in diseased horses.[796] The combination of airway inflammation and hypoxemia, if severe enough, stimulates the respiratory controller in the ventral medulla to increase the respiratory drive and to activate inspiratory and expiratory muscles (abdominal heave). Recruitment of respiratory muscles increases the maximum pleural pressure excursion (ΔP_{plmax}), the work of breathing, and the total body oxygen consumption.[797] However, much of the increased expiratory effort (and increased intrathoracic pressures) serves to collapse the noncartilaginous airways, further compounding gas trapping and impairing gas exchange.

31.26.6 Pathology

The lungs obtained from RAO-prone horses that are asymptomatic at the time of death macroscopically appear normal.[794] In symptomatic horses, the lungs are pink, soft, hyperinflated, and imprinted with rib impressions.

Lungs fail to collapse when the chest is opened because of gas trapping distal to occluded airways.[772] Emphysematous bullae are lacking, but accumulations of mucus and cellular debris occlude the small airways, forming "spiral-shaped casts" known as *Curschmann's spirals*. Light and electron microscopic examinations of lung segments from diseased horses demonstrate that the peripheral airways are the most severely affected, although pathologic alterations do occur in the central airways.[792,793] Histologic changes include goblet cell hyperplasia, epithelial cell damage, bronchial and bronchiolar epithelial cell hyperplasia, smooth muscle hypertrophy and hyperplasia, collagen deposition, and overinflation of the alveoli.[798–800] It is interesting to note that the extent of the bronchiolar epithelial cell hyperplasia is correlated with the increase in dead space ventilation that occurs in RAO-affected horses.[796] Peribronchiolar infiltrates consist of lymphocytes and plasma cells, along with collagen deposition.[801] Eosinophils are rarely observed either within the airways or in the lung parenchyma.

Despite these pathologic changes, the clinical signs are usually considered to be reversible. However, in rare instances bronchiectasis may develop in RAO-affected horses. In a single case study of one such affected horse, histopathologic alterations of the affected airway demonstrated separation of the cartilaginous plates of the dilated bronchus, disorganization of the chondrocytes, reduction in the elastic fibers surrounding the perichondrium and lamina propria, and a lymphoplasmacytic infiltrate.[767]

In RAO-affected horses with cor pulmonale, reductions in the circumferential ratio of the aorta to the pulmonary artery and in the mass ratio of the left ventricle and septum to the right ventricle are found.[769,802]

31.26.7 Treatment and Prognosis

31.26.7.1 ENVIRONMENTAL MANAGEMENT

Environmental management changes are the single most important aspect of the treatment protocol to be implemented. Whenever possible, RAO-prone and RAO-affected horses should be kept outside at all times, blanketed during inclement weather as needed, and provided access to a well-ventilated three-sided shelter from which manure and urine are frequently removed. Horses should be allowed pasture access (except for those with SPAOPD, which improve with stabling) and fed pellets or hay cubes when pasture is unavailable. Some horses will tolerate hay that has been soaked in water, but this practice reduces the nutrient value of the hay and is often forsaken when the weather becomes cold. Reducing dust exposure is critical, as inhaling organic dusts for as little as 1.5 hours causes a significant increase in R_L. By 5 hours, horses exhibit significant decreases in C_{dyn} and Pao_2 and evidence of pulmonary neutrophilia.[703,803] The ensuing inflammation from a single 5 hour dust exposure takes approximately 4 days to resolve.[804] For chronically affected horses that have been turned out to pasture, clinical remission and normalization of pulmonary function test results take 4 to 8 weeks depending on weather conditions.[690,805]

Horses for which optimal management changes cannot be implemented should be fed pellets and/or hay cubes and kept in well-ventilated stalls that are bedded with a material that has a low respirable dust particle count and mold concentration. Cardboard bedding has a significantly lower particulate concentration (dust, *A. fumigatus, F. rectivirgula*, and *T. vulgaris*) than wood shavings, wheat, or flax straw, although cardboard may be difficult to obtain and store.[805,806] Typically, when affected horses are bedded on shaving and fed pelleted rations, significant improvements in the pulmonary function test results occur within 3 days.[807] When RAO-susceptible horses that are in clinical remission are fed low dust—containing forages and bedded on low dust

—containing materials, they can remain clinically normal for months. However, even though BALF neutrophil percentages, pulmonary function test results, and indices of airway inflammation such as exhaled ethane are normal, bronchial hyperreactivity of RAO-prone horses remains increased in these horses.[783,806,808,809] Therefore these horses will always be more susceptible to disease development than healthy horses when dust levels increase in the environment.

Environmental management considerations should also be implemented when horses are transported. Their heads should not be tied in close proximity to the hay net, as this practice places their breathing zone near a concentrated source of organic dusts and molds and restricts their head position so as to further decrease mucociliary clearance of respiratory secretions.[760,810]

31.26.7.2

BRONCHODILATORS

During acute exacerbations of RAO, bronchodilators can be very effective in improving lung mechanics. Three main classes of bronchodilators have been examined in RAO-affected horses and include the anticholinergics (muscarinic antagonists), the β_2-agonists, and the phosphodiesterase (PDE) inhibitors.

The muscarinic antagonists, of which atropine and ipratropium are examples, block the smooth muscle constricting effects of acetylcholine. These actions have the greatest effects in the central as opposed to the peripheral airways. Murphy and colleagues reported on the efficacy of atropine sulfate used in 25 clinical cases of RAO. IV administration (0.02 mg/kg) decreased ΔP_{Plmax}, respiratory rate, and Pa_{O_2} (2 to 3 torr) within 30 minutes of administration.[811] In another clinical study of 18 RAO-affected horses, Pearson and Riebold found that atropine (0.01 mg/kg IV) decreased ΔP_{Plmax} 83% and produced clinical improvement in 87% of the cases. Despite its bronchodilating effects, atropine's short duration of action (2 hours) and undesirable side effects of mydriasis, ileus, tachycardia, dry airway secretions preclude its routine use in the treatment of RAO.[813] In contrast, ipratropium bromide is poorly absorbed from either the respiratory or GI tract, minimizing the development of systemic effects. The onset of action of inhaled ipratropium is 30 minutes, and the duration of effect ranges from 4 to 6 hours.[814] The powder form may be nebulized (dose of 2 to 3 µg/kg), or the dry powder inhaler may be attached to a specially constructed mask that allows the generation of a sufficiently negative inspiratory pressure to dispense the inhalant.[815] When given to RAO-affected horses before an incremental exercise test, ipratropium reduces R_L and ΔP_{plmax} and increases C_{dyn} in resting horses. However, during exercise the drug produces no significant improvement in lung mechanics, blood gas tensions, or oxygen consumption. It also does not prolong the time to fatigue (or prevent exercise intolerance) in treated horses when compared with diseased horses that received a placebo.[816] During exercise the pulmonary resistance values of the treated RAO-affected horses is twice that of healthy controls, suggesting that despite bronchodilation, mucosal thickening and accumulations of intraluminal secretions and cellular debris probably continue to obstruct airflow.[816]

The β_2-adrenergic agonists—clenbuterol, albuterol, fenoterol, pirbuterol, and salmeterol—produced relaxation of smooth muscle by increasing the intracellular levels of cAMP. Clenbuterol is one of the earliest drugs to be evaluated for use in RAO-affected horses. Because its bioavailability is greater than 90%, clenbuterol can be given orally. When the drug is administered at a dose of 1.6 µg/kg of body weight twice per day (bid), there is a significant improvement in the clinical signs of horses with RAO.[817] However, the effective dose of clenbuterol may vary among horses: Traub-Dargatz and colleagues[818] found that 400 µg of oral clenbuterol hydrochloride administered twice daily failed to improve the severity of clinical signs, the BALF or tracheal

cytologies, or the arterial blood gases in affected horses. During the treatment, horses were maintained outside but still fed hay. It is likely that 1 µg/kg was too low a dose for horses continuously exposed to hay dust. Based on the study of Erichsen and colleagues,[817] it has been recommended to increase the dose of clenbuterol if clinical improvement is not observed with 3 days of initiating treatment (e.g., 2.4 µg/kg for 3 days, 3.2 µg/kg for 3 days). Adverse side effects—anxiety, shivering, sweating, and tachycardia—occur at higher dosages but appear to be minimized when clenbuterol is increased in a stepwise manner. Erichsen reported that side effects developed in <7% of the cases when clenbuterol was administered at 3.2 µg/kg using an incremental approach. In addition to its bronchodilatory effect, clenbuterol also exerts an antiinflammatory effect. When administered intravenously (0.75 µg/kg bid) to RAO-susceptible horses before hay dust exposure, there is a significant attenuation of the BALF neutrophilia, the ΔP_{Plmax}, and the transcription of the proinflammatory genes, TNF-α and IL-1.[819]

Other β_2-agonists have been administered as aerosolized drugs to RAO-affected horses. Inhalation therapy has increased in popularity for the treatment of these cases because it allows direct delivery of the drug to the respiratory tract, minimizing the total amount of drug needed to be delivered as well as the prevalence of unfavorable systemic effects. In most instances, inhalation therapy can be performed by the client. Aerosolized drug is delivered by attaching the metered dose inhaler (MDI) to a mask (Aeromask, Trudell Medical, Inc.) or other drug delivery system (Equine haler, Equine Health Care, Inc.). Both systems contain spacers to optimize the drug particle size that is inhaled (larger sized particles drop out) and deposited in the lower respiratory tract. The inhaled rapidly acting β_2-agonists pirbuterol, albuterol sulfate, and fenoterol improve pulmonary function by 60% to 70% in RAO-affected horses for approximately 1 to 3 hours, necessitating frequent administration of the drugs.[820–822] They are poorly absorbed, so systemic effects are uncommon. The recommended dose of albuterol is 600 to 720 µg q4-6h, that of pirbuterol is 16 µg/kg q4-6h, and that of fenoterol is 2 mg q4-8h. More frequent administration may be necessary in some horses. Recently the efficacy of a longer-acting β_2-agonist, salmeterol, was evaluated in RAO-affected horses.[823] Clinical improvement developed within 2 hours of administration, but significant changes in pulmonary resistance lasted for only 6 hours, necessitating repeated administration every 6 to 8 hours.[823]

The PDE inhibitors are the third class of bronchodilators that have been used in horses. These drugs inhibit the breakdown of intracellular cAMP, thus maintaining smooth muscle relaxation. Because cAMP facilitates the proinflammatory effects of certain cytokines, the PDE inhibitors exert antiinflammatory properties.[824] Examples of PDE inhibitors are aminophylline, pentoxifylline, and the recently studied PDE-4 inhibitor L-826, 141. The clinical efficacy of aminophylline (the soluble salt of theophylline) was evaluated by Pearson and Riebold in their study of 18 clinical cases of RAO. They found that when the drug was administered at 12 mg/kg IV in 1 L of 5% dextrose to achieve blood levels of 10 µg/mL, there was an improvement in the clinical signs in 50% of the cases and a 41% reduction in the ΔP_{Plmax}. Horses also became hyperesthetic and hyperexcitable and trembled.[812] Because of the narrow therapeutic range—pharmacologic benefits are achieved at serum concentrations of 10 µg/mL, and toxicities develop at 15 µg/mL—and because of erratic drug absorption after oral administration, aminophylline is not routinely used for the treatment of RAO. However, pentoxifylline, another methylxanthine derivative and PDE inhibitor, is well absorbed after oral administration (16 g bid). Pentoxifylline improves pulmonary function test results (effects are similar to those produced with atropine) and lacks adverse side effects. However, at a dose of 16 g PO bid it lacks discernible antiinflammatory effects: BALF neutrophilia is not improved.[825] Another PDE inhibitor (L-826,141) that was evaluated in RAO-affected horses failed to improve either lung mechanics or airway inflammation.[826]

561
562

31.26.7.3 ANTIINFLAMMATORY DRUGS

Corticosteroids are efficacious in the treatment of RAO, whereas NSAIDs have not proven to be beneficial.[729] Yet, oral prednisone also does not improve the clinical signs, the BALF cytologic alterations, or the pulmonary function test results in RAO-affected horses.[807,817,827] Its therapeutic failure is attributed to its poor absorption and the lack of conversion to the active metabolite, prednisolone.[828] In contrast, both the liquid and tablet forms of prednisolone are rapidly absorbed from the equine GI tract. The bioavailability is approximately 50%, peak concentrations of prednisolone are detected 45 minutes postadministration, and the pharmacologic effects (based on changes in serum cortisol levels) last for 8 hours.[828] Nevertheless, although oral prednisolone (2.2 mg/kg PO once per day [sid]) is routinely prescribed for the treatment of RAO, its efficacy and its duration of effect in improving pulmonary function test results and in resolving airway inflammation have not been demonstrated.

In contrast, the beneficial effects of dexamethasone in the treatment of RAO-affected horses have been investigated by several different research groups.[828–831] Within 2 hours of its IV administration to RAO-affected horses (0.1 mg/kg) there is a 37% decrease in ΔP_{plmax} that is further reduced 59% by 4 hours posttreatment.[828] Oral administration of the IV formulation of dexamethasone (0.164 mg/kg sid) produces a significant improvement in lung function parameters within 6 hours of treatment, with peak effects occurring 24 hours later.[828] For horses that are maintained in dusty environments during a 10-day treatment period, IV dexamethasone (0.1 mg/kg sid) or dexamethasone isonicotinate (0.04 mg/kg IM every 3 days for three treatments) improves pulmonary function within 3 days of initiating therapy[827] and reduces airway inflammation (BALF neutrophilia) within 10 days of treatment.[830] As might be predicted, a single dose of dexamethasone isonicotinate (0.06 mg/kg IM) administered to RAO-affected horses maintained in a dusty environment fails to provide discernible improvements in the clinical score, the pulmonary function test, the BALF cytologies, or the activities of the transcription factors NF-κB or AP-1 evaluated 10 days posttreatment.[831]

The therapeutic efficacy of two other parenteral glucocorticoids, triamcinolone acetonide and isoflupredone, has also been evaluated in RAO-affected horses maintained in a dusty environment.[832,833] A single IM dose of triamcinolone acetonide (0.09 mg/kg) markedly improved lung mechanics evaluated 7 and 14 days posttreatment, and this effect lasted for 4 weeks. Cytologic changes were also evaluated 14 days posttreatment and demonstrated a reduction in airway neutrophilia (neutrophil percentages decreased from 62% to 32%), but this improvement was not statistically significant.[832] Adverse effects of triamcinolone administration were not reported. In another study, RAO-affected horses received isoflupredone acetate for 14 days (0.03 mg/kg IM sid) while being maintained in a dusty environment. Significant increases in C_{dyn} and reductions in R_L and P_{plmax} occurred within 3 days of initiation of the treatment,[833] and the beneficial effects continued 7 days beyond the cessation of drug therapy. The only adverse effect noted was the development of hypokalemia.

The effectiveness of a prolonged course of inhaled fluticasone on pulmonary function, BALF cytologies, and BAL cell gene expression was examined by Giguère and colleagues.[710] RAO-affected horses that received 2 mg of fluticasone propionate bid for 21 days while still being fed hay demonstrated marked (and significant) improvements in P_{plmax}, C_{dyn}, and R_L by day 21 of the treatment period. Furthermore, BALF neutrophil counts became normal and IL-8 copy numbers in the BALF cell were reduced to levels equivalent to those found during remission.[710] Fluticasone is approximately 18 times more potent than beclomethasone

dipropionate (which is no longer available in the United States). Nasal or oral administration of fluticasone has no effect on circulating glucocorticoids levels, suggesting that the bioavailability across nasal and intestinal epithelium is poor.[834]

Inhaled steroids are often used in conjunction with inhaled bronchodilators for maximal therapeutic effects. When separate formulations are used, it is recommended that the bronchodilator be administered first so as to improve subsequent glucocorticoid deposition in the peripheral airways.[835] When treating horses with glucocorticoids, adrenal gland atrophy, immunosuppression, and precipitation of laminitis remain the main concerns of many clinicians. All of the previously discussed parenteral and inhaled glucocorticoids reduce endogenous serum cortisol levels. However, despite prolonged treatment protocols with glucocorticoids, adrenal gland responsiveness to adrenocorticotropic hormone (ACTH) administration remains.[832,833,836] It is interesting to note that none of the studies cited examined the development of laminitis, secondary infections, or gastritis or gastric ulcers. In my clinical and research experience, gastric ulceration is a problem in RAO-affected horses that are receiving long-term dexamethasone therapy while being fed pelleted rations. Affected horses respond to gastroprotectants.

31.26.7.4 OTHER THERAPIES

In horses that develop respiratory distress because of the bronchospasm and airway inflammation, additional therapies are required. Administering nasal oxygen at flow rates as low as 5 L/min improves arterial oxygen tensions by as much as 30 mm Hg in some severely affected horses.[837] As the total nasal oxygen flow increases, so too will the mean arterial oxygen tension, although not to the same degree that occurs in healthy horses. Flow rates of 30 L/min (delivered by 2 nasal cannulae at 15 L/min) are associated with coughing and gagging in the horse. Nasal oxygen supplementation does not reduce breathing frequency, suggesting that stimulation of vagally mediated afferents—perhaps responding to inflammatory mediators—is responsible for the tachypnea.

Furosemide (1 mg/kg IV or nebulized) provides beneficial effects to RAO-affected horses within 20 minutes of its administration, decreasing R_L and increasing C_{dyn} without affecting PaO_2.[838] The beneficial effects appear to be mediated by prostaglandin E_2, derived from either the renal or airway epithelium, which promotes smooth muscle relaxation. Prior treatment with the cyclooxygenase inhibitor flunixin meglumine prevents the furosemide-induced bronchoconstriction.[839]

Other therapies that have been evaluated and found not to be efficacious in the treatment of RAO-affected horses include a single acupuncture treatment,[840] the oral administration of an herbal preparation containing thyme and primula,[841] and the rapid IV administration of 30 L of isotonic saline.[842]

562

563

31.26.8 Prognosis

RAO-prone horses are likely to develop acute exacerbations of the disease when husbandry practices lapse or when weather conditions become adverse. Horses do not “outgrow” the disorder, and, in fact, some clinicians believe that the inflammation becomes more difficult to manage as the horse ages. The basis for the lack of clinical response is unknown but may be the result of lung remodeling—development of fibromuscular hyperplasia in the alveolar septa,[769] excessive smooth muscle hyperplasia,[800] bronchiectasis,[767] or potential downregulation of the glucocorticoid receptor.

If proper environmental management changes are implemented and if the appropriate therapy is initiated, then clinical remission occurs in most cases. In a follow-up survey conducted by Naylor of RAO-affected horses that had been examined and treated at a referral center 2 to 4 years previously, it was found that 20% of the original cases (3 of 15) had been euthanized, that 33% were still receiving bronchodilators on an as-needed basis, and that the athleticism had not decreased in 92% of the horses.[756] Similarly, in a follow-up survey conducted by Aviza and colleagues,[757] 13% of the horses that had been diagnosed with RAO 3 to 4 years earlier had been euthanized. However, in contrast to Naylor's findings, Aviza noted that more than 50% of the respondents in that survey stated that the athletic performance of the horse had been compromised by the disease. Perhaps this difference between the two surveys simply reflected a failure of the owners to comply with environmental management recommendations. When queried about the husbandry practices, 77% of the respondents still stabled the horse for part of the day, and 84% still fed dry hay.[757]

Because the effects of repetitive episodes on the development of irreversible changes in lung structure have yet to be determined, clients should be encouraged to implement effective husbandry changes that minimize the recurrences of RAO.

31.27 INFLAMMATORY AIRWAY DISEASE IN THE HORSE

MELISSA MAZAN

31.27.1 What Is Inflammatory Airway Disease?

IAD, small airway inflammatory disease, small airway disease, allergic airway disease—these names are often used interchangeably, but the once-fluid definition of IAD is slowly taking form. Although low-grade inflammation of the small airways is recognized as a common cause of poor performance in young to middle-aged, athletic horses, it is only recently that the clear distinction has been made between heaves, or RAO, and IAD. Workers in the field continue to debate whether IAD is a discrete disease entity[843] or whether it is merely a part of the continuum of airway inflammation that if left untreated will progress inexorably to the more well-characterized syndrome of RAO.[844] Horses with IAD are generally young, although middle-aged horses may also be affected[845]; have impaired performance that may go unnoticed at rest or during light work[846–848]; have mild to moderate airway inflammation that may involve neutrophils,[848,849] mast cells,[846,850,851] eosinophils,[844] or lymphocytes[848]; have variable clinical signs, including cough, nasal discharge, and abnormal lung sounds[844,851,852]; may have endoscopic evidence of tracheobronchial mucus accumulation[844,851,853]; and may have normal lung function at rest but show evidence of airway hyperresponsiveness on exposure to nonspecific agents such as histamine[855] or evidence of low limitations on forced expiratory maneuvers.[856] These observations were confirmed by a consensus agreed on in October 2002,[857] which also stated that the clinical picture of horses with IAD includes poor performance or exercise intolerance, coughing, and excessive tracheal mucus—although not all of these need be present—and nonseptic inflammation as detected by bronchoalveolar lavage cytology. In addition, these horses may have lung dysfunction as evidenced by airway obstruction, airway hyperresponsiveness, or abnormal blood gas exchange. This definition specifically excludes horses that appear systemically sick or that have overt evidence of respiratory dysfunction, such as flaring nostrils or excessive thoracic or obvious abdominal breathing efforts.

The prevalence of IAD is somewhat of a guessing game. One study involving 965 standardbreds in active racing founding that 22% had evidence of mucopus at the trachea or bronchial bifurcation when examined

endoscopically, although these were diagnosed as horses with COPD; undoubtedly these horses properly belong in the IAD group.[854] Similarly, 27% of actively racing thoroughbreds in one study had IAD.[858] A remarkable 55% of 2-year-old thoroughbreds in training could be classified as having lower airway disease on the basis of finding mucus in the trachea on endoscopy and inflammation on examination of tracheal aspirate fluid,[859] and abattoir studies have shown up to 37% of horses with histopathologic evidence of airway inflammation.[860] Because a standard definition of IAD has only recently been agreed on, the prevalence of IAD has varied according to the individual researcher's case definition. Nonseptic airway inflammation, regardless of whether it causes overt signs of respiratory disease, appears to be very common in performance horses. For the purpose of this discussion, we will adhere to the definitions of IAD and RAO as developed by the International Workshop on Equine Chronic Airway Disease,[843] the Havemeyer Workshop,[857] and the recent American College of Veterinary Internal Medicine (ACVIM) consensus statement on IAD. With RAO, horses have demonstrable lower airway obstruction, characterized by peak pleural pressures of at least 15 cm H_2O, induced by an environmental challenge of moldy hay, largely reversible by use of a bronchodilator or return to nonchallenge environment, and accompanied by an increase in BALF neutrophils during challenge. In contrast, IAD refers to a nonseptic airway disease in athletic horses that does not have a clearly defined allergic cause. When we look at the data, we find that many studies involving horses with what was traditionally known as COPD and is now more properly referred to as RAO, or heaves, did not conform with these guidelines, and many of the horses would more properly be characterized as having IAD.

31.27.2 Clinical Findings

Although most investigators agree that IAD is a disease of younger horses expected to do athletic work, and as such is distinct from the picture of the dyspneic horses with overt RAO, there remains a plethora of clinical signs and case definitions for IAD. One of the most common findings in IAD is exercise intolerance, with or without overt signs of respiratory disease. Of 25 horses referred either for routine physical examination or poor performance, and without any clinical signs or history of respiratory disease, 76% had evidence of airway inflammation according to an inflammation scoring system based on endoscopy and tracheal wash findings.[861] Subclinical airway disease may result simply in mild abnormalities on auscultation and endoscopy, and occasional in coughing.[862] Signs such as nostril flaring and excessive abdominal effort at rest, however mild, are usually associated with the true RAO horses, as clinical signs that can be reliably detected using clinical scoring systems usually are accompanied by significant mechanical dysfunction of the respiratory system.[863] The prevalence of cough in IAD horses is hard to estimate, as many studies use the presence of cough as an inclusion criterion.[851,856,864] Other studies have shown that cough may be seen less than 16% to 50% of the time.[848,864,865] On endoscopic examination, excessive airway mucus is often seen, ranging from multiple specks to streams of mucus.[866] Other clinical signs that are frequently noticed include prolonged respiratory recovery,[845] respiratory embarrassment at exercise,[867] worsening of signs during hot, humid weather, and inability to perform work during collection. Racehorses with IAD are typically described as fading during the last quarter of the race (personal observation).

563

564

How does IAD affect performance? The answer depends on the use of the horse and the expectations of the owner. A practitioner with a primarily pleasure-horse practice or with show-hunter clientele might report a very low incidence of IAD in younger horses, primarily because the level of exercise in these horses is not likely to force a diagnosis through signs of exercise intolerance. A racetrack practitioner, on the other hand, would be far more likely to detect exercise intolerance resulting from lower airway disease in young horses because the level of expected athletic output is much higher and the horses have a greater likelihood of being examined

endoscopically. As might be expected, cough is more common in sport horses than in racehorses, as is an elevated respiratory rate, reflecting the generally earlier diagnosis in racehorses.[865] Indeed, racehorses with excessive tracheal mucus performed at a lower level than those with no mucus found on endoscopy.[854,867] Persson, looking at standardbred trotters and saddle horses, found that low-grade nonseptic airway inflammation does have a negative impact on ventilatory capacity, but that this is more pronounced in racehorses.[868] Moreover, using bronchiolar biopsy, this group also demonstrated that oxygen uptake and pulmonary ventilation correlated inversely with the morphologic grade of small airway disease and the height of the bronchiolar epithelium—the last finding suggesting that the extent of obstruction may determine the extent of exercise impairment. Racehorses with IAD have impaired gas exchange during exercise.[847,869] However, other studies have found that horses with obvious evidence of airway inflammation do not necessarily have a history of exercise intolerance.[858,870] This may reflect the difficulty of diagnosing low-grade respiratory impairment and the trainer's failure to recognize poorer performance than nature intended, however, rather than the benign nature of the underlying disease.

31.27.3 Diagnosis

31.27.3.1 BRONCHOALVEOLAR LAVAGE

Varying levels of specificity are used when documenting the presence of airway inflammation. The least specific is the documentation of mucus in the trachea; however, it is the method that best lends itself to large studies in the field.[854,867] Visualization of mucus in the trachea gives little information, however, as to the nature and the exact origin of the inflammation. Many workers have used and continue to use tracheal aspirate cytology to describe the nature of inflammation in IAD. Although tracheal aspiration can be used to explore the presence of inflammation and has been used to document neutrophilia, mastocytosis, and eosinophilia in young performance horses,[858,871] the question of the nature and exact origin again presents itself. Studies have shown poor correlation between tracheal aspiration and BAL cytology in horses,[872,873] with tracheal aspiration harvesting primarily neutrophils and epithelial cells, whereas BAL yields primarily alveolar macrophages and lymphocytes in normal horses. Moreover, there is no evidence of correlation between tracheal wash findings and performance. Consequently, to avoid the problem of neutrophil count sensitivity to the collection method, the recent International Workshop on Equine Chronic Airway Disease[843] recommended use of BAL to characterize horses with chronic airway disease; this recommendation was seconded by the Havemeyer Workshop on IAD.[857]

Different pictures of inflammation emerge from various BAL studies, leading to speculation that different genetic predispositions and environmental exposures are important to the inflammatory phenotype. In comparison with healthy horses, BAL cytology in horses with IAD has shown, variably, both neutrophilia and lymphocytosis,[848,856] neutrophilia and lymphopenia,[874] neutrophilia and mastocytosis,[845,846,851] and eosinophilia.[845] In general, horses with IAD have airway inflammation that may involve increases in nucleated cells or may also involve lymphocytosis. This is distinguished from RAO by the relatively low percentage of abnormal cells in IAD; whereas horses with RAO may exhibit almost entirely neutrophils in the BALF, horses with IAD seldom have greater than 2–15% neutrophils. The Havemeyer consensus has established that horses with IAD will have airway inflammation characterized by BAL cytology with any one of the following: mast cells >2%; PMNs >5%; or eosinophils >1%.

31.27.3.2

HISTOPATHOLOGY

Histopathologic studies of IAD are sparse, but useful information can be teased from COPD studies that on inspection included horses with what we would more appropriately term IAD. Bronchiolar biopsies of athletic young horses with lower airway inflammation have shown inflammatory mucosal cellular infiltrates and luminal exudates, bronchiolar hyperplasia, and goblet cell metaplasia.[868] It is interesting to note that 80% of supposedly normal horses had minimal evidence of peribronchiolitis—raising the question, of course, of what constitutes normal. O'Callaghan, while directing his concern to EIPH, nevertheless found plentiful evidence of multifocal, small airway—centered disease on postmortem examination of young racehorses. These findings included thickened walls caused by increased quantities of mucosal and peribronchiolar connective tissue, mononuclear bronchiolar cuffs, and extension of nonciliated bronchiolar epithelial cells into alveolar ducts.[875] Lakritz,[876] looking at lung tissue of clinically normal, young thoroughbred horses in training, found evidence of increased collagen, disruption of the epithelial basement membrane, and duplication of the epithelial basement membranes, suggesting previous airway inflammation and epithelial injury, which correlate with an increased interstitial pattern on radiographs. An ultrastructural study of young horses with “mild COPD” in one study found a decreased number of typical Clara cell granules and goblet cell metaplasia before the bronchioles began to show signs of inflammation typical of RAO.[877] Although the authors state that there was good correlation between histopathology and the results of a battery of pulmonary function tests, auscultation, bronchoscopy, blood gas analysis, and BAL in these horses, it is a lasting disappointment that the results of the ancillary testing remain unpublished. These data in sum certainly suggest that the histopathologic lesion of IAD is not only local bronchiolar inflammation, but also remodeling and thickening of the bronchioles themselves, which lends itself to at least low-grade airway obstruction.

31.27.3.3

LUNG FUNCTION TESTING

The esophageal balloon and pneumotach method for measuring lung function tends not to detect airway obstruction even in horses with RAO in remission.[878] However, use of the forced oscillatory technique[879] and forced expiratory maneuvers[856] has shown the existence of low-grade obstruction of the small airways of some horses with IAD. The mechanical behavior of the respiratory system has been shown to differ with sampling frequencies in asthmatic humans,[880] and a pattern of decreasing respiratory system resistance (RSR) with increasing frequency has been termed *negative frequency dependence of resistance* and has been interpreted as evidence of underlying small airway obstruction despite baseline measurements within the expected range. Similarly, horses with IAD as a group have significantly higher values for respiratory system resistance at the lower frequencies (1 to 3 Hz) and mild frequency dependence of resistance compared with controls,[879] although the baseline measurement of RSR may still frequently fall within the normal range. A study finding that lower oxygen uptake capacity and tidal volume correlated to a reduced diameter of the bronchiolar lumen owing to epithelial hyperplasia is strongly supportive of the existence of airway obstruction in IAD.[868] Consequently, without dynamic, frequency-dependent tests of lung function, forced maneuvers, or bronchoprovocation, it seems that we are simply failing to document a common feature of small airway obstruction in horse with IAD because our testing devices are not sufficiently sensitive to these changes.

564 565

31.27.3.4 AIRWAY RESPONSIVENESS

Horses with clinical signs compatible with IAD also exhibit signs of airway hyperresponsiveness when they are exposed to nonspecific agents such as histamine aerosol.[845,855,881,882] The basis for airway hyperresponsiveness remains hotly debated among pulmonary physiologists. It is likely a multifactorial phenomenon that has been associated with airway wall thickening undetectable by conventional lung function testing,[883] airway inflammation, and autonomic nervous system dysfunction.[843] There is a paucity of information concerning the mediators of airway hyperresponsiveness in horses with IAD, although the presence of elevated levels of leukotriene C4 levels has been documented.[881] In our laboratory, horses with a clinical history and signs compatible with IAD have significantly greater airway reactivity than controls, although some control horses display airway hyperresponsiveness as well.[879] This nonspecific airway hyperresponsiveness has been seen in humans and is associated with a greater risk of eventual development of asthma.[884] Although nonspecific airway hyperresponsiveness has been noted both in adult horses without signs of respiratory disease and in foals,[885] the significance of this finding remains unclear.

31.27.3.5 RADIOGRAPHY

Although radiography can be useful in helping to exclude septic causes of lower respiratory disease, such as pneumonia, lung abscess, or pleuropneumonia, its sensitivity in IAD is too low for it to be useful for identification of this disease. Moreover, no correlation exists among thoracic radiographs, airway hyperresponsiveness, and BAL cytology.[886] However, the more frequent finding of a bronchial pattern on thoracic radiographs supports the existence of airway obstruction in these horses.

31.27.4 Etiology

No single cause of IAD has been identified, although there has been plentiful speculation about the role of environment, viral disease, bacterial infection, air pollution, and genetic predisposition. Although horses with IAD do not seem to experience bouts of overt airway obstruction on exposure to an allergenic environment, organic dust associated with stabling likely contributes to the initial inflammation. Sweeney noted that the racehorses in her study lived in conditions of poor ventilation, and speculated that covert IAD may be instigated by the organic dusts, especially mold, in hay.[858] Others have noted that there is more mucopus in the tracheas of horses kept in poorly ventilated conditions,[887] and in one study thoroughbred racehorses in training, housed on straw, were found to be twice as likely to suffer from lower airway disease as those kept on shredded paper.[866] More recently, Holcombe and co-workers[887] showed that yearlings had a significantly higher number and percentage of neutrophils (PMNs as high as 18%) in BALF when they were stabled versus when they were at pasture. Although none of these horses had any clinical signs of respiratory disease or evidence of exercise intolerance, they were not in work, and subtle signs of performance impairment could easily have gone undetected. Dust levels in the horse's breathing zone can be as high as 25 mg/m^3—a level that would be considered unacceptable in any human workplace[888]—which can go far to explain the development of airway neutrophilia as a nonspecific response to high levels of particulates.[889] It is also likely that increased levels of endotoxin in hay and grain dust contribute to the development of airway neutrophilia.[890–892]

Although previous viral disease is commonly invoked as a predisposing factor in the development of IAD, little evidence exists to implicate viral disease. As in human asthmatics, viral respiratory disease has been shown to cause airway hyperresponsiveness for a period of time after infection,[885] perhaps due to denuding of the respiratory epithelium. However, no known virus was associated with poor performance and respiratory disease in 68% of cases in the United Kingdom.[893]

Recently there has been considerable speculation as to the role of bacterial infection in IAD, particularly in young racehorses. In several studies there was a strong relationship between inflammation of the lower respiratory tract and the presence of streptococcal species; horses with greater evidence of airway inflammation on tracheal aspiration and endoscopy had higher mean bacterial counts in tracheal aspirate,[866] and horses with bacteria found in the tracheal aspirate had a greater tendency to cough.[859] However, it is important to remember that association is not necessarily causation, and increased numbers of bacteria may reflect impaired airway clearance rather than a causative role for bacteria. The role of bacterial and viral infection in IAD remains unclear at this time.

Horses sample the ambient air on a continual basis: it seems logical that air pollution might contribute to the development of IAD. In one study clinically normal horses exposed to ozone had a significant increase in the glutathione redox ratio as well as total iron levels in the pulmonary epithelial lining fluid—both markers of exposure to oxidizing agents—and there was a strong correlation between airway inflammation score and the glutathione redox ratio in horses examined for poor performance but without overt airway disease.[861] In contrast, horses living in urban environments have been shown to have less airway reactivity, although greater levels of iron in the BALF, than do horses living in rural environments.[894]

Although heaves has been shown to be at least partially allergen mediated, in which horses manifest a Th2-type cytokine response,[895] and although environmental challenge can produce a consistent exacerbation of disease,[891] there is no such convincing evidence of an allergic response in horses with IAD. However, the presence of elevated numbers of mast cells in BALF of horses with poor performance,[850] the association of BAL mastocytosis with airway hyperresponsiveness,[846,896] and IHC studies showing more IgA-containing cells and occasionally increased numbers of IgM- and IgG-containing cells are suggestive of a degree of allergic response and a heightened immune response. It is most likely that multiple factors contribute to the development of IAD in individual horses; a critical level of risk factors or exposure is probably necessary for the disease to manifest itself.

565

566

31.27.5 Differential Diagnoses

The diagnosis of IAD often requires the exclusion of other diseases that may have a similar clinical picture. Whereas horses with RAO (heaves) or summer pasture—associated RAO (SPARAO) in remission may be very difficult to distinguish from horses with IAD, horses with RAO or SPRAO have a history of episodes of obvious breathing difficulty associated with exposure to either moldy hay or summer pasture. Upper airway disease, such as sinus infection or guttural pouch infection, may cause cough and nasal discharge, and both static and dynamic upper airway obstructions may cause poor performance and poor recovery from exercise. These may be largely ruled out by endoscopy. Horses with pneumonia, bronchopneumonia, or lung abscess commonly have abnormalities suggesting systemic disease, such as abnormal findings on CBC, recent history of fever, weight loss, or inappetence. In these cases tracheal wash can be very helpful in determining a septic cause of disease. Thoracic radiographs or ultrasound will also aid in the detection of these septic respiratory diseases. EIPH may

be seen in conjunction with IAD, but the presence of epistaxis, blood on endoscopy of the trachea, or red cells or hemosiderophages on BAL confirm the diagnosis of EIPH. Overt viral respiratory disease is difficult to confuse with IAD, as it usually manifests with fever and malaise, but horses with viral respiratory disease may exhibit prolonged cough and airway hyperresponsiveness for weeks to months after resolution of primary disease.

31.27.6 Therapy

There is remarkably little evidence-based support for any particular therapy in treating IAD. However, the mainstay of treatment has become a combination of environmental remediation, corticosteroid therapy, and bronchodilators.

31.27.6.1 ENVIRONMENTAL REMEDIATION

The barn environment is a hotbed of particulate matter, respirable endotoxin, molds, and volatile gases such as ammonia. The worst offenders appear to be hay and straw. A study looking at different management systems showed that when hay and straw bedding were replaced by pelleted feed and wood shavings, the respirable particulate levels were remarkably reduced.[888] Further improvements can be made by using cardboard bedding to reduce dust and mold levels.[897] Indoor arenas present another high dust challenge to the horse, with respirable particulate levels 20 times the level recognized to cause respiratory dysfunction in humans.[898] Other fairly commonsense strategies can be used. I make the following recommendations to owners in addition to the suggestion to change to low-dust feeds and beddings:

- Sprinkle aisles with water before sweeping.
- Avoid storing hay overhead. If unavoidable, lay a tarp under the hay to avoid dust raining down on the horses.
- Use a humectant or hygroscopic agent to reduce dust in the indoor and outdoor arenas.
- Remove horses from the barn while cleaning stalls or moving hay.
- Do not use blowers to clean aisles.
- Wet hay before feeding or use Dengie or other baked hay products.
- Remove cobwebs and other dust collectors routinely.

It is important to note that a recent study demonstrated that environmental control was by far the most important means of treating airway inflammation and dysfunction in horses with heaves, a more severe disease than IAD.[899] It is logical, therefore, to suppose that environmental management is equally important in the treatment of IAD.

31.27.6.2 CORTICOSTEROID THERAPY

Either parenteral or inhaled corticosteroids form the mainstay of drug therapy for IAD. Although the utility of corticosteroids for preventing or ameliorating airway remodeling in human asthma is debated,[900] corticosteroids have recently been demonstrated to prevent airway smooth muscle thickening in mice with

experimental asthma.[901] The degree of efficacy in decreasing BAL neutrophilia is not completely known, with some studies showing obvious benefit for dexamethasone in improving clinical signs and lung function and reducing BAL neutrophilia,[902] whereas others show primarily improvement in lung function with little effect on BAL cytology.[899,903] Corticosteroid treatment certainly causes adrenocortical dysfunction, but this is less pronounced with inhaled therapy versus systemic.[902] Although concerns about precipitating laminitis with corticosteroid therapy are frequently expressed, the actual risk of laminitis with corticosteroid therapy is completely unknown. Prednisone has been used in the past, but studies have shown lack of effect in horses with RAO.[904] In our clinic we frequently treat with an initial course of parenteral corticosteroids, typically a 4-week decreasing course of prednisolone followed by inhaled corticosteroids.

31.27.6.3 BRONCHODILATOR THERAPY

Bronchodilators, especially the inhaled form, appear to be efficacious in treating IAD in conjunction with corticosteroids. The most commonly used bronchodilators in IAD include aerosolized β-adrenergics, such as albuterol, and aerosolized parasympatholytics, such as ipratropium. Despite very legitimate concerns about development of tolerance to β-adrenergic drugs, a small study has shown that a chronic (2-week) course of aerosolized albuterol did not increase airway responsiveness to histamine in horses with preexistent airway hyperresponsiveness.[905] β-Adrenergic drugs such as albuterol also increase mucociliary transport. The use of systemic β-adrenergics such as clenbuterol is not advised, as the extent of bronchoconstriction in IAD does not warrant risking the adverse effect of cardiovascular remodeling, which has been shown to occur in horses.[906]

31.27.6.4 MAST CELL INHIBITORS

Sodium cromoglycate can be efficacious in treating known mast cell—mediated IAD[850] but will not be of use for treating the majority of horses with neutrophil-mediated disease. However, it requires considerable owner compliance, as the maximum response to this drug occurs at 1 to 2 weeks after beginning treatment.

31.27.6.5 AEROSOLIZED THERAPY

Aerosolized therapy using a combination of inhaled corticosteroids and bronchodilators is well established clinically in the treatment of IAD; however, there are no clinical trials establishing the efficacy of these drugs. When using inhaled drugs, we use a spacer and mask in order to improve delivery of the drug. Regardless of the type of mask and spacer device used, actual delivery of particles to the lower airways is poor in horses, as indeed it is even in humans, and the least efficacious means of delivering aerosolized drugs is by nebulization.[907–910] Unfortunately, strategies that we know improve lung deposition of aerosolized drugs in humans, such as slow deep breathing and breath holding, are not practical in horses. Devices currently on the market include the Aeromask and the Equine Haler. Individual horse and owner preference determines which device should be used. Inhaled corticosteroids commonly used in the treatment of IAD include beclomethasone and fluticasone.

Although there are no reported clinical trials using corticosteroids in horses with IAD, horses with RAO treated with 3750 μg of beclomethasone dipropionate twice daily using the Aeromask had improvement in both clinical signs and in lung function.[911] Smaller doses (500 to 1500 μg twice daily) administered with a device that is no longer on the market were shown to be efficacious in horses with heaves.[902] I commonly use small doses (500 to 1000 μg twice daily) using the Aeromask with good clinical effect in horses with IAD.

Fluticasone is a more potent corticosteroid than beclomethasone and has been shown to be efficacious when administered in conjunction with the Aeromask in treating horses with heaves, as well, using doses of 2000 µg twice daily. Unlike beclomethasone, in this study fluticasone did not cause adrenocortical dysfunction.[912] I use a decreasing-dose regimen, starting at 1500 to 2000 µg twice daily, working down to 1000 µg once daily or every other day. The lowest dose is arrived at over a 3- to 4-week period. Use of a short-acting bronchodilator, such as inhaled albuterol, 5 to 15 minutes before treatment with inhaled corticosteroid may help to increase deposition of the latter by fully opening the small airways. It is important that the owner understand that even with the higher doses of inhaled corticosteroid it may require 1 to 2 months for the best therapeutic effects to be achieved.

The most commonly used inhaled bronchodilator is albuterol, a β_2-specific adrenergic drug. The onset of effect with albuterol is quite rapid, with maximum bronchodilation being seen within 15 minutes. However, it is important to note that the maximum effect lasts in some horses for only an hour, and there are side effects with higher doses of drug, even in the inhaled form, such as anxiety, nervousness, trembling, and tachycardia. There is no evidence to suggest that the oral form of albuterol is even absorbed in the horse, and it is not suggested as appropriate therapy. Longer-acting β_2-adrenergic agonists, such as salmeterol and formoterol, can also be used, with bronchodilation lasting 6 to 8 hours. Parasympatholytic drugs such as ipratropium have a slower onset of action but longer duration than albuterol—at least 6 hours—and lack the severe side effects of parenteral use of drugs such as atropine. It is important to remember that these bronchodilators are symptomatic drugs only; they do not treat the underlying inflammation and therefore are unsuitable for single-drug therapy.

Mast cell inhibitors that can be administered by MDI include Intal (cromolyn) and Tilade (nedocromil sodium). They are discussed in earlier sections.

In summary, IAD is a disease characterized by nonseptic inflammation, visible on BAL cytology as excessive neutrophils, mast cells, or eosinophils, and involving low-grade airway obstruction and airway hyperresponsiveness. Clinical signs include variable cough, nasal discharge, and poor performance. Excessive amounts of mucus may also be visualized in the trachea using endoscopy. The cause of IAD is unknown, but the disease is probably best avoided by achieving a low-dust and low-endotoxin environment. Treatment logically begins with environmental remediation and is supplemented by antiinflammatory drug therapy using systemic or inhaled corticosteroids and inhaled bronchodilators. IAD that involves an excess of mast cells in the airways can be further treated with inhaled mast cell inhibitors.

31.28 TUBERCULOSIS

PEGGY S. MARSH

Tuberculosis refers to any infectious disease caused by *Mycobacterium* species and associated with the formation of focal granulomatous lesions with caseous necrosis. In humans many forms of the disease exist, with the primary site of infection most commonly being the lungs. *M. tuberculosis* is the typical causative agent in humans, whereas *Mycobacterium avium* or *Mycobacterium bovis* is usually implicated in animal cases. Tuberculosis is extremely rare in horses, especially in the United States. Most cases in horses have reported isolation of *M. avium*[913–916]; however, there are more recent reports of infection with *Mycobacterium bovis*.[917] In equine cases the organism is usually ingested, although primary respiratory infection may occur. Spread is hematogenous, and the organism frequently settles in lymph nodes and the spleen.

The most frequent presenting complaint is chronic weight loss with ensuing weakness and lethargy. Terminally ill horses with the pulmonary form are febrile and dyspneic and have a cough. Radiographic or sonographic evaluation of the thorax may be helpful in defining the pattern and distribution of lesions. Other clinical signs may be noted depending on the organ systems affected and include intestinal tract signs, hepatitis, and osteomyelitis of the cervical vertebrae, as well as guttural pouch and ocular infections.[913–917]

Diagnosis is based on presence of tubercles and isolation of the organism and probably most frequently is made after the horse's death. The intradermal skin test is not reliable in the horse because a majority of clinically normal horses may have positive test results.[918] Cytologic or histologic evaluation of a wash or aspirate of a lesion may reveal acid-fast bacilli. Biopsy of the lesion(s) is necessary for a definitive diagnosis. When tuberculosis is suspected, culture of an appropriate sample, such as a tracheal aspirate with primary pulmonary involvement, is advisable. However, this is a very slow-growing organism, and isolation may take multiple weeks. More recently PCR technology has proven a useful tool.[917]

Treatment is not usually attempted, because of public health concerns. I am unaware of any published report on treating horses with tuberculosis. If treatment is undertaken, the horse should be isolated, with precautions taken to prevent spread of disease and in consultation with the handler's physician and/or public health officials. Tuberculosis is a reportable disease in other species. Drugs used in other species (rifampin, isoniazid, and streptomycin) could be considered, but there are no guidelines for their use in horses with this condition. Isoniazid has been used in horses for other conditions at a dose of 5 to 15 mg/kg PO twice daily.[919] Although a study on rifampin pharmacokinetics in horses recommended using 10 to 25 mg/kg PO twice daily,[920] clinical results in foals with *R. equi* pneumonia suggest that 5 to 10 mg/kg PO twice daily is adequate. In humans, treatment periods are very prolonged, frequently a year or more. Because treatment is usually not a viable option in horses, prognosis is very poor.

Bacillus Calmette-Guérin (BCG) vaccine has been used in humans with potential exposure, but the benefit of its use in horses to providing increased resistance after exposure to a tuberculosis infection is unknown.

31.29 PNEUMOCONIOSIS (SILICOSIS)

PEGGY S. MARSH

Pneumoconiosis refers to lower respiratory tract disease associated with deposition of small particles (dust) within the lungs. In human medicine the majority of cases are occupation related and include coalworker's lung, silicosis, and asbestosis.[921] There are two related reports of horses with silicosis.[922,923] The majority of the horses originated from the Monterey-Carmel Peninsula in California. Silicosis is a disease caused by inhalation of crystalline silica. There are several clinical forms of silicosis in humans, including simple and complicated chronic forms as well as acute silicosis (silicoproteinosis). Silicosis has also been associated with immune system deficits, in particular alteration of cell-mediated immunity. Freshly fractured silica is more toxic to alveolar macrophages than aged silica. Crushing silica leads to the formation of reactive radials.[924] The small (0.5 to 5 mm) particles are deposited in small airways and alveoli and subsequently phagocytosed, initiating a cycle of granulomatous inflammation, oxidative stress, and apoptosis leading to chronic fibrotic interstitial disease.[921,924]

The clinical signs reported in the horses were similar to those of COPD and included weight loss, cough, exercise intolerance, and, sometimes, exercise-induced respiratory distress (sweating, nostril flaring, abducted elbows, reluctance to move, and shaking). Resting respiratory rates are often increased. Physical examination revealed a

restrictive pattern of breathing. Auscultation revealed harsh breath sounds and some wheezing, which was exacerbated by exercise.

Diagnosis was based on the presence of birefringent crystalline inclusions within pulmonary macrophages.[923] Samples were obtained via tracheal aspiration, BAL, or lung biopsy or at necropsy. In some cases repeated tracheal sampling was required. Radiographs of the thorax revealed a variety of findings including most commonly an interstitial pattern (miliary, reticulonodular, and linear) that was most severe in the caudodorsal lung fields. Other radiographic abnormalities noted were lymphadenopathy, pleural effusion or thickening, hyperinflation, and pulmonary consolidation.[923]

Gross pathologic analysis revealed interstitial granulomatous pneumonia and fibrosis. Histologic examination with both light and electron microscopy revealed peribronchitis, perivasculitis, and cellular infiltrates consisting of mostly macrophages and giant cells, with refractile inorganic dust particles noted both intracellularly and extracellularly.[922,923]

In general the horses reported to have silicosis had a poor prognosis. The original study discussed postmortem findings of nine horses.[922] In the other related paper a total of 19 horses were identified.[923] Short-term (2 to 12 months) follow-up evaluation was available in eight of these individuals, with a progressive loss of respiratory function noted in four of the cases, leading to euthanasia. Treatment consisted of environmental change and glucocorticoid therapy. Novel forms of therapy, including inhibition of inflammatory mediators as well as inhibition of apoptosis, may be seen in the future.[924]

There are no recent reports of silicosis or other forms of pneumoconiosis in the horse. However, there are reports in other domestic species in areas of environmental contamination.[925] Also, new forms of pneumoconiosis are being investigated in humans, such as World Trade Center Cough.[926] It may be prudent to keep environmental contamination in mind when investigating chronic noninfectious forms of lower respiratory tract disease in the horse.

31.30 MYCOPLASMA

PEGGY S. MARSH

Mycoplasma species are a group of bacteria that differ from other bacteria because they lack a cell wall, are much smaller than most bacteria, and need cholesterol to survive. These organisms are proven to cause respiratory disease in humans, cattle, and pigs. *M. felis* has been isolated as a pathogen causing pleuritis and pericarditis in the horse.[927–929] Experimental infection with *M. felis* in ponies induced pleuritis.[929] The relative importance of *Mycoplasma* species as a pathogen in acute respiratory disease of the horse has been debated. Several species of mycoplasma can be isolated from the respiratory tract of healthy and diseased animals, both adults and foals. A report from Australia did not yield growth of mycoplasmas in any of the samples from young racing horses with coughs.[930] However, a similar case control type study from the United Kingdom showed an association between *M. felis* and IAD in young racehorses.[931] Also, a Canadian report demonstrated growth of *M. equirhinis* and *M. felis*, along with other bacteria commonly thought of as respiratory pathogens, in horses with acute lung disease.[932] *M. felis* has been reported as a potential cause of an outbreak of acute respiratory disease in a stable of young racehorse, as well as of respiratory disease in foals.[933,934]

Clinical signs of pleuritis caused by mycoplasma infection, including fever, depression, and pleurodynia, mimic other bacterial pleural pneumonia cases. Auscultation of the thorax may reveal pleural friction rubs and dull lung sounds over the cranioventral thorax. Sonographic examination of the thorax reveals pleural effusion, often bilateral. Thoracocentesis should be performed for both diagnostic and, if necessary, therapeutic purposes. The fluid is most often an exudate, lacking any odor. Cytologic examination reveals large numbers of neutrophils within the pleural fluid.

Crucial to diagnosis of mycoplasma infection is the elimination of more common pathogens, such as streptococcal infections. Thus routine cultures for aerobic and anaerobic bacteria should be performed in any case of pleuritis. Culture for the presence of mycoplasma is difficult. Immediate centrifugation of pleural fluid is ideal, because supernatants are the preferred culture samples.[935] These samples should then be placed in mycoplasma-specific media. Seroconversion can also be an aid in diagnosis, with seroconversion occurring in a large number of the reported cases of *M. felis* infection.[927,928,933] Experimental infection revealed that once seroconversion has occurred, the organism can no longer be isolated from culture samples.[929] Seroprevalence in this country is not known.

Experimentally infected ponies recovered without treatment in one study, so the requirements of treatment specific for mycoplasma are unclear.[929] Although sensitivity testing should be performed on any isolate, *Mycoplasma* species have been found to be sensitive to gentamicin, tetracyclines, and erythromycin.[936] The role these organisms play in equine respiratory disease is still unclear, and investigation continues.

31.31 EXERCISE-INDUCED PULMONARY HEMORRHAGE

K. W. HINCHCLIFF

EIPH is a pervasive disorder of horses that perform strenuous exercise and is best recognized in thoroughbred and standardbred racehorses. The disorder is associated with reduced performance of thoroughbred racehorses, and probably in other breeds, and costs the thoroughbred and standardbred racing industries in the United States and Canada between $100,000,000 and $225,000,000 (U.S. dollars [USD]) annually.[937] The disease occurs commonly in horses but less commonly in camels, greyhounds, and, rarely, human athletes.[938–940]

31.31.1 Etiology

Epistaxis and hemorrhage into airways can occur as a result of a number of diseases, including disorders of the upper airways and lungs. Hemorrhage into trachea or bronchi can be a result of EIPH, pulmonary abscess, fungal granuloma, trauma, pneumonia, pulmonary foreign body, or hemangiosarcoma or other pulmonary neoplasia. 568
Epistaxis can be associated with all of these causes of hemorrhage into the lower airway and, in addition, 569
diseases of the upper airway including guttural pouch mycosis, ethmoidal hematoma, trauma, and neoplasia of the upper airways and associated structures. Thrombocytopenia can cause epistaxis.

The likely proximate cause of hemorrhage in horses with EIPH is rupture of alveolar capillary membranes with subsequent extravasation of blood into interstitial and alveolar spaces.[941] The source of blood in such instances is the pulmonary circulation. Bleeding from bronchial circulation during exercise has been suggested based on histologic evidence of bronchial angiogenesis in horses that have experienced previous episodes of EIPH,[942] but contribution of the bronchial circulation to EIPH has not been demonstrated. Regardless of the contribution of

bronchial circulation to blood in the airways, the likely initial lesion is in capillaries associated with the pulmonary circulation. Hemorrhage into the interstitial space and alveoli, with subsequent rostral movement of blood in the airways, results in blood in the trachea and bronchi, which in rare instances results in epistaxis.

31.31.2 Clinical Signs and Differential Diagnosis

31.31.2.1 HISTORY AND PRESENTING COMPLAINT

Poor athletic performance and epistaxis (Fig. 31-37) are the most common presenting complaints for horses with EIPH. Although poor performance may be attributable to any of a large number of causes, epistaxis associated with exercise is almost always secondary to EIPH.

Epistaxis due to EIPH occurs during or shortly after exercise and is usually first noticed at the end of a race, particularly when the horse is returned to the paddock or winner's circle and is allowed to lower its head. It is usually bilateral and resolves within hours of the end of the race. Epistaxis can occur on more than one occasion in the same horse.

Fig. 31-37 Horse with exercised-induced pulmonary hemorrhage and epistaxis.

31.31.3 EXERCISE-INDUCED PULMONARY HEMORRHAGE AND PERFORMANCE

Failure of racehorses to perform to the expected standard (poor performance) is often, accurately or not, attributed to EIPH. Many horses with poor performance have cytologic evidence of EIPH on microscopic examination of tracheobronchial aspirates or BALF or have blood evident on endoscopic examination of the tracheobronchial tree performed 30 to 90 minutes after strenuous exercise or racing.[943,944] However, it is important to recognize that EIPH is very common in racehorses and it should be considered the cause of poor performance only after other causes have been eliminated. Severe EIPH undoubtedly results in poor performance and, on rare occasions, death of thoroughbred racehorses.[945–948] A relationship between finishing position and incidence of EIPH, diagnosed by bronchoscopic examination, was not detected for 191 thoroughbred racehorses that finished in first, second, or third place.[946] Furthermore, there was no relationship between the proportion of horses with EIPH and placing (first, second, or third versus other) in another 98 horses.[947] Similarly, there was no relationship between finishing position and proportion of horses with EIPH in 191 thoroughbreds examined after racing.[948] There was no relationship between severity of EIPH, assessed on tracheobronchoscopic examination, and race performance in 258 thoroughbreds or 296 standardbred racehorses.[949] Together, these studies do not demonstrate a clear relationship between the presence of EIPH, or its severity, and race performance.

In contrast to the studies just discussed, among 452 thoroughbred horses examined after racing in Hong Kong, those finishing in the first three positions had less severe EIPH than did horses finishing in lower positions.[950] Of horses finishing in the first three places, 43.9% had evidence of EIPH on tracheobronchoscopic examination after racing, whereas 55.9% of horses finishing in fourth to fourteenth place had evidence of EIPH.

A recent study demonstrated that thoroughbred horses with EIPH racing in Victoria, Australia have impaired performance compared with unaffected horses. Horses were assessed as having no EIPH or grades 1 to 4 EIPH on the basis of endoscopic examination performed within 2 hours of racing. After statistical correction of other factors that could influence performance, there was a clear association between EIPH of >grade 1 (i.e., grades 2 to 4) and impaired performance.[951] Horses with EIPH ≤1 were 4 times more likely to win, 1.8 time more likely to finish in the top three positions, and 3 times as likely to be in the 90th percentile for earning as horses with EIPH ≥grade 2. Horses with EIPH finished further behind the winner than did horses that did not have EIPH.[951]

Results of studies in standardbred racehorses indicate either a lack of effect of EIPH on performance or an association between EIPH and superior performance. There was not a relationship between presence of EIPH and finishing position in 29 standardbred racehorses with intermittent EIPH examined on at least two occasions,[952] nor in 92 standardbred racehorses examined on one occasion.[953] However, of 965 standardbred racehorses examined after racing, those finishing first or second were 1.4 times more likely (95%, confidence interval 0.9 to 2.2) to have evidence of EIPH on tracheobronchoscopic examination than were horses that finished in the seventh or eighth position.[954]

31.31.4 Physical Examination

569

Apart from epistaxis in a small proportion of affected horses, there are few abnormalities detectable on routine physical examination of horses with EIPH. Rectal temperature and heart and breathing rates may be elevated as a consequence of exercise in horses examined soon after exercise, but values of these variables in horses with EIPH at rest are not noticeably different from those in horses with no evidence of EIPH. Affected horses may

570

swallow more frequently during recovery from exercise than do unaffected horses, probably as a result of blood in the larynx and pharynx. Coughing is common in horses recovering from strenuous exercise, and after recovery from exercise horses with EIPH are no more likely to cough than are unaffected horses.[955] Other clinical signs related to respiratory abnormalities are uncommon in horses with EIPH. Respiratory distress is rare in horses with EIPH and when present indicates severe hemorrhage or other serious lung disease such as pneumonia, pneumothorax, or rupture of a pulmonary abscess. Lung sounds are abnormal in a small number of EIPH-affected horses and when present are characterized by increased intensity of normal breath sounds during rebreathing examination.[956] Tracheal rales may be present in horses with EIPH but are also heard in unaffected horses.[957]

Horses that have experienced one episode of epistaxis are more likely to have a second episode. For this reason most racing jurisdictions do not permit horses with epistaxis to race for a period of weeks to months after the initial instance, with more prolonged enforced rest after a subsequent episode of epistaxis and retirement from racing after a third bout. The recurrence rate after one episode of epistaxis in thoroughbred horses is approximately 13.5% despite affected horses not being permitted to race for 1 month after the initial episode of epistaxis.[958] This high rate of recurrence suggests that the inciting pulmonary lesions have not healed.

31.31.5 Diagnostic Approach

31.31.5.1 DIAGNOSTIC TESTS

Various techniques are available for determining the presence and severity of EIPH, including direct examination of the airways through a flexible endoscope or examination of bronchial lavage fluid or tracheal aspirates for evidence of hemorrhage. The utility of these diagnostic tests varies, and choice of examination technique depends on the time between the racing of the horse and the examination and on the desired sensitivity of the test. For instance, tracheobronchoscopic examination is most appropriate if a horse is examined within 1 to 2 hours of exercise, whereas examination of airway washings is most appropriate if the examination is days to a week after strenuous exercise. Radiography, pulmonary scintigraphic examination, and lung function tests are useful in eliminating other respiratory diseases as causes of poor performance but are minimally useful in confirming a diagnosis of EIPH or in determining the severity of hemorrhage.

31.31.5.2 TRACHEOBRONCHOSCOPY

Observation of blood in the trachea or large bronchi of horses 30 to 120 minutes after racing or strenuous exercise provides a definitive diagnosis of EIPH. The amount of blood in the large airways varies from a few small specks on the airway walls to a stream of blood occupying the ventral third of the trachea (Fig. 31-38). Blood may also be present in the larynx and nasopharynx. If there is a strong suspicion of EIPH and blood is not present on a single examination conducted soon after exercise, the examination should be repeated in 60 to 90 minutes. Some horses with EIPH do not have blood in the rostral airways immediately after exercise, but do so when examined 1 to 2 hours later. Blood is detectable by tracheobronchoscopic examination for 1 to 3 days in most horses, with some horses having blood detectable for up to 7 days.

Bronchoscopic examination can be used to estimate the severity of EIPH through use of a grading system.[946,959] The interobserver repeatability of tracheobronchoscopic assessment of severity of EIPH using a 0 to 4 grading scale has been demonstrated[959] (see Fig. 31-38).

- Grade 0: No blood detected in the pharynx, larynx, trachea or mainstem bronchi.
- Grade 1: Presence of one or more flecks of blood or ≤2 short (<¼ length of the trachea) narrow (<10% of the tracheal surface area) streams of blood in the trachea or main stem bronchi visible from the tracheal bifurcation.
- Grade 2: One long stream of blood (>half the length of the trachea) or >2 short streams occupying less than ⅓ of the tracheal circumference.
- Grade 3: Multiple, distinct streams of blood covering more than ⅓ of the tracheal circumference. No blood pooling at the thoracic inlet.
- Grade 4: Multiple, coalescing streams of blood covering >90% of the tracheal surface with pooling of blood at the thoracic inlet.

It is assumed that a higher score represents more severe hemorrhage, but although the repeatability of this scoring system has been established, the relationship between the amount of blood in the large airways and the actual amount of hemorrhage has not been established.

31.31.5.3 TRACHEAL ASPIRATION AND BRONCHOALVEOLAR LAVAGE

The presence of red cells or macrophages containing either effete red cells or the breakdown products of hemoglobin (hemosiderophages) in tracheal fluid or BALF provides evidence of EIPH. Detection of red cells or hemosiderophages in tracheal aspirates or BALF is believed to be both sensitive and specific in the diagnosis of EIPH.[944,960] Examination of airway fluids indicates the presence of EIPH in a greater proportion of horses than does tracheobronchoscopic examination after strenuous exercise or racing. The greater sensitivity of examination of airway fluid is likely attributable to the ability of this examination to detect the presence of small amounts of blood or its residual products and the longevity of these products in the airways. Whereas endoscopic examination may detect blood in occasional horses up to 7 days after an episode of EIPH, cellular evidence of pulmonary hemorrhage persists for weeks after a single episode.[944,960,961] Red blood cells and macrophages containing red cells are present in BALF or tracheal aspirates for at least 1 week after strenuous exercise or instillation of autologous blood into airways, and hemosiderophages are present for at least 21 days and possibly longer.[944,961]

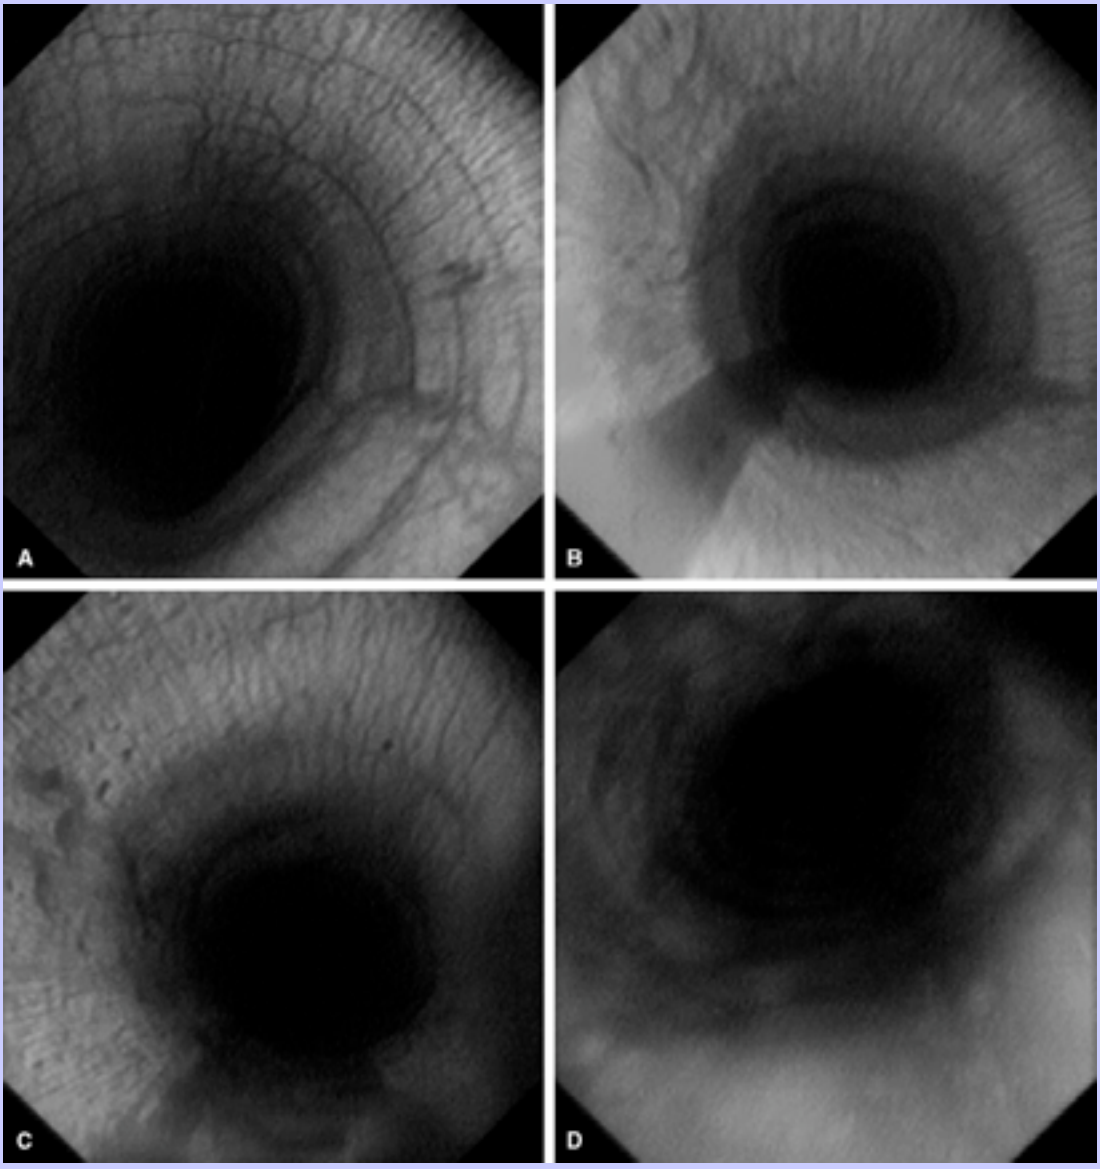
Recent studies have reported on the use of red cell numbers in BALF as a quantitative indicator of EIPH.[962–965] However, this indicator of EIPH severity has not been validated or demonstrated to be more reliable or repeatable than tracheobronchoscopic examination and visual scoring. Furthermore, considerable concern exists over the suitability of red cell counts in BALF for assessment of severity of EIPH given that an unknown area, although presumably small, of the lung is examined by lavage and there is a risk that this area of lung may not be representative of the lung as a whole, similar to the situation of examination of BALF of horses with pneumonia.[966] BAL of sections of both lungs, achieved using an endoscope, may obviate some of these concerns.

Tracheal aspirates may be obtained any time after exercise by either aspiration during tracheobronchoscopic examination or aspiration through a percutaneous intratracheal needle. Aspirates obtained through an endoscope may not be sterile, depending on the collection technique. BALF can be obtained through either an endoscope wedged in the distal airway or a cuffed tube inserted blindly into a distal airway. Collection of fluid

570
571

through an endoscope has the advantage of permitting examination of the distal airways and selection of the area of lung to be lavaged. However, it does require the use of an endoscope that is longer (2 m) than those readily available in most equine practices. Use of a commercial BAL catheter does not require use of an endoscope and can be readily performed in field situations.

Fig. 31-38 Tracheobronchoscopic findings in horses with exercise-induced pulmonary hemorrhage. **A** is from a horse with grade 1 hemorrhage. **B** is from a horse with grade 2 hemorrhage. **C** is from a horse with grade 3 hemorrhage. **D** is from a horse with grade 4 hemorrhage.



31.31.5.4 RADIOGRAPHY

Thoracic radiography is of limited use in detecting horses with EIPH. Radiographs may demonstrate the presence of densities in the caudodorsal lung fields of some horses, but many affected horses have minimal to undetectable radiographic abnormalities.[967] Examination of thoracic radiographs of horses with EIPH may be useful in ruling out the presence of another disease process, such as a pulmonary abscess, that is contributing to the horse's pulmonary hemorrhage or poor athletic performance.

31.31.6 Pathophysiology

Rupture of alveolar capillaries occurs secondary to an exercise-induced increase in transmural pressure (pressure difference between the inside of the capillary and the alveolar lumen). If the transmural stress exceeds the tensile strength of the capillary wall, the capillary ruptures.[968] The proximate cause of alveolar capillary rupture is the high transmural pressure generated by positive intracapillary pressures that are largely attributable to capillary blood pressure and the lower intraalveolar pressure generated by the negative pleural pressures associated with inspiration.

571 572

During exercise the absolute magnitudes of both pulmonary capillary pressure and alveolar pressure increase, with a consequent increase in transmural pressure. Strenuous exercise is associated with marked increases in pulmonary artery pressure in horses.[963,969,970] Values for mean pulmonary arterial pressure at rest of 20 to 25 mm Hg increase to greater than 90 mm Hg during intense exercise because of the large cardiac output achieved by exercising horses. The increases in pulmonary artery pressure, combined with an increase in left atrial pressure during exercise, likely result in an increase in pulmonary capillary pressure. Combined with the increase in pulmonary capillary pressure is a marked decrease (more negative) in pleural, and therefore alveolar, pressures during exercise. Pleural pressures of normal horses during inspiration decrease from approximately −0.7 kPa (−5.3 mm Hg) at rest to as low as −8.5 kPa (−64 mm Hg) during strenuous exercise.[971] Together, the increases in pulmonary capillary pressure and decrease (more negative) in intrapleural (alveolar) pressure contribute to a marked increase in stress in the alveolar wall. Although the alveolar wall and pulmonary capillary of horses are stronger than those of other species, rupture may occur because the wall stress in the alveolus exceeds the mechanical strength of the capillary.[972]

Other theories of the pathogenesis of EIPH include small airway disease, upper airway obstruction, hemostatic abnormalities, changes in blood viscosity and erythrocyte shape, intrathoracic sheer forces associated with gait, and bronchial artery angiogenesis.[942,973] It is likely that the pathogenesis of EIPH involves several processes, including pulmonary hypertension, lower alveolar pressure, and changes in lung structure, that summate to induce stress failure of pulmonary capillaries.

Obstruction of either the upper or lower airways has been proposed as a cause of EIPH.[974] Inspiratory airway obstruction results in more negative intrapleural and therefore alveolar pressures. This effect is exacerbated by exercise, with the result that alveolar transmural pressure is greater in horses with airway obstruction.[975,976] The higher transmural pressure in such horses may increase the severity of EIPH, although this has not been demonstrated. Moreover, although inspiratory airway obstruction may predispose to EIPH, the prevalence of this condition is much less than that of EIPH, indicating that it is not the sole factor inducing EIPH in most horses.

Horses with moderate to severe EIPH have histologic evidence of inflammation of the small airways,[977,978] and there is a clear association between presence of EIPH and inflammatory changes in bronchoalveolar or tracheal aspirate fluid.[979] However, instillation of autologous blood into the airways induces a marked inflammatory response in normal horses,[980] and it is therefore unclear if inflammation alone induces or predisposes to EIPH or if the inflammation is a result of EIPH. Theoretically, small airway inflammation and bronchoconstriction have the potential to produce intrathoracic airway obstruction and therefore a more negative alveolar pressure. Given that small airway disease is common in horses, there is the potential for an important effect of factors, such as viral infections, air pollution, and allergic airway disease, to contribute to the initiation or propagation of EIPH.[981]

Exercise is accompanied by marked changes in blood flow characteristics attributable to an increase in hematocrit and decrease in red cell deformability.[982,983] These changes cause an increase in microvascular shear stress and thus could conceivably contribute to capillary rupture. However, there is at present no direct evidence that indicates that this is an important feature of development of EIPH.

The characteristic location of lesions of EIPH in the caudodorsal lung fields has lead to the proposal that hemorrhage is a result of tissue damage occurring when waves of stress, generated by forelimb foot strike, are focused and amplified by the narrowing cross-sectional area of the caudal lung lobes.[973] According to the theory, the locomotory impact of the forelimbs results in transmission of forces through the scapula to the body wall; from there they pass into the lungs and caudally and dorsally. As the wave of pressure passes into the narrower caudodorsal regions of the lungs, it generates progressively greater shearing forces that disrupt tissue and cause EIPH. However, studies of intrapleural pressures have not demonstrated the presence of a systemic pressure wave passing through the lung and do not provide support for this hypothesis.[984] The observation that horses competing in hurdles or steeplechase events on hard ground have increased incidence of epistaxis lends support to the suggestion that locomotory impact might influence the development of EIPH.[985]

Horses with EIPH have been suspected of having defects in either hemostasis or fibrinolysis. However, although exercise induces substantial changes in blood coagulation and fibrinolysis,[986] there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[987,988]

Regardless of the cause, rupture of pulmonary capillaries and subsequent hemorrhage into airways and interstitium causes inflammation of both airways and interstitium, with subsequent development of fibrosis and alteration of tissue compliance. Heterogeneity of compliance within the lungs, and particularly at the junction of normal and diseased tissue, results in development of abnormal shear stress with subsequent tissue damage. These changes are exacerbated by inflammation and obstruction of small airways with resulting uneven inflation of the lungs.[989] The structural abnormalities, combined with pulmonary hypertension and the large intrathoracic forces associated with respiration during strenuous exercise, cause repetitive damage at the boundary of normal and diseased tissue with further hemorrhage and inflammation. The process, once started, is life-long and continues for as long as the horse continues to perform strenuous exercise.[942]

31.31.7 Epidemiology

EIPH occurs in horses throughout the world. It is a disorder of horses that run at high speed, such as thoroughbred or standardbred racehorses, quarter horses (racehorses and barrel racing horses), and polo ponies. The disorder is apparently uncommon in endurance horses and is very uncommon in draft breeds, such as

Clydesdales, Percherons, or Belgians, after participation in weight-pulling competition.[990] As a general rule, the more intense the exercise or the higher the speed attained, the greater the proportion of horses with EIPH.

The prevalence of EIPH varies with the method used to detect it and the frequency with which horses are examined, as discussed later in this section. Almost all thoroughbred racehorses in active training have hemosiderophages in BALF, indicating that all have some degree of EIPH.[944] The prevalence of EIPH decreases when diagnosis is based on endoscopic examination of horses after exercise or racing.

31.31.8 Risk Factors

31.31.8.1 BREED

572

EIPH is very common in thoroughbred racehorses, with estimates of prevalence, based on a single endoscopic examination of the trachea and bronchi, of 43% to 75%.[948,950,991] The prevalence increases with the frequency of examination, with over 80% of horses having evidence of EIPH on at least one occasion after examination after each of three consecutive races.[992] The prevalence of EIPH in standardbred racehorses is assumed to be lower, with 26% to 34% of horses reported to have blood in the trachea after racing.[953,993] However, these studies were based on a single examination, and one study [993] reported as positive only those horses with blood covering more than one half of the tracheobronchial tree. When examined after each of three races, 87% of standardbred racehorses have evidence of EIPH on at least one occasion,[952] suggesting that EIPH is as common in standardbred racehorses as it is in thoroughbred racehorses.

573

EIPH occurs in approximately 62% of racing quarter horses and has been observed in quarter horses used for barrel racing.[994] The disorder occurs in racing Appaloosa horses.[995] Approximately 11% of polo ponies are affected with EIPH[996] and the disorder occurs in Chilean Criollo horses.[997]

31.31.8.2 AGE

Age is considered an important risk factor for EIPH, with the prevalence of the disorder being higher in older horses.[946,947,998,999] There is no consistent effect of sex on prevalence of EIPH.[948,950,953,991]

Among thoroughbred racehorses the prevalence of EIPH increases with increasing speed,[948,977] being greater in thoroughbreds after racing than after breezing (galloping). Lesions of EIPH are not detected in young thoroughbred racehorses that have trained at speeds less than 7 m/sec.[948,977]

Epistaxis associated with exercise is almost always attributable to pulmonary hemorrhage but occurs only in a small proportion of racehorses.[958,1000,1001] The prevalence of epistaxis in racehorses varies between 0.1% and 9%, with the frequency depending on the breed, age, and sex of horses selected for study, the type of racing, and the timing and frequency of observation of horses after racing. Epistaxis is more common in older horses.[958,1000] There are conflicting reports of a sex predisposition, although epistaxis may be more common in female thoroughbreds.[958,1000] Epistaxis is more common after races <1600 m than in longer races,[958] although not all sources agree on this point.[1000] However, horses in steeplechase races, which are typically longer than 2000 m, are at greater risk of epistaxis than are horses in flat races.[958,985] In addition, horses racing in hurdle or steeplechase races over hard ground in Britain are more likely to have epistaxis.[985]

The effect of genetics on the incidence of EIPH has been examined only minimally, with one study of horses with epistaxis, which is characteristically associated with severe EIPH, suggesting a hereditary predisposition among thoroughbred racehorses in South Africa.[1002] The heritability of the predisposition to epistaxis was considered low.[1002]

31.31.9 Necropsy

EIPH is a cause of sudden death of horses during racing and training[1003–1005] and in most studies is secondary to musculoskeletal injury as the cause of death. Necropsy examination reveals that approximately 60% of horses that die during racing or training or are euthanized because of acute injury during racing or training have evidence of EIPH.[1005] Necropsy examination of affected horses is usually but not always incidental to examination for another cause of death.

Pertinent abnormalities detected on necropsy of horses with EIPH are restricted to the respiratory tract. Grossly, horses examined within hours of strenuous exercise, such as horses examined because of catastrophic musculoskeletal injuries incurred during racing, often have severe petechiation in the caudodorsal lung fields. Horses that die of EIPH also have pulmonary congestion and edema.[1005] Horses with chronic disease have blue-gray or blue-brown discoloration of the visceral pleural surfaces of the caudodorsal lung fields that is often sharply demarcated, especially on the diaphragmatic surface.[1005,1006] The discoloration affects both lungs equally, with 30% to 50% of the lung fields being discolored in severe cases. Affected areas do not collapse to the same extent as unaffected areas and, in the deflated lung, have a spleenlike consistency. On the cut surface the discolored areas of lung are predominantly contiguous with the dorsal pleural surface and extend ventrally into the lung parenchyma. Areas of affected lung may be separated by normal lung. There is proliferation of bronchial vessels, predominantly arteries and arterioles, in affected areas.[1007] Histologically, affected areas exhibit bronchiolitis, hemosiderophages in the alveolar lumen and interstitial spaces, and fibrosis of interlobular septa and pleura and around vessels and bronchioles.[978]

31.31.10 Therapy, Prevention, and Control

Therapy for EIPH is usually a combination of attempts to reduce the severity of subsequent hemorrhage and efforts to minimize the effect of recent hemorrhage. Treatment of EIPH is problematic for a number of reasons. First, the pathogenesis of EIPH has not been determined, although the available evidence supports a role for stress failure of pulmonary capillaries secondary to exercise-induced pulmonary hypertension (see later). Second, there is a lack of information using large numbers of horses under field conditions that demonstrates an effect of any medication or management practice (with the exception of bedding) on EIPH. There are numerous studies of small numbers of horses (less than approximately 40) under experimental conditions, but these studies often lack the statistical power to detect treatment effects, and, furthermore, the relevance of studies conducted on a treadmill to horses racing competitively is questionable. Treatments for EIPH are usually intended to address a specific aspect of the pathogenesis of the disease and will be discussed in that context.

31.31.10.1 PREVENTION OF STRESS FAILURE OF THE PULMONARY CAPILLARIES

There is interest in reducing the pressure difference across the pulmonary capillary membrane in an effort to reduce EIPH. Theoretically, this can be achieved by reducing the pressure within the capillary or increasing (making less negative) the pressure within the intrathoracic airways and alveolus.

Furosemide apparently reduces pulmonary capillary pressure in exercising horses. Furosemide administration as prophylaxis against EIPH is permitted in a number of racing jurisdictions worldwide, most notably Canada, the United States, Mexico, and most of the South American countries.[1008] Within the United States and Canada, almost all thoroughbred, standardbred, and quarter horse racing jurisdictions permit administration of furosemide before racing. The vast majority (>90%) of thoroughbred horses racing in the United States receive furosemide before racing, at an estimated annual cost of between $6,000,000 and $20,000,000.[937] Although accurate numbers are not available, it appears that a smaller proportion of standardbred and quarter horse racehorses receive furosemide before racing. Furosemide is administered to 22% to 32% of standardbred racehorses and 19% of racing quarter horses in two racing jurisdictions.[1009–1011]

The efficacy of furosemide in treatment of EIPH is uncertain. Although field studies of large numbers of horses do not demonstrate an effect of furosemide on the prevalence of EIPH,[992] studies of thoroughbred horses running on a treadmill provide evidence that furosemide reduces the severity of EIPH.[964,965,1012] Under field conditions, based on tracheobronchoscopic evaluation of the severity of bleeding, furosemide has been reported to reduce or have no influence on the severity of bleeding.[1013] This apparent inconsistency may be attributable to measurement of red blood cell counts in BALF of horses that have run on a treadmill not being representative of effects of furosemide under field conditions. The weight of evidence, albeit unconvincing, from field studies does not support a role for furosemide in preventing or reducing the severity of EIPH.

The mechanism by which furosemide may reduce the severity of EIPH is unknown, although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.[970,1014,1015]

Furosemide is associated with superior performance in both thoroughbred and standardbred racehorses.[1009,1016] Thoroughbred horses treated with furosemide are 1.4 times as likely to win the race, earn more money, and have a standardized 6-furlong race time 0.56 to 1.09 seconds less than that of untreated horses.[1016] Similarly, furosemide reduces 1-mile race times of standardbred pacers by 0.31 to 0.74 seconds.[1009]

Enalapril inhibits angiotensin-converting enzyme (ACE) activity in horses but does not affect pulmonary artery pressure of exercising horses.[1017] Similarly, the efficacy of enalapril in preventing EIPH has not been demonstrated.

Nitric oxide is a potent vasodilator in many vascular beds. Administration of nitroglycerin (a nitric oxide donor) reduces pulmonary artery pressure of standing horses but does not affect pulmonary artery pressure of horses during intense exercise.[1018] L-Arginine is a nitric oxide donor with no demonstrated efficacy in reducing pulmonary capillary pressure or EIPH in horses. The effect of L-NAME, an inhibitor of nitric oxide synthetase, on pulmonary artery pressure during maximal exercise is controversial, with either no effect or a decrease in pulmonary artery pressure reported.[1019,1020] It is interesting to note that L-NAME administration has been reported to cause an increase in severity of EIPH.[1019] Sildenafil, a PDE inhibitor that accentuates the effect of nitric oxide and is used in the treatment of erectile dysfunction in men, has been administered to horses in an apparent attempt to reduce EIPH. However, its efficacy in preventing EIPH or reducing pulmonary capillary pressure has not been demonstrated.

An increase in pulmonary capillary pressure secondary to altered rheostatic properties of blood during exercise has been suggested as a possible contributing factor for EIPH.[982] Furosemide increases blood viscosity, whereas pentoxifylline increases red blood cell deformability and may attenuate the increase in blood viscosity that occurs during exercise.[1021–1023] However, pentoxifylline does not affect pulmonary capillary pressure of exercising horses and did not affect the prevalence of EIPH in a small experimental study.[1024]

Airway obstruction, either intrathoracic or extrathoracic, increases airway resistance and results in a more negative intrathoracic (pleural) pressure during inspiration to maintain tidal volume and alveolar ventilation. Causes of extrathoracic airway obstruction include laryngeal hemiplegia and other abnormalities of the upper airway, whereas intrathoracic obstruction is usually a result of bronchoconstriction and IAD. Horses with partial extrathoracic inspiratory obstruction or bronchoconstriction and airway inflammation associated with recurrent airway obstructive disease (heaves) have pleural (and hence alveolar) pressures that are lower (more negative) than those in unaffected horses or in horses after effective treatment.

Partial inspiratory obstruction, such as produced by laryngeal hemiplegia, exacerbates the exercise-induced decrease in intrapleural pressures, with a consequent increase in transmural capillary pressures.[975,976,1025] These changes may exacerbate the severity of EIPH, although an association between upper airway obstructive disease and EIPH has not been demonstrated. Surgical correction of airway obstruction is expected to resolve the more negative intrapleural pressure, but its effect on EIPH is unknown.

Recently the role of the nares in contributing to upper airway resistance, and therefore lowering inspiratory intrapleural pressure, during intense exercise has attracted the attention of some investigators. Application of nasal dilator bands (Flair strips) reduces nasal resistance by dilating the nasal valve[1026] and reduces red cell count of BALF collected from horses after intense exercise on a treadmill.[964,965] Furthermore, application of the nasal dilator strips to horses in simulated races reduces red cell count in BALF of some, but not all, horses.[1027]

The role of small airway inflammation and bronchoconstriction in the pathogenesis of EIPH is unclear. However, horses with EIPH are often treated with drugs intended to decrease lower airway inflammation and relieve bronchoconstriction. β-Adrenergic bronchodilatory drugs such as clenbuterol and albuterol are effective in inducing bronchodilation in horses with bronchoconstriction, but their efficacy in preventing EIPH is either unknown or, in very small studies, is not evident. Clenbuterol does not alter the hemodynamic responses of horses to exertion nor attenuate exercise-induced arterial hypoxemia in normal horses.[1028,1029] Ipratropium, a parasympatholytic drug administered by inhalation, showed promised in a very small study (two horses) of preventing EIPH.[1030] Corticosteroids, including dexamethasone, fluticasone, and beclomethasone administered by inhalation, parenterally, or enterally reduce airway inflammation and obstruction but have no demonstrated efficacy in preventing EIPH. Cromolyn sodium (sodium cromoglycate) has no efficacy in preventing EIPH.[1031]

Water vapor treatment (inhalation of water-saturated air) has been proposed as a treatment for EIPH because of its putative effect on small airway disease. However, water vapor treatment has no effect on EIPH.[1032]

The use of bedding of low allergenic potential (shredded paper) to prevent EIPH has no apparent effect on prevalence of the condition.[1033] Although it is suggested that preventing or minimizing small airway disease may reduce the severity of EIPH, studies to demonstrate such an effect have not been reported. However,

optimizing the air quality in barns and stables and preventing infectious respiratory disease appear to be sensible precautions.

31.31.11 INTERSTITIAL INFLAMMATION AND BRONCHIAL ANGIOGENESIS

Hemorrhage into interstitial tissues induces inflammation with subsequent development of fibrosis and bronchial artery angiogenesis.[980,1007,1034] The role of these changes in perpetuating EIPH in horses is unclear but likely is of some importance. Treatments to reduce inflammation and promote healing with minimal fibrosis have been proposed. Rest is an obvious recommendation, and many racing jurisdictions have rules regarding enforced rest for horses with epistaxis. Although the value of rest is intuitive, there is no information that rest reduces the severity or incidence of EIPH in horses with prior evidence of this disorder.

Similarly, corticosteroids are often administered by inhalation, enterally, or parenterally in an attempt to reduce pulmonary inflammation and minimize fibrosis. Again, the efficacy of this intervention in preventing or minimizing severity of EIPH has not been documented.

574

575

31.31.12 EXCESSIVE BLEEDING

Exercise induces substantial changes in blood coagulation and fibrinolysis.[986] However, there is no evidence that horses with EIPH have defective coagulation or increased fibrinolysis.[987,988,1035] Regardless, aminocaproic acid, a potent inhibitor of fibrin degradation, has been administered to horses to prevent EIPH. Although appropriate doses of aminocaproic acid do inhibit fibrinolysis in stationary horses,[1035] the efficacy of aminocaproic acid in preventing EIPH has not been demonstrated. Tranhexamic acid is similarly administered to horses in the hope of preventing or mitigating EIPH. Estrogens are given to horses with the expectation of improving hemostasis, although the effect of estrogens on coagulation in any species is unclear. There is no evidence that estrogens prevent EIPH in horses.

Vitamin K is administered to horses with EIPH, presumably with the expectation that it will decrease coagulation times. However, because EIPH is not associated with prolonged bleeding times, it is unlikely that this intervention will affect the prevalence or severity of EIPH.

Herbal preparations are marketed for treatment of EIPH. The only scientific study of these products examined the efficacy of Yunnan Paiyao or Single Immortal on red cell count in BALF of horses that had run on a treadmill. Neither product affected red cell count or coagulation variables.[1036]

Aspirin inhibits platelet aggregation in horses and increases bleeding time.[1037] Seemingly paradoxically, aspirin is sometimes administered to horses with EIPH because of concerns that increased platelet aggregation contributes to EIPH.[1038] There is no evidence that aspirin exacerbates or prevents EIPH.

31.31.13 CAPILLARY INTEGRITY

Capillary fragility increases the risk of hemorrhage in many species. Various bioflavinoids have been suggested to increase capillary integrity and prevent bleeding. However, hesperidin and citrus bioflavinoids have no efficacy in prevention of EIPH in horses.[1039] Similarly, vitamin C is administered to horses with EIPH without scientific evidence of any beneficial effect.

31.31.14 SUMMARY OF TREATMENT OPTIONS

Selection of therapy for horses with EIPH is problematic. Given that most horses have some degree of pulmonary hemorrhage during most bouts of intense exercise, the decision must be made not only as to which type of treatment to use and its timing, but also which horses to treat. Moreover, the apparent progressive nature of the disease with continued work highlights the importance of early and effective prophylaxis and emphasizes the need for studies of factors such as air quality and respiratory infections in inciting the disorder.

The currently favored treatment for EIPH is administration of furosemide before intense exercise. Its use is permitted in racehorses in a number of countries. Increasingly persuasive laboratory evidence of an effect of furosemide to reduce red cell count in BALF collected from horses soon after intense exercise supports the contention that furosemide is effective in reducing the severity of EIPH in racehorses. However, it should be borne in mind that neither the relationship between severity of EIPH and red cell count in BALF nor the efficacy of furosemide in reducing severity of EIPH in racehorses in the field has been demonstrated. In fact, there is evidence that furosemide does not reduce the prevalence of EIPH and other evidence that it does not reduce the severity of EIPH under field conditions. The association between furosemide administration and superior performance in standardbred and thoroughbred racehorses should be borne in mind when recommending use of this drug.

Rest is an obvious recommendation for horses with EIPH, but the hemorrhage is likely to recur when the horse is next strenuously exercised. The duration of rest and the optimal exercise program to return horses to racing after EIPH is unknown, although some jurisdictions require exercise no more intense than trotting for 2 months. Firm recommendations cannot be made on duration of rest because of a lack of objective information.

Although a role for lower airway disease (either infectious or allergic) in the genesis of EIPH has not been demonstrated, control of infectious diseases and minimization of noninfectious lower airway inflammation appear prudent.

31.31.15 Prognosis

The prognosis for racing for horses with clinically significant EIPH is guarded because of the progressive nature of the disease. Horses that have experienced severe EIPH on one occasion are likely to do so again regardless of treatment. However, the risk of horses experiencing a repeated bout of severe hemorrhage and the effect of EIPH on career longevity are unknown.

31.31.16 Cost

The cost to the industry of treating horses for EIPH has not been determined. The costs of administration of furosemide are readily estimated (see later) but not so the costs of other treatments, absences from racing because of EIPH, shortened racing careers, and impaired performance. Conservatively estimated, this cost could easily exceed $400 per horse per year (and could be as high as $500 to $1000 per year). For example, costs associated with endoscopic examination (two or three examinations annually at $50 to $75 each) and alternative, herbal, and hormonal treatments ($1 to $5 per day) easily amount to more than $400 annually, without including costs associated with furosemide administration or the opportunity costs of lost racing days, poor performance, and shortened racing career. Spread over the 250,000 standardbred and thoroughbred racehorses starting annually in the United States, the total cost of EIPH to the thoroughbred and standardbred racing industries may well exceed $100,000,000 per year.

The high incidence of EIPH in racehorses and recognition of the adverse effect of EIPH on performance results in the widespread use of furosemide in racehorses in the United States. Ninety percent of thoroughbred and 50% to 70% of standardbred racehorses receive the drug before racing. Administration of furosemide to thoroughbred and standardbred horses racing in the United States costs the racing industry $17,000,000 to $35,000,000 annually. Costs associated with use of furosemide are incurred not just for injection of the drug into horses before racing (direct costs), but also for diagnosis of EIPH to determine eligibility for furosemide administration; clerical and administrative costs associated with enforcing policies governing use of furosemide, such as supervision of drug administration and documentation in race records and programs; and drug testing before or after racing to ensure appropriate dosing.

The direct cost for administration of furosemide, which includes the veterinary fee and cost of drug and supplies, varies geographically but is between $20 and $30 per administration per horse.[1040] Costs associated with enforcement of rules governing use of furosemide, including documentation and drug testing, are estimated at an additional $25 to $35 per head. The estimated total cost of furosemide administration is therefore approximately $50 but may be as high as $65 per dose. These estimates of the total cost of furosemide use in racehorses are the same as an estimate of the cost made in 1995 and therefore are conservative estimates.[1041]

There were 444,586 starts by 107,437 horses in thoroughbred racing in the United States in 2003. Assuming that furosemide is administered to 90% of these starters and that there is no cost for horses not administered furosemide, the direct cost of furosemide administration is $10,003,150 annually (444,586 × 0.9 × $25). However, if the total costs associated with furosemide administration are considered, the annual cost for administration of furosemide in thoroughbred racing is $20,006,300 (444,586 × 0.9 × $50) and could be as high as $28,000,000.

Similarly, there were 635,292 standardbred starts in the United States in 2003 (United States Trotting Association, October, 2004). If 50% of these horses were administered furosemide (a conservative estimate of the prevalence of furosemide administration) at a direct cost of $25 per dose, the cost to the industry would be $7,941,000. The total cost, assuming $50 per dose, is $15,882,000 per annum.

The cost to the racing industry of furosemide administration is therefore over $35,800,000 annually, and EIPH costs the racing industry over $100,000,000 annually.

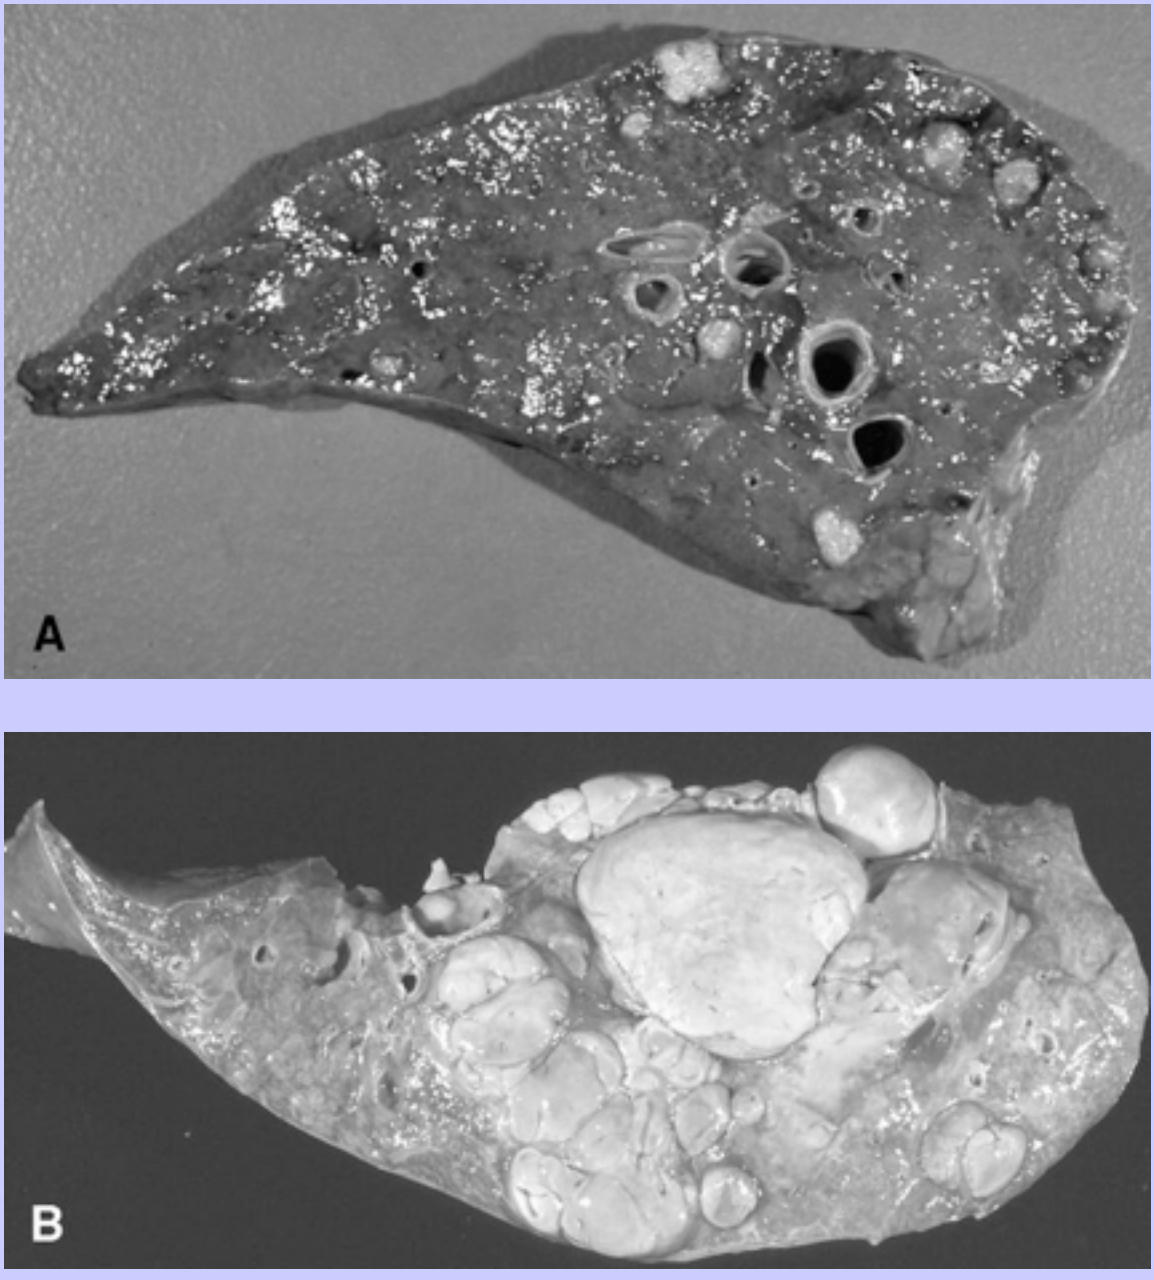
31.32 EQUINE THORACIC NEOPLASIA

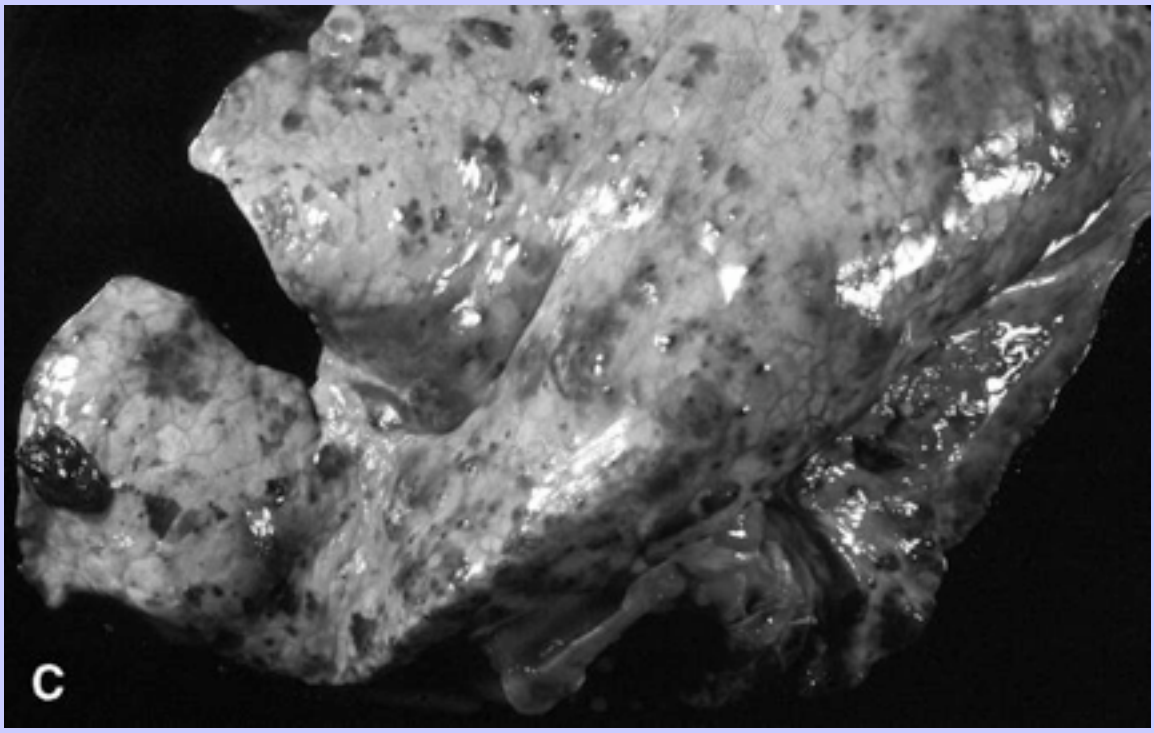
FABIO DEL PIERO

PAMELA A. WILKINS

Surveys of equine neoplasms indicate a low incidence of thoracic neoplasia in the horse (Fig. 31-39). In an abattoir survey in London of 1308 horses, two horses had pulmonary tumors, one granular cell tumor, and one bronchiolar adenoma.[1042] Two other necropsy surveys of 155 and 687 equines reported no thoracic neoplasms.[1043,1044] A report on chronic pulmonary disease in the horse states that the practical importance of lung tumors is negligible.[1044] University of Pennsylvania researchers examined 5629 horses between 1968 and 1987. Thirty-five horses had neoplasia involving the thoracic cavity, for an incidence of 0.62%.[1045]

Fig. 31-39 **A**, Metastatic undifferentiated sarcoma. **B**, Granulosa cell tumor. **C**, Metastatic hemangiosarcoma. **D**, Metastatic squamous cell carcinoma.





C

D

Primary pulmonary tumors are rare in the horse. The incidence of primary lung tumors of any type is reported to be less than 1% of all reported tumors in domestic animals.[1046] The lungs are susceptible to tumor emboli because of the filter action of the capillary bed associated with small capillary diameter and, perhaps, specific adhesion factors. It can sometimes be difficult or impossible to distinguish gross and microscopic patterns of metastatic disease from those of primary lung neoplasia; thus an important part of the diagnosis is exclusion of possible primary sites elsewhere in the body. Primary pulmonary tumors reported in the horse include granular cell tumor, bronchial myxoma, adenoma, adenocarcinoma, anaplastic bronchogenic carcinoma, and pulmonary carcinoma and perhaps undifferentiated sarcoma. Other primary thoracic tumors reported in the horse include pulmonary chondrosarcoma, plural mesothelioma, thymoma, and malignant lymphoma. All these neoplasms generally occur in the mature or aged horse. The exception is malignant lymphoma, which may also be observed in young animals.

Antemortem diagnosis of thoracic neoplasia depends first on recognition of thoracic disease. Most of the reported cases of thoracic neoplasia involve metastatic disease. The horses' clinical signs are generally related to the primary site of the neoplasm; therefore the clinician often has no reason to suspect thoracic involvement. When respiratory signs, such as dyspnea, tachypnea, hemoptysis, cough, cyanosis, nasal discharge, and epistaxis, are present, relevant diagnostic tests are more likely to be performed. Ultrasonography and bronchoscopy increase the frequency of antemortem diagnosis of thoracic neoplasia.

576

577

Granular cell tumor is the most frequently reported primary pulmonary tumor of the horse, with at least 15 articles in the literature. Granular cell tumors in horses are usually confined to the lungs. The neoplasia usually has consisted of single to multiple well-defined whitish compact nodules associated with a major bronchus, often protruding into the bronchial lumen or more distally within the parenchyma. Most granular cell tumors have been diagnosed only at postmortem examination, often as incidental findings. In a population of 350 mature and elderly horses examined in an abattoir by one of us (Fabio Del Piero), two pulmonary granular cell tumors were observed. These homogeneous growths of granular eosinophilic cells expressed S-100 and occasionally neuron-specific enolase, as previously observed.[1047] The ultrastructural morphology of this tumor may suggest a neural origin, leading to the definition of granular cell schwannoma.

Primary pulmonary chondrosarcoma has been reported in a horse.[1048] In this horse, cytologic examination of pleural fluid and an antemortem needle aspirate of the pulmonary mass revealed neoplastic chondrocytes. Another report describes metastatic chondrosarcoma in the lungs of a horse with a primary tumor in a rib.[1049] A primary bronchial myxoma, characterized by loose spindloid mesenchymal cells, was reported in a 25-year-old Arabian mare with a history of intermittent coughing, hyperpnea, and respiratory disease of 2 years' duration.[1050]

Primary pleural tumors are also rare. The specific type reported in the horse is pleural mesothelioma. The tumor frequently is associated with a large volume of pleural effusion. Cytologic examination of the pleural effusion revealing numerous pleomorphic mesothelial cells may aid in the antemortem diagnosis.

Thymomas are neoplasms of thymic epithelial cells, regardless of the presence or absence of lymphocytes. They are infrequently reported in the horse.[1051–1053] Equine malignant lymphoma occurs in mediastinal, alimentary, multicentric, cutaneous, and generalized forms; combinations of one or more of these are not infrequent.[1054,1055] In a 1973 review of 54 cases of equine malignant lymphoma,[1044] the lung was involved in 16.6% of the cases, whereas the thoracic lymph nodes were involved in 35.2%.[1056] In the University of Pennsylvania survey, thoracic malignant lymphoma was the single most common neoplasia of the thorax and was present in 19 (54%) of the cases.[1044] Pleural fluid cytologic evaluation was diagnostic in six (75%) of the eight horses. Diagnosis was made by biopsy of a peripheral lymph node in several cases. In a report from the University of Bristol, thoracic malignant

lymphoma accounted for 74% of the cases of thoracic neoplasia.[1056] Metastatic adenocarcinoma accounted for 20% of the cases in the University of Pennsylvania study[1045] and 11% of the cases in the University of Bristol study.[1056] The primary sites of the tumor were thought to be kidney, uterus, thyroid, and ovary.

Gastric squamous cell carcinomas commonly metastasize to the thoracic cavity. Cytology of pleural fluid with identification of neoplastic epithelial pleomorphic and squamous cells has allowed for antemortem diagnosis of the carcinoma in several cases. Metastatic squamous cell carcinoma of the thorax was found in 14% and 5% of the cases in the University of Pennsylvania[1045] and University of Bristol[1056] surveys, respectively. Neoplastic epithelial cells may also be identified in biopsy specimens using “cocktails” of primary antisera containing antibodies recognizing cytokeratins of various molecular weights.

Hemangiosarcoma with pulmonary involvement has been previously reported and was found in 9% of the horses in the University of Pennsylvania survey.[1045] Hemothorax, anemia, and dyspnea were commonly seen with pulmonary hemangiosarcoma. Tentative antemortem diagnosis of the hemangiosarcoma has been made by transcutaneous direct thoracoscopy and observation of the hemorrhages distributed over the visceral and parietal pleural surfaces and biopsy of these sites. Identification of neoplastic endothelial cells demarcating variously irregular, sometimes blood-filled cavities allows diagnosis from the biopsy specimen. Neoplastic endothelium still expresses a variable amount of immunohistochemically identifiable factor VIII.

Malignant melanoma in a 20-year-old gelding had widespread infiltration of many organs including the lungs and pleura.[1056] This pattern of distribution is not uncommon in malignant, less pigmented melanomas. Amelanotic melanomas are very rare in the horse, and microscopic identification of melanin simplifies the diagnosis of these tumors. Melanocytes express S-100 protein and may demonstrate cross- reactivity to melanoma cell markers of other species.

Other pulmonary metastatic tumors reported are mammary carcinoma,[1057] seminoma,[1058] and malignant pheochromocytoma.[1059] Metastatic pulmonary tumors have been so far examined only morphologically. The use of IHC for the detection of specific cell markers and other sophisticated molecular studies may lead to different diagnoses.

Occasionally, a myxomatous multifocal to coalescing infiltrative neoplastic-like growth can be observed within the lung of mature and aged horses generally as an incidental finding. This infiltration is composed of loosely arranged mesenchymal cells with moderate collagen deposition.

Pulmonary hamartomas are occasionally observed in the newborn foal. Although they are nonneoplastic growths, they appear as tumorlike masses that can compress the surrounding parenchyma and cause systemic passive congestion and hydrops of the amnion in the fetus. Histologically they may be characterized by an organized proliferation of bronchiolar-like structures lined by cuboidal epithelium with lack of alveolar development or by normal alveoli, bronchi, and blood vessels but with alveolus:artery ratio greater than normal. Generally they are not compatible with a long period of extrauterine life.

An unusual progressive idiopathic multifocal granulomatous pneumonia of adult horses may resemble neoplasia behaviorally and morphologically during clinical examination.[1060,1061] Pulmonary biopsy may allow the identification of EMPF, pulmonary fibrosis associated with EHV-5 infection[1061] (Fig. 31-40).

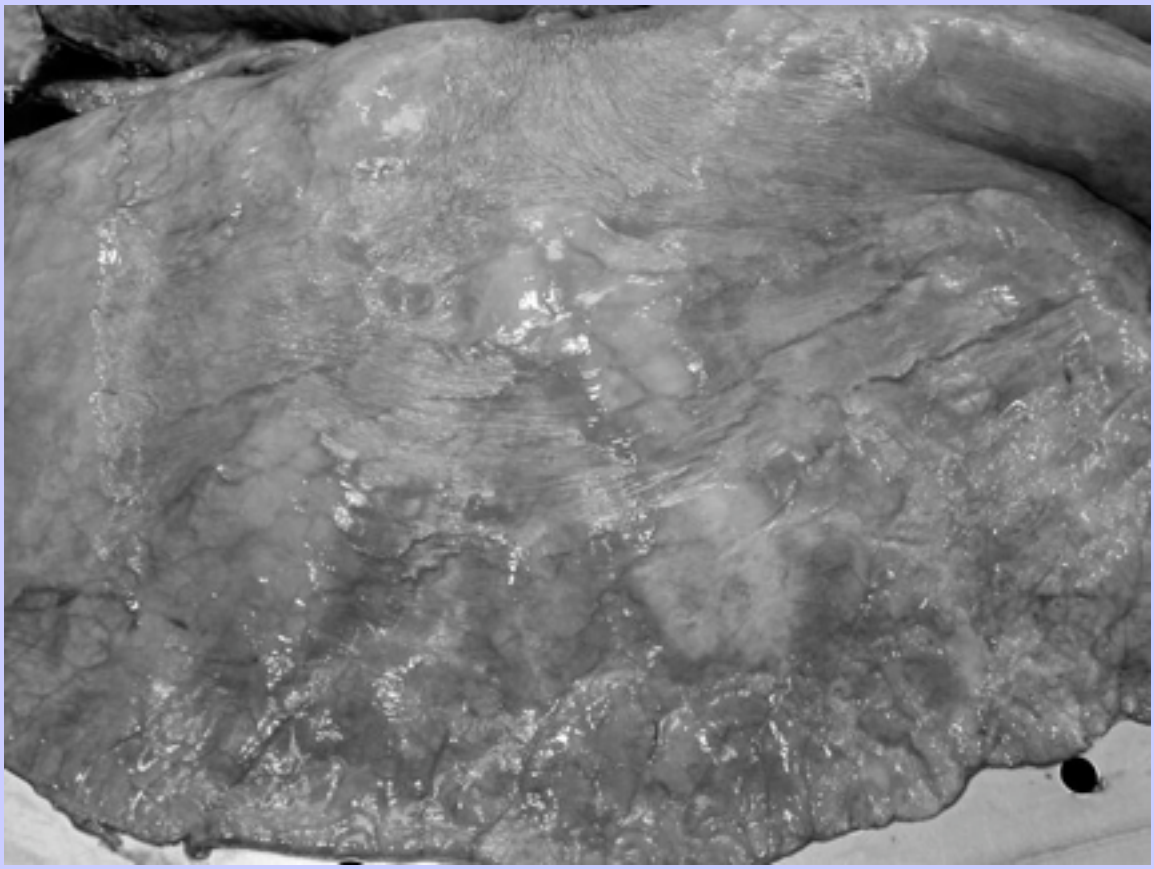
Clinical signs of thoracic neoplasia are often inapparent or nonspecific—for example, depression, inappetence, weight loss, and pyrexia. More specific signs include cough, epistaxis, and dyspnea. Cytologic examination of a

tracheobronchial aspirate, bronchoalveolar lavage fluid, or pleural fluid or histologic examination of a thoracic mass biopsy with ancillary histochemistry and IHC may allow for antemortem diagnosis of the tumor. Occasionally, electron microscopy may provide additional information. In equine patients with respiratory signs, all causes of infectious or allergic lung disease should be eliminated before neoplasia is considered in the differential diagnosis.

577

578

Fig. 31-40 Equine multinodular pulmonary fibrosis.



31.33 DISEASES OF LYMPH NODES, VASCULATURE, AND PHARYNX

31.33.1 RETROPHARYNGEAL LYMPH NODE ABSCESSATION

JOHN R. PASCOE

31.33.2 Definition and Etiology

In horses the retropharyngeal lymph nodes consist of medial and lateral lymphoid chains. The lateral chain (8 to 15 nodes) is located ventral to the atlas and along the lateral sides of the guttural pouches. These lymph nodes are covered by the parotid gland and are not clearly distinguishable from the medial retropharyngeal lymph

nodes (20 to 30 nodes). The medial retropharyngeal lymph nodes are located ventral to the lateral chain on the dorsolateral aspect of the pharynx and the caudoventral aspect of the guttural pouches.[1062]

Retropharyngeal lymph node abscesses in horses are generally caused by *S. equi* subsp. *equi* infection (see Strangles, p. 533) or are secondary to trauma.[1063,1064] Other bacterial isolates have included *S. equi* subspecies, *Streptococcus zooepidemicus, Corynebacterium pseudotuberculosis*, and *Actinobacillus* species. An unusual case of granulomatous infection of the guttural pouch caused by *M. avium* complex was believed to have originated from the retropharyngeal lymph nodes.[1065] Extension of guttural pouch infections into the retropharyngeal space has been suggested as another source of infection.[1066] Lymphadenopathy of the retropharyngeal nodes may also occur during viral respiratory infections, including EHV, influenza, and viral arteritis.[1067] Retropharyngeal abscesses not associated with regional lymph nodes can result from perforation of the oropharynx or nasopharynx by ingested foreign bodies,[1068] passage of an NGT,[1069] or use of a balling gun.

In ruminants the medial retropharyngeal lymph nodes are located on the dorsolateral aspect of the pharynx, one on each side of the midline. One to three lymph nodes may be present in cattle. The lateral retropharyngeal lymph nodes are located caudal to the medial retropharyngeal lymph nodes in the cranial neck region and are caudal to the retropharyngeal space.[1062]

Abscessation of the medial retropharyngeal lymph nodes in cattle may result from pharyngeal actinobacillosis, foreign body penetration, or traumatic perforations by balling guns or dose syringes.[1070,1071] Frequently *Arcanobacterium (Actinomyces) pyogenes* or *Actinobacillus* species can be isolated.[1072] Cattle with abscessed pharyngeal lymph nodes often have a small ulcer in the mouth, most frequently at the junction of the base and shaft of the tongue. This is more likely to occur when cattle are eating dry scabrous roughage. In addition to traumatic perforations and foreign bodies, caseous lymphadenitis (CLA) caused by *C. pseudotuberculosis* frequently results in abscessation of these lymph nodes in sheep and goats.[1067]

31.33.3 Clinical Signs and Differential Diagnosis

The clinical signs associated with retropharyngeal lymph node infection or abscessation in horses include dysphagia, odynophagia (painful swallowing), nasal or oral regurgitation, excess salivation, difficult and often noisy breathing, painful throatlatch swelling, mucoid to mucopurulent nasal discharge, extension of the head and neck, and weight loss.[1062] In a retrospective study of 46 horses referred because of retropharyngeal lymph node abscessation, the frequency of abnormal clinical signs was as follows: fever and increased heart and respiratory rates, 80%; unilateral or bilateral throatlatch swelling, 65%; respiratory stertor or distress, 35%; purulent nasal discharge, 20%; inappetence and signs of depression, 15%; and dysphagia, 9%.[1073] Other clinical signs observed endoscopically include reduction in size or collapse of the pharyngeal lumen, asymmetry of the dorsal pharyngeal wall, and deviation of the laryngeal aperture away from the retropharyngeal mass.[1063,1073] The differential diagnosis for a retropharyngeal mass should include abscess, cellulitis, guttural pouch empyema or tympany, parotiditis, lymphadenopathy, neoplasia, and hematoma.

Clinical signs observed in cattle with infection or abscessation of the medial retropharyngeal lymph nodes include difficult breathing, excessive salivation, extension of the head and neck, anorexia, enlarged submandibular lymph nodes, nasal discharge, and swelling in the retropharyngeal space.[1070] Other disease conditions that affect the oropharynx and surrounding lymph nodes should be considered in the differential

diagnosis. These include actinobacillosis, lymphosarcoma, sialolithiasis, and necrotic laryngitis, laryngeal edema, or severe tracheitis caused by infectious bovine rhinotracheitis (IBR) virus.[1067,1070]

Affected sheep and goats may exhibit excessive salivation, increased respiratory rate, stertorous breathing, mucopurulent nasal discharge, regurgitation, gagging, depression, SC crepitation, weakness, and fetid breath. A false carotid aneurysm in the retropharyngeal space has been reported; on external examination it may be confused with abscessation of the medial retropharyngeal lymph nodes.[1074] Enlarged retropharyngeal lymph nodes are usually easily palpated and identified in sheep and goats. CLA (see Chapter 37) is the most frequent cause of enlarged retropharyngeal lymph nodes in these species.

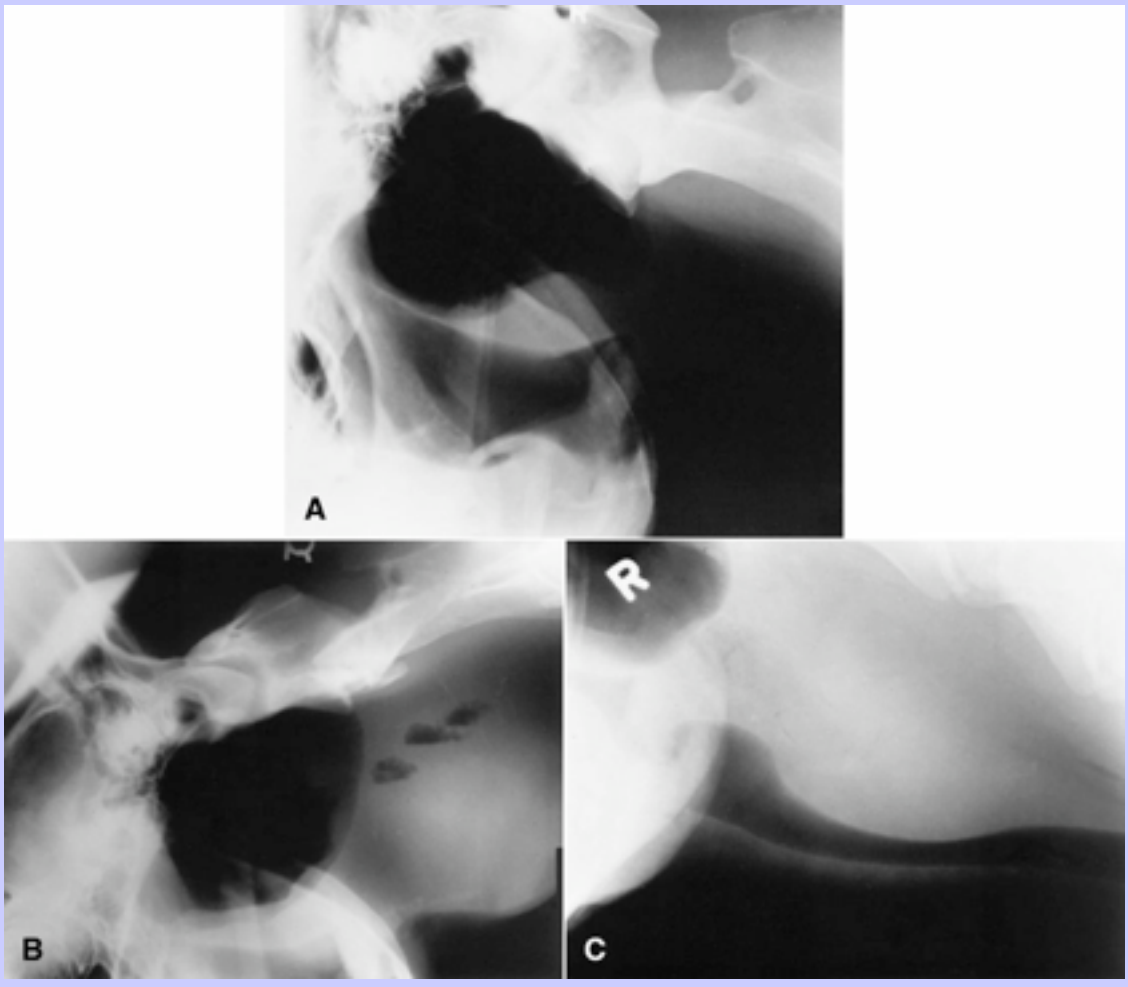
31.33.4 Clinical Pathology

Collection of purulent material from abscessed lymph nodes may assist in identification of the causal agent. Leukocytosis may be evident on the hemogram, with neutrophilia peaking as the lymph nodes abscess.

31.33.5 Laboratory Aids and Definitive Diagnostic Tests

Lateral radiographs of the pharynx, diagnostic ultrasound, and endoscopy aid in the diagnosis of retropharyngeal infections or abscesses. In horses, radiography may reveal a large soft-tissue mass impinging on the guttural pouch from a caudoventral direction (Fig. 31-41, *A*), as well as thickening of the pharyngeal roof. The soft-tissue swelling may contain gas (Fig. 31-41, *B*). Compression of the larynx and trachea with ventral displacement may also be evident (Fig. 31-41, *C*).[1063] Observation of a gas-fluid interface on radiographs of the pharynx generally indicates abscessation, but care should be taken to distinguish a retropharyngeal abscess from guttural pouch empyema.[1065] Foreign bodies associated with pharyngeal trauma are not usually radiopaque and therefore are not visible radiographically unless outlined by contrast medium. Exceptions include small wire foreign bodies likely ingested from baled hay that can perforate the tongue or oropharynx causing cellulitis and dysphagia[1068] and, in cattle, magnets that have been inadvertently placed retropharyngeally.

Fig. 31-41 **A**, Lateral radiograph. A soft-tissue density (retropharyngeal abscess) is distorting the floor of the guttural pouch. **B**, Lateral radiograph. There is increased soft-tissue density with gas shadows ventral to the cervical vertebrae. These changes are consistent with abscessation of the retropharyngeal lymph nodes. **C**, Lateral radiograph. There is increased soft-tissue density ventral to the cervical vertebrae, with compression of the dorsal border of the trachea. These changes were caused by cellulitis and abscessation of the retropharyngeal lymph nodes.



On endoscopy, asymmetry or collapse of the pharyngeal lumen or both signs suggests a retropharyngeal space-occupying mass. Recognition of drainage from the guttural pouch openings or examination of the guttural pouches may be necessary to differentiate between guttural pouch empyema and retropharyngeal lymphadenopathy or pharyngeal neoplasia. Occasionally the pharyngeal wall ruptures, allowing endoscopic

observation of retropharyngeal drainage into the pharynx, usually near the esophageal entrance.[1063] Percutaneous needle aspiration may yield a definitive diagnosis if purulent material is obtained. Ultrasonography improves diagnostic precision by permitting more accurate identification of the abscess and highlighting its anatomic relationships as an aid to surgical drainage.[1075]

Clinical examination, radiography, ultrasonography, endoscopy, and percutaneous centesis may all prove helpful in making a diagnosis of medial retropharyngeal lymph node infection or abscessation in ruminants. In cattle, localized swelling cranial to the larynx may be detected by digital palpation of the oropharynx.[1070] Oropharyngeal examination must be performed carefully in animals with respiratory distress to prevent further airway compromise.

31.33.6 Pathophysiology

Upper respiratory disease, trauma, and foreign body penetration with resulting infection and drainage to local lymph nodes result in clinically apparent infection and abscessation of the retropharyngeal lymph nodes. In horses the retropharyngeal space is occupied primarily by the guttural pouches. Because the vagus, glossopharyngeal, hypoglossal, spinal accessory, and sympathetic nerves traverse this area, their function can be affected by infectious or inflammatory processes involving the retropharyngeal space.[1063] If such infections are contained within the lymph nodes or are confined within the fibrous capsule of the abscess, cranial nerve dysfunction is not usually evident.[1063] Clinical evidence of dysphagia or odynophagia such as the presence of feed and saliva at the external nares may result from inflammation or injury of the glossopharyngeal nerve or pharyngeal branch of the vagus nerve,[1063] compression, or obstruction of pharynx or esophagus and from angina. It has been suggested that retropharyngeal lymphadenitis may result in neuritis of the pharyngeal branch of the vagus nerve in young horses and contribute to the pathogenesis of dorsal displacement of the soft palate.[1076]

Respiratory distress may result when enlargement of the retropharyngeal lymph nodes compresses or obstructs the nasopharyngeal, laryngeal, or tracheal lumen,[1063,1070] and the disease caused by *S. equi* subsp. *equi* in horses is appropriately named *strangles*.

The most common cause of pharyngeal inflammation and infection in cattle is pharyngeal trauma associated with balling guns, dose syringes, paste wormer guns, esophageal feeders, or stomach tubes. A careful history to determine whether any of these devices were used is important in ascertaining the source of pharyngeal abscessation. Such infections usually involve mixed bacterial flora, because they are directly connected with the oral pharynx.

579

580

31.33.7 Epidemiology

Infection with *S. equi* usually results from contact (inhalation or ingestion) with pasture, feed, or water contaminated with nasal discharge from infected horses. Asymptomatic carrier horses have also been implicated as source of infection.[1077] The likely bacterial reservoir in carrier horses is the guttural pouch, particularly if chondroids are present in one or both pouches[1077–1079] or if swollen or discharging lymph nodes are present in the floor of the medial compartment of the guttural pouch. Infection of the pharyngeal and nasal mucosa results in an acute pharyngitis and rhinitis, and drainage to regional lymph nodes results in lymphadenopathy and possibly abscessation.[1067]

CLA is spread through the discharges from ruptured lymph nodes. The causal agent *C. pseudotuberculosis* may persist in the environment for long periods, and infection results from contact of shearing, docking, or castration wounds with contaminated soil, equipment, or freshly ruptured abscesses. Sheep dips have been reported as another important source of infection.[1067] Spread of infection from skin wounds often leads to involvement of local nodes and abscess formation. The mode of spread in goats is still not well understood, but the disease usually spreads in a low-grade contagious manner, often involving most of the herd over a period of years.

31.33.8 Necropsy Findings

Fatalities are rare and most likely result from respiratory compromise or septicemia. Postmortem lesions include cellulitis with compression and ventral displacement of the larynx and cranial cervical trachea. Abscesses are variable in size and may contain either caseous *(C. pseudotuberculosis)* or liquid material *(S. equi* subsp. *equi)*. A thick, fibrous capsule may occur in response to the infectious process and may account for the surrounding tissue compression. Occasionally, draining tracts may connect the abscess to the pharynx, guttural pouch, or skin.[1069,1080]

31.33.9 Treatment and Prognosis

Treatment goals are relief of respiratory distress and control of infection. Temporary tracheotomy may be needed for relief of respiratory distress and may be prudent, especially in foals with singular, large, or multiple abscesses, before percutaneous drainage is attempted. After surgical drainage, appropriate systemic antibiotics are administered and supportive therapy to further reduce swelling may be beneficial.

Surgical approaches include percutaneous drainage, intraoral drainage, and marsupialization.[1063,1070] In horses an intraoral approach is very difficult because of the long narrow oral cavity, and for this reason percutaneous drainage is commonly used. For abscesses visible through the mucosal lining of the guttural pouch, endoscopically assisted drainage into the pouch can also be considered. Surgical access to the retropharyngeal space has been described, including dorsal and ventral approaches, an approach through Viborg's triangle, and a lateral approach.[1073,1081] A ventral surgical approach is recommended because of the relative lack of vital structures encountered and the excellent ventral drainage achieved. A less invasive drainage technique can be accomplished in standing sedated horses, by ultrasound-guided percutaneous needle placement into abscessed lymph nodes. Affected nodes can have a wall thickness of 1 to 2 cm and a diameter of 5 to 11 cm.[1075] Aspiration of purulent matter and cavity lavage with antiseptic solutions and concurrent administration of parenteral antibiotics may be sufficient for resolution. If aspiration is not possible because the purulent material is too viscous, incision directly along the needle shaft, after careful consideration of regional anatomy, provides adequate exterior drainage and access for cavity lavage with antiseptic solutions or use of a seton or gauze packing. If the abscess is endoscopically visible beneath the guttural pouch mucosa, drainage into the guttural pouch and subsequent lavage of the purulent material can be accomplished. Before or at the time of abscess drainage or excision, the horse should be started on broad-spectrum antimicrobials, followed by the appropriate specific antimicrobial drug when results of the culture and susceptibility test are known.

Occasionally, medical management alone may resolve infection; however, this is less likely if abscessation has occurred. Because the most common bacterial isolate in the horse is *S. equi*, parenteral antimicrobial therapy with procaine penicillin G (22,000 IU/kg IM twice daily) or potassium penicillin (20,000 IU/kg IV four times daily) is recommended. Systemic NSAIDs are useful to reduce inflammation and swelling, and fluid and

electrolyte therapy may be necessary if there is odynophagia or dysphagia. Aspiration pneumonia can occur with dysphagia or if there is oral or nasal regurgitation associated with painful swallowing.

In cattle with pharyngeal trauma, an existing wound is often draining from the retropharyngeal area to the oropharynx, making surgical drainage unnecessary. Such animals tend to respond well to parenteral broad-spectrum antimicrobial therapy.[1082] Parenteral antimicrobial therapy alone has been ineffective in treating retropharyngeal abscesses when there is no draining tract.[1070,1071] Intraoral or percutaneous drainage has been used successfully in conjunction with broad-spectrum, parenteral antimicrobial therapy.[1071] After drainage, the abscess cavity is flushed daily with an antiseptic or antibiotic solution.[1070] Surgical drainage into the oral cavity must be handled with caution. The patient's head should be lowered so that exudate or flush solution is not aspirated; inspection of the granulating abscess cavity is necessary if feed impaction is suspected.[1063,1070] Aspiration pneumonia may be a serious complication when dysphagia is present.

In sheep and goats, walled-off *C. pseudotuberculosis* abscesses may often be most safely drained by suturing the skin to the heavy abscess capsule (a procedure known as *marsupialization*) before opening the capsule. Marsupialization prevents contamination of other retropharyngeal structures with infected material and markedly reduces postsurgical cellulitis. Although *C. pseudotuberculosis* is susceptible in vitro to a number of antimicrobial agents, abscesses associated with the condition have not been well controlled by antimicrobial therapy. Walled-off *C. pseudotuberculosis* abscesses are difficult to eliminate solely with antimicrobial therapy, and drainage or removal of the entire lymph node gives the best results.

31.33.10 Prevention and Control

Preventive measures to limit infection and abscessation of retropharyngeal lymph nodes include proper administration of therapeutic agents with balling guns and dose syringes, isolation of horses affected with viral or bacterial upper respiratory disease, vaccination against strangles, and vigorous treatment in the early stages of streptococcal infection. Preventing contamination of shearing equipment and dipping vats with *C. pseudotuberculosis* is important in limiting the spread of this organism in sheep. Culling affected sheep and goats may also help to reduce the incidence of CLA.

31.34 PHARYNGITIS

JOHN R. PASCOE

31.34.1 Definition and Etiology

Pharyngitis is inflammation of the pharyngeal tissues. It is not generally considered to be a specific disease entity but rather a response to other diseases, particularly viral and bacterial respiratory disease, and to a lesser extent to local physical, chemical, or allergic causes. Acute and chronic forms of pharyngitis are recognized.

580
581

Although physical and chemical causes of pharyngitis may be identified with certainty, the role and specificity of microbial pathogens as causative agents remain controversial. In horses, *Streptococcus* species, picornavirus, rhinovirus 1 and 2, herpesvirus (EHV-1, EHV-2), myxovirus (influenza A/equi 1, A/equi 2), and paramyxovirus (parainfluenza 3) have been incriminated as specific causes of pharyngitis.[1083–1087] In cattle, *Arcanobacterium (Actinomyces) pyogenes, Actinobacillus* species, and *Fusiformis necrophorus* are frequently isolated.[1088]

In horses, synonyms for chronic pharyngitis include pharyngeal lymphoid hyperplasia (also PLH), chronic pharyngitis, chronic lymphoid follicular hyperplasia, follicular pharyngitis, and follikelkatarrh.[1089–1091]

31.34.2 Clinical Signs and Differential Diagnosis

In acute pharyngitis, signs are associated with pharyngeal pain (odynophagia, dysphagia), nasal discharge (serous, seromucous, mucopurulent, purulent, feed-contaminated), regional lymphadenopathy (submandibular, retropharyngeal nodes), ptyalism (especially in cattle), respiratory noise (often inspiratory), pharyngeal swelling, and cough. Mouth breathing may occur in cattle when there is increased resistance to breathing associated with excessive exudate, diphtherous membranes, and lymphadenopathy or lymph node abscess. Pharyngitis from local pharyngeal trauma or incarcerated foreign bodies may also be associated with odor of either the breath or nasal discharge. Calves with necrotic laryngitis, pharyngitis, and stomatitis also have a characteristic malodorous breath. Acute laryngeal inflammation and edema of unknown cause can occur in horses and ruminants and is characterized by marked inspiratory difficulty and stertor without malodorous breath. Treatment of acute edema with dexamethasone (0.05 mg/kg IM) and broad-spectrum antimicrobials or penicillin has produced rapid clinical improvement.

Signs observed on endoscopic or oropharyngeal examination in cattle include pharyngeal hyperemia and edema, lymphonodular swelling, and either a moist appearance of the pharyngeal surface or the presence of exudate or a diphtherous membrane adhering to the pharyngeal surface. Focal necrosis or ulceration of the mucous membrane and tonsillar tissue may occur; signs associated with rhinitis and laryngitis may also be evident. Signs of chronic pharyngitis are similar. In horses there may be endoscopic evidence of more marked hyperplasia of the lymphonodular follicles within the pharyngeal mucosa, and single or multiple lymphonodular masses may be within, or protrude from, the pharyngeal mucosa. Biopsy and cytologic evaluation are recommended to rule out neoplasia, particularly squamous cell carcinoma, lymphoma, and lymphosarcoma. Differential diagnostic possibilities include rhinitis and laryngitis, and in cattle rabies should be strongly considered before oropharyngeal examination. If the predominant sign is dysphagia (see Chapter 7), other diagnostic ruleouts include tongue foreign bodies, fractures of the hyoid apparatus or jaws, and, in the horse, diseases of the guttural pouches. If exercise intolerance is the primary complaint in a horse, pharyngitis should be considered only after all other possible causes of impaired performance have been eliminated (see Chapter 5).[1092–1096] Pharyngitis has not been shown to be a risk factor for poor racing performance.[1097]

Upper airway inspiratory pressures recorded during strenuous exercise in horses with grade IV lymphoid hyperplasia do not appear to be different from those recorded in normal horses under the same exercise conditions.[1095] If the assumption is made that airflow in both groups of horses is comparable, then severe lymphoid hyperplasia does not appear to cause functional upper airway obstruction. It is conceivable that pharyngeal pain associated with lymphoid hyperplasia may contribute to bronchoconstriction and impaired performance; however, this effect remains unproven.

31.34.3 Clinical Pathology

Changes in the hemogram and biochemical profiles are likely to result from concurrent respiratory disease (increases or decreases in absolute or differential leukocyte counts, hyperfibrinogenemia, anemia) or to reflect abscess formation (neutrophilia, hyperfibrinogenemia) or dehydration and fasting associated with dysphagia.

31.34.4 Laboratory Aids and Definitive Diagnostic Tests

Although a presumptive diagnosis can be made from the clinical signs, definitive diagnosis requires observation of the pharynx (Fig. 31-42) and, more important, exclusion of other conditions that might have similar signs. Radiography of the pharynx can provide information on pharyngeal anatomy, radiodense foreign bodies, soft-tissue masses, fractures, and, in horses, guttural pouch disorders. Ultrasonography of the pharyngeal region and, if indicated by the clinical examination, both radiographic and ultrasound examination of the thorax may help define the extent of concurrent pulmonary disease.

Microbial culture of pharyngeal secretions can be considered, but interpretation is difficult because (1) the pharynx normally has resident microflora with considerable individual variation, and (2) many of the microorganisms isolated are capable of opportunistic infection. In horses with grades III and IV pharyngeal lymphoid hyperplasia, the number of bacteria recovered per gram of pharyngeal secretion was almost 100-fold greater than in normal horses.[1096] The pattern of microbial isolation was not consistent among horses, suggesting that these organisms were not the source of the pharyngitis but rather other factors had made conditions for colonization more favorable.

581
582

Fig. 31-42 Endoscopic view showing the nodular appearance of pharyngeal lymphoid hyperplasia.

Biopsy and cytologic examination are indicated in refractory cases and when abnormal masses are present to rule out neoplasia.

31.34.5 Pathophysiology

Acute pharyngitis occurs as a sequela to inflammation of regional lymphoid tissue (see Kumar and colleagues[1098] for a description of the morphologic and histochemical features of the normal equine nasopharyngeal tonsil).[1099] In horses the pharyngeal tonsil consists of discrete lymphoid follicles diffusely distributed in the dorsal and lateral walls of the pharynx. In ruminants the pharyngeal tonsil is located caudal to the pharyngeal septum in the caudodorsal wall of the pharynx and is bounded by long ridges and grooves into which mucous glands open. In response to local or lymphogenous spread of infection, the tonsillar tissue becomes inflamed and the tonsillar crypts become filled with desquamated epithelium, leukocytes, and bacteria. Clinically this is seen as hyperemia and edema of the pharyngeal tonsil with diffuse white or yellow tips to the lymph nodules. The edematous appearance is associated with hyperplasia of the lymph nodules and sequestration of perinodular inflammatory fluid.

If extensive destruction of the lymphoid cells or subsequent invasion of the nodules or supporting soft tissue is evident, the result is focal or diffuse necrosis, which may be seen as pinpoint areas of follicular necrosis or diffuse necrosis with associated purulent or fibrinonecrotic exudate. With resolution, atrophy of some follicles and increased fibrosis are present. Follicular atrophy also occurs with aging.

31.34.6 Epidemiology

No specific epidemiologic data are available on pharyngitis. When pharyngitis occurs as a sequela to respiratory tract infection, the population demographics should be similar to those known for the specific respiratory disease. For example, grade II pharyngeal lymphoid hyperplasia was identified in 60% of foals with distal respiratory tract infection and in only 13% of control foals.[1100] Because physical and chemical injury to the pharynx occur sporadically, no universal epidemiologic characteristics would be anticipated.

Pharyngeal lymphoid hyperplasia has been reported to be particularly prevalent in horses younger than 5 or 6 years of age.[1089,1093,1097,1101–1103] In an endoscopic survey of 479 horses, primarily thoroughbreds in race training, 141 (29%) had pharyngeal lymphoid hyperplasia. Of the 2-year-olds, 63% were affected, and the prevalence decreased with age; less than 20% of horses older than 5 years were affected.[1093] In a subsequent survey of 678 thoroughbred horses in training, the prevalence of pharyngeal lymphoid hyperplasia was 34%; the prevalence was again age-related, and severe grades of pharyngeal lymphoid hyperplasia were observed more often in younger horses.[1101] Grade II pharyngeal lymphoid hyperplasia was observed in 45% of 2-year-old horses, whereas only 16%, 15%, and 12% of 3-, 4-, and 5-year-old horses were classified as grade II. Similar results were reported from Japan for racing thoroughbreds with a history of cough or abnormal respiratory noise.[1102]

31.34.7 Treatment and Prognosis

The approach to treatment is largely symptomatic and directed to palliation of pharyngeal pain and maintenance of unobstructed breathing until the initiating disease process has abated. In many instances the signs are sufficiently mild that treatment is unnecessary. When pharyngeal angina is causing inappetence or dysphagia,

administration of NSAIDs should be considered. Dehydration should be corrected by either parenteral or enteral fluid administration. Enteral fluid therapy may be difficult because passage of an NGT may elicit too much pain. If the animal has been inappetent for several days, nutritional support may be necessary until pharyngeal pain subsides sufficiently to allow normal eating to resume. Soft feeds, especially green grass, should be offered when available to encourage animals with pharyngeal discomfort to eat.

Although routine antimicrobial therapy is probably not indicated, it is often given to limit development of secondary bacterial infection. Infections caused by foreign body injuries should be treated with antibiotics that have broad aerobic and anaerobic sensitivity. Daily lavage of any cavitary wounds, debridement, and removal of feed material may be necessary to prevent additional abscess formation and hasten healing.

Custom topical preparations, usually containing an antibiotic, an antiinflammatory drug, and a hygroscopic agent (glycerine) or DMSO, are often used for palliation of clinical signs, especially in horses with pharyngeal lymphoid hyperplasia.[1103,1104] These preparations are usually administered two or three times daily through a transnasal catheter and sprayed onto the pharyngeal surface. Despite their frequent use, it is not known whether this form of therapy is effective or whether the response merely reflects natural resolution of the predisposing cause.

Treatment of pharyngeal lymphoid hyperplasia is also empiric and generally palliative. Rest from training for 4 to 8 weeks is commonly advocated, and, although some horses experience recurrence when training resumes, this enforced rest is beneficial as a convalescent period for any concurrent subclinical respiratory disease. Horses that are kept in training are often initially treated empirically with sulfa compounds and topical throat preparations. With continued clinical signs, penicillin or broad-spectrum antibiotics are often given. If the pharyngeal lymphoid hyperplasia does not improve or resolve after this therapy, pharyngeal cautery is often used. Techniques for pharyngeal cautery include topical application of trichloroacetic acid, electrocautery, freezing with liquid nitrogen or Freon, and photoablation by neodymium: yttrium aluminum garnet (Nd:YAG) laser with either contact or noncontact technique.[1103–1106] Cauterization techniques have received considerable testimonial support, but it should be realized that cautery does not really effect a cure but rather obliterates the reactive tissue so that it is no longer clinically evident.

Routine immunization at frequent intervals for known viral respiratory pathogens is also advocated for both the treatment and the prevention of pharyngeal lymphoid hyperplasia.[1103,1107]

31.34.8 Prevention and Control

Methods used to control and prevent most of the common viral and bacterial respiratory diseases (see Chapter 48) should limit herd problems with acute pharyngitis. Non—respiratory disease—related causes such as trauma from balling guns, NGTs and dose syringes, foreign objects, and chemical burns can be minimized by improvement of husbandry practices.

Although preventing pharyngeal lymphoid hyperplasia in horses by prophylactic immunization against common equine viral respiratory agents at regular intervals has been discussed at length, there are no substantive data to support this practice. Nevertheless, racetrack veterinarians maintain that frequent immunization (60-day intervals) against influenza and rhinopneumonitis markedly reduces the severity of pharyngeal lymphoid hyperplasia and improves exercise tolerance.[1107] Considering the mobility of racing and show horse populations, this approach should at least be beneficial for limiting outbreaks of viral respiratory disease and consequently perhaps limiting chronic pharyngeal lymphoid hyperplasia. Until more is understood about the clinical appearance of the pharyngeal tonsil in horses, along with normal variations that occur with aging in exercised

582 583

and nonexercised horses, and these findings can be correlated with immunopathologic events and indexes of performance, it will remain difficult to treat, control, and prevent pharyngitis in a systematic manner.[1108]

31.35 GUTTURAL POUCH DISEASES

JOHN R. PASCOE

31.35.1 Definition and Etiology

The guttural pouches are paired air-filled diverticula of the eustachian tubes that communicate between the middle ear and the pharynx. They are located ventral to the atlas, dorsocaudal to the pharynx, and rostrodorsal to the retropharyngeal lymph nodes and occupy a large part of the retropharyngeal space. Each pouch is divided into medial and lateral compartments by a stylohyoid bone that courses through the caudolateral aspect of each pouch. The medial compartments appose each other on the midline. The lateral walls of each guttural pouch contain cranial nerves VII (facial), IX (glossopharyngeal), X (vagus), XI (spinal accessory), and XII (hypoglossal); the cranial sympathetic trunk; the internal carotid artery; and branches of the external carotid artery.[1109] The intimate relationship of these vessels and nerves with the mucous membrane lining the guttural pouches explains why epistaxis and nerve dysfunction frequently accompany guttural pouch disease. Each pouch has a capacity of approximately 300 mL, with the medial compartment accounting for approximately two thirds of this volume. Communication with the pharynx occurs through a slitlike opening situated rostral and ventral to the pharyngeal recess. The pharyngeal opening of the guttural pouch is funnel shaped and wider rostrally than caudally. The plica salpingopharyngea is a fold of mucous membrane that contributes to the caudal narrowing of the pharyngeal opening and makes catheterization of the guttural pouch difficult. Redundancy of this fold of tissue may contribute to guttural pouch tympany.[1109]

The guttural pouch is not a sterile environment; as an extension of the pharynx, it normally contains bacteria. In one report of 30 normal horses, 59% of percutaneous guttural pouch lavage aspirates had bacterial growth, although only 7% were considered to have bacteria considered to be pathogenic; no fungi were isolated.[1110] Inflammatory cell counts and distribution were correlated with recovery of bacteria. Aspirates were considered normal if there were less than 5% neutrophils; typical cell distribution was primarily ciliated columnar epithelial cells, a few nonciliated cuboidal epithelial cells, and less than 1% monocytes, lymphocytes, and macrophages.[1110] Horses exercised strenuously on a regular basis had lower total cell counts, lower neutrophil counts, and fewer bacteria isolated.[1110] Preventing horses from head lowering for 12 to 24 hours increases the frequency of bacterial isolation, especially at 24 hours, including an increase in neutrophil counts, and likely indicates reduced ability to clear guttural pouch secretions.[1111] Interpretation of microbial isolates from guttural pouches requires correlation with cytologic characteristics of guttural pouch fluid and clinical signs.[1112]

Three disease conditions commonly affect the guttural pouches: tympanitis, empyema, and mycosis.[1109] Less common conditions include neoplasia,[1113] fractures of the hyoid bone, foreign bodies,[1109,1114] and cystic structures.[1115]

31.36 GUTTURAL POUCH TYMPANY

Tympany of the guttural pouch occurs infrequently and is recognized in foals after birth up to 1½ years of age[1109,1116–1118]; affected foals are usually identified within the first 2 weeks of life. Fillies are more commonly

affected, with the ratio of females to males ranging from 2:1 to 4:1. Arabian foals may have a higher risk for tympany, which may be an inherited trait.[1119] Tympany is characterized by unilateral or bilateral distention of the guttural pouch with air. The exact cause is unknown, but numerous reports have implicated a congenital redundancy of the plica salpingopharyngea, which acts as a one-way valve that apparently permits airflow into but not out of the pouch.[1116] It has also been postulated that upper airway infections and inflammation may result in enlargement of this fold of tissue, with subsequent air trapping in the pouch.[1120]

31.36.1 Clinical Signs and Differential Diagnosis

Affected foals usually have a nonpainful, soft, fluctuant swelling in the retropharyngeal space (Fig. 31-43, *A*) with variable respiratory distress, extension of the head and neck, and signs of dysphagia.[1116,1117] Mild tympany may not result in signs other than swelling of the throatlatch region.[1120] Respiratory distress occurs when continued distention of the pouch compresses the pharyngeal area. The differential diagnosis should include guttural pouch empyema and retropharyngeal abscesses or cellulitis.

31.36.2 Clinical Pathology

Stress leukocytosis may occur if there is marked respiratory distress.

31.36.3 Diagnostic Aids

Diagnosis of guttural pouch tympany is based on recognition of characteristic swelling in the retropharyngeal space and confirmation by physical examination. Although the distention is most often unilateral, extreme distortion of a single pouch may give the impression of bilateral involvement.[1121] Differentiation between unilateral and bilateral involvement can be difficult and may require deflation of the affected guttural pouch by catheterization or percutaneous needle aspiration combined with external compression. Other adjunctive diagnostic procedures include radiographic demonstration of gas distention of one or both pouches (see Fig. 31-43, *B*) and endoscopic observation of pouch distention and pharyngeal distortion.

31.36.4 Treatment and Prognosis

Guttural pouch tympany and respiratory distress can be alleviated temporarily by aspiration of air from the affected pouch by means of either percutaneous decompression at the point of greatest distention through Viborg's triangle or introduction of a catheter through the pharyngeal opening of the guttural pouch.[1109] These measures are palliative, and the pouch rapidly refills when decompression is discontinued. Treatment methods of choice include surgical excision or photoablation of the redundant plica salpingopharyngea; fenestration of the medium septum between the two pouches by excision, electrosurgery, or photoablation; and creation of a salpingopharyngeal fistula by photoablation and temporary stenting of the fistula.[1116–1118,1122–1124] The latter technique is similar to an older, successful approach that involved incising the floor of the guttural pouch into the pharynx.[1125] If the condition is bilateral, fenestration of the median septum alone does not successfully resolve the condition, and either excision of one or both plica salpingopharyngea in combination with septal fenestration or septal fenestration and salpingopharyngeal fistula formation must be performed. After surgery the prognosis for resolution of guttural pouch tympany is generally considered favorable[1118] unless complicating factors such as aspiration pneumonia exist.[1117] Early recurrence after surgery can range from 15% to 30%, but further

583
584

resection of the plica salpingopharyngea or refenestration of the mesial septum or enlargement of the fenestration typically results in resolution of signs.[1117,1118]

31.37 GUTTURAL POUCH EMPYEMA

Guttural pouch infections are introduced either directly through the pharyngeal opening or by lymphatic spread.[1126] Accumulation of purulent material (empyema) is considered to be a secondary, chronic, localized manifestation of a more generalized ascending respiratory infection. Empyema is usually unilateral and is often a sequela to an infectious respiratory disease, especially infection by *S. equi* subsp. *equi*.[1127–1130] Typically a horse with guttural pouch empyema displays continued nasal discharge after recovery from streptococcal infection.[1121,1130] In a case control study of foals with distal respiratory tract infection, 21% had concurrent mucopurulent drainage from the pharyngeal openings of the guttural pouches.[1131] *S. equi* subsp. *zooepidemicus* was isolated from respiratory secretions of the majority of infected foals and from exudate collected from guttural pouches.[1132] Rupture of retropharyngeal abscesses into the guttural pouch has also been associated with empyema, suggesting that strangles or other upper respiratory tract infections may have an important role in the development of guttural pouch infection in horses.[1128,1130,1133]

31.37.1 Clinical Signs and Differential Diagnosis

The clinical signs of guttural pouch empyema include intermittent nasal discharge that may worsen when the head is lowered, retropharyngeal swelling, cough, fever, parotid swelling and pain, dysphagia, difficult breathing, dysphagia, and pneumonia.[1134] Nasal discharge can be unilateral or bilateral, even if only one pouch is affected, because the pharyngeal openings of the guttural pouches are located caudal to the nasal septum. The nasal discharge is generally nonodorous, white, and opaque. Signs of dysphagia may be observed secondary to pharyngeal compression or paresis. Labored breathing may result from gradual collapse of the pharynx as the guttural pouch distends. Inspissation of the purulent material results in chondroids, which are hard concretions of inspissated pus.[1135] The differential diagnosis of guttural pouch empyema should include those diseases with chronic mucopurulent nasal discharge such as pneumonia, sinusitis, upper respiratory tract infections, and guttural pouch tympany.

31.37.2 Clinical Pathology

Leukocytosis is often present. Plasma fibrinogen levels are often increased, [1134] and these changes generally parallel the development of leukocytosis, pyrexia, and clinical signs of strangles or primary guttural pouch empyema. Analysis of fluid obtained by catheterization of the guttural pouch often reveals a beta-hemolytic *Streptococcus* species,[1128,1135] although other bacterial species have been isolated.[1134]

31.37.3 Diagnostic Aids

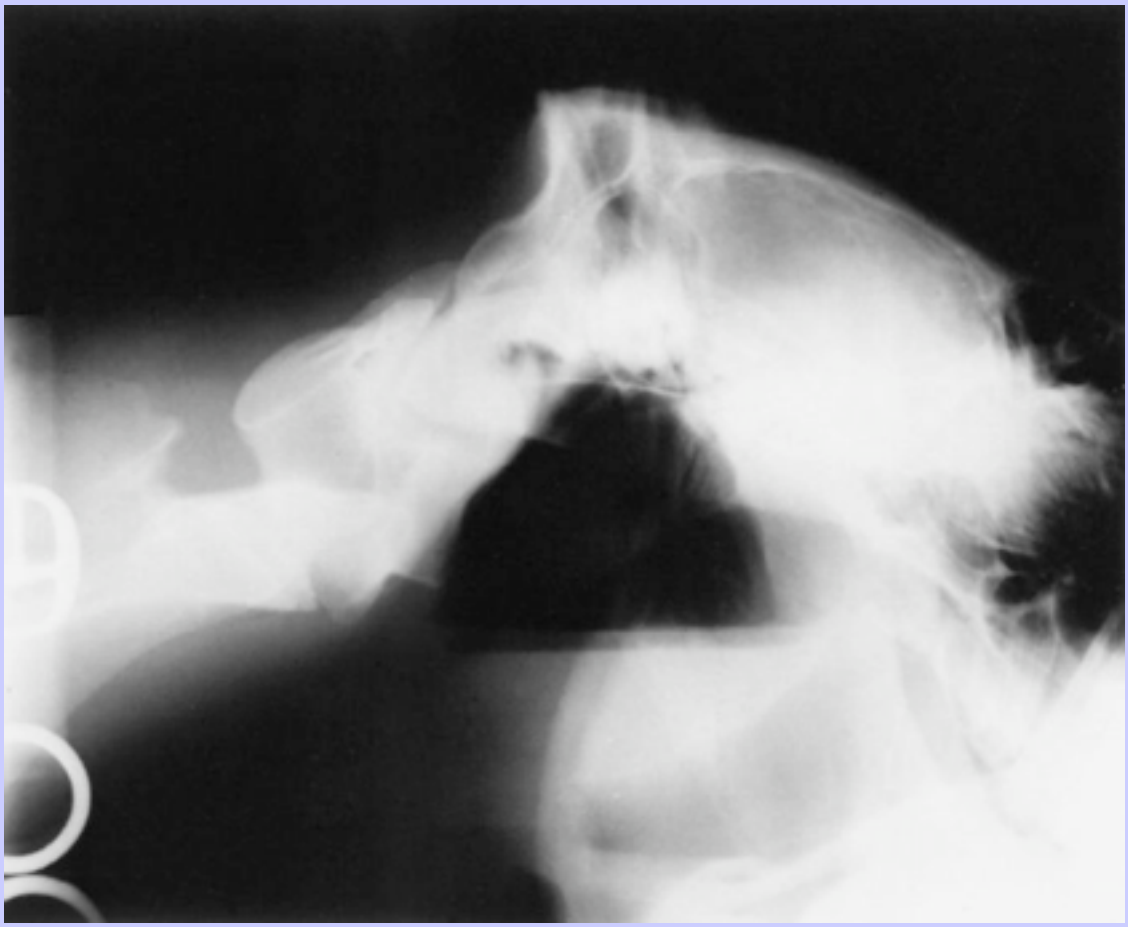
Guttural pouch empyema should be considered in any patient with a chronic, nonresponsive nasal discharge.[1121] Diagnostic aids include radiography, endoscopy, percutaneous centesis, and aspiration of material from the pouch through the pharyngeal opening.[1109] Recognition of fluid (Fig. 31-44) or radiodense masses (chondroids) within the pouch on standing lateral radiographs supports a diagnosis of empyema. Physical and endoscopic examination or oblique radiographic projections may be necessary to identify which pouch is involved. Endoscopic examination permits identification of the affected pouch and evaluation of the character of the fluid. Endoscopic examination of the lateral compartment is important to avoid missing sequestered fluid or

chondroids.[1136] Absence of fluid at the pharyngeal ostium does not preclude the possibility of guttural pouch empyema, especially if the fluid has become inspissated[1121] or the ostium is sealed closed.[1137] Fluid identified on radiographs should be characterized by endoscopic examination of the pouches or aspiration of the fluid with appropriate cytologic and microbial analysis. Fluid samples can be aspirated through the pharyngeal ostium with a sterile artificial insemination (AI) pipette, a Chambers catheter, or tubing advanced through the biopsy channel of an endoscope. Alternately, fluid can be aspirated percutaneously, but this may lead to cellulitis along the needle tract if pathogenic bacteria are tracked through tissues on needle withdrawal.

584

585

Fig. 31-44 Lateral radiograph demonstrating distinct fluid lines in both guttural pouches.



31.37.4 Pathophysiology

Strangles is a common upper respiratory disease affecting young horses. Primary clinical signs of strangles usually develop after a short incubation period of 2 to 6 days and include depression, pyrexia, coughing, and ocular and nasal discharges that become mucopurulent as the disease progresses. Lymph nodes of the head and neck become enlarged and painful, often forming abscesses. Guttural pouch empyema may result from extension of the upper respiratory infection with *S. equi* (strangles) to the guttural pouches or from rupture of

retropharyngeal lymph node abscesses into the guttural pouch.[1127,1128] Commonly isolated bacteria from guttural pouch empyema include *S. equi, S. zooepidemicus, E. coli*, and *Klebsiella* species.[1134] Not all horses with empyema have a history of strangles or previous respiratory infection, and empyema seemingly can occur by many of the same mechanisms as middle ear infection: that is, fluid accumulates in the area, and uncontrolled growth of bacteria normally present results in inflammation and exudation. Most streptococcal isolates are resistant to potentiated sulphonamides and sulfadimethoxine.[1134]

31.37.5 Treatment and Prognosis

Treatment of guttural pouch empyema is complicated by poor drainage from the affected pouch.[1109] In the normal horse the pharyngeal opening of the guttural pouch is located rostrodorsal to the floor of the guttural pouch, and drainage can be achieved only by lowering the horse's head.[1109,1122,1126] However, in horses with empyema, lowering the head may not achieve adequate drainage if there is ventral distortion of the pouch.[1109] Inflammation of the lining mucosa may result in swelling of the tissue surrounding the pharyngeal opening, further compromising normal drainage.[1109]

Choice of medical or surgical treatment depends on the duration and nature of the empyema. Parenteral antimicrobial therapy may reduce the quantity of the nasal discharge, but relapse often follows cessation of treatment.[1121,1134] The early stages of empyema may respond to daily lavage of the affected guttural pouch with physiologic solutions or saline antibiotic solutions injected through a catheter. A volume of 500 mL should be flushed into the involved pouch under moderate pressure to create contact with as much of the interior of the guttural pouch as possible.[1138] During lavage the head should be lowered to prevent aspiration of fluid. Purulent fluid from the affected guttural pouch should be aspirated on initial catheterization and submitted for bacterial culture and antimicrobial susceptibility testing. This can be accomplished with most flexible uterine culturettes under direct endoscopic observation. Parenteral antimicrobial drugs should be administered on the basis of susceptibility testing results; although medication may be of benefit in treating empyema, adequate drainage and local therapy are of primary therapeutic importance.

Irrigating the guttural pouch with an indwelling catheter may result in the development of severe inflammatory changes in the guttural pouch.[1139] Indwelling catheters placed in horses with normal guttural pouches have caused increasing purulent discharge with time; nasal discharge diminished after catheter removal and was absent after 3 days. Povidone iodine (1% available iodine) diluted to a 10% solution (0.1% available iodine) for lavage of the guttural pouch caused considerable reaction, including inflammatory infiltrates, hemorrhage, necrosis, and lymphoid reaction. Therefore, if possible, other means should be used to achieve antiseptic or antimicrobial therapeutic goals.[1139] Consideration should be given to using nonirritating solutions to prevent initiating cranial nerve neuritis. Although indwelling catheters are convenient, it may be well to suggest daily catheterization and irrigation with an AI pipette or Chambers catheter to diminish the inflammatory response associated with indwelling catheters in an already inflamed guttural pouch. Consideration of daily catheterization must be weighed against stress, possible tissue trauma, and time requirements for intermittent catheterization.[1139]

Treatment with parenteral antimicrobials and local lavage is successful and requires a patent opening for adequate drainage, but the course of treatment may be protracted. Acetylcysteine, a mucolytic, has been used successfully to resolve inspissated empyema.[1140] If response to lavage is poor or if secretions reaccumulate and empyema returns, surgical drainage of the guttural pouch should be considered.[1109]

Surgery is generally indicated when purulent material becomes inspissated or chondroids have formed,[1109,1141] although resolution has been reported in one horse after prolonged lavage (14 days) through an indwelling catheter.[1142] Surgical approaches include percutaneous drainage through standard approaches to the guttural pouches in anesthetized recumbent or standing sedated horses and creation of a nasopharyngeal fistula by use of an Nd:YAG laser.[1143] Other approaches when chondroids are present include removal by retrieval snares passed endoscopically, standing removal through a modified Whitehouse approach,[1144] and removal from the contralateral pouch after fenestration of the mesial septum when the ipsilateral ostium is closed.[1137]

The prognosis for guttural pouch empyema is generally favorable if it is recognized promptly and treated appropriately.[1134] Likewise, removal of chondroids typically carries a good prognosis.[1134]

31.38 GUTTURAL POUCH MYCOSIS

Guttural pouch mycosis is a fungal disease of the guttural pouch that typically affects the dorsocaudal region of the medial compartment, although lesions affecting larger areas, including the lateral compartment, have been seen.[1121,1145–1148] Fungal invasion of neurovascular structures coursing through the walls of the guttural pouches results in clinically apparent disease. Although the exact cause of guttural pouch mycosis is not known, a number of fungi, especially *Aspergillus (Emericella) nidulans* and *A. fumigatus*, have been isolated from the lesions.[1109,1148–1154]

585
586

31.38.1 Clinical Signs and Differential Diagnosis

Lesions are usually unilateral and occasionally bilateral. The wide spectrum of clinical signs that can occur in association with guttural pouch mycosis reflects the degree of fungal invasion and subsequent inflammation of vascular structures or nerves beneath the mucous membrane lining the guttural pouch. Common clinical signs include intermittent spontaneous epistaxis and dysphagia.[1109,1145] Epistaxis generally results from fungal erosion of the wall of the internal carotid artery in the roof of the medial compartment and, less commonly, from erosion of the external carotid artery and maxillary artery in the lateral compartment.[1109,1145] Epistaxis is usually unilateral, occurring from the ipsilateral nostril, but can also be bilateral because the pharyngeal openings of the guttural pouches are located caudal to the caudal border of the nasal septum.[1147] Episodes of epistaxis generally occur while the horse is at rest and can vary from mild to severe, with several premonitory bleeds that generally culminate in a fatal episode of epistaxis.[1146,1147] Occasionally a horse dies of a single episode of epistaxis without previous clinical signs. Epistaxis may recur at intervals varying from 24 hours to 3 weeks.[1147]

Dysphagia, the second most common clinical sign, likely results from damage to the pharyngeal branches of the vagus and glossopharyngeal nerves and generally occurs later than epistaxis in the course of the disease.[1147] Horses with dysphagia cough during attempts to eat solid food, and, in addition to the presence of food material in nasal discharge, a considerable quantity of food is coughed out the mouth. Recovery from dysphagia may occur,[1147] but in general the prognosis for full recovery is poor.

Other clinical signs include parotid pain, abnormal head posture, unilateral or bilateral nasal discharge, head shyness, abnormal respiratory noise, sweating and shivering, Horner's syndrome, visual disturbances, colic, and facial paralysis.[1146,1147,1152–1155] These signs are the result of angina and dysfunction of cranial nerves and the sympathetic nervous system.

The differential diagnosis for the horse with epistaxis should include EIPH, ethmoid hematoma, guttural pouch or pharyngeal neoplasia, tracheobronchial foreign bodies, and guttural pouch mycosis.[1147] Differentiation of these diseases is aided by a thorough history and endoscopic examination. Differential diagnosis for dysphagia should include fractures of the hyoid apparatus; pharyngeal and guttural pouch fistula; cleft palate; esophagitis; pharyngeal paralysis; foreign body entrapment in the mouth or esophagus; pharyngeal neoplasia; lead poisoning; bacterial, viral, and mycotic CNS infections; and guttural pouch mycosis.[1147,1153]

31.38.2 Clinical Pathology

If epistaxis is the presenting complaint, there may be moderate to severe anemia with accompanying hypoproteinemia. Differential white cell distributions may be normal or may indicate a stress response. If dysphagia becomes a dominant clinical sign, other hematologic changes indicative of infection secondary to aspiration pneumonia may be evident.

31.38.3 Diagnostic Aids

Clinical signs of epistaxis or cranial nerve dysfunction are suggestive of a diagnosis of guttural pouch mycosis. A thorough physical examination may reveal abnormal sensitivity on digital palpation of the parotid area on the affected side.[1146] A definitive diagnosis of guttural pouch mycosis requires endoscopic observation of the characteristic diphtheritic lesion in the dorsocaudal aspect of the medial compartment or elsewhere within the guttural pouch.[1147] A healed lesion may be identified by the presence of scar tissue within the mucous membrane.[1147] Lesions may vary in color (brown, yellow, black, or white) and in size (from discrete nodules to diffuse irregular patches covering the roof of both the medial and lateral compartments)[1148,1155]; erosion with fistula formation can occur into the opposite guttural pouch or pharynx. Occasionally the characteristic lesion is obscured by clotted blood, so that the diagnosis is based on the clinical signs of epistaxis correlated with blood present in the guttural pouch. Because hemorrhage may originate from the internal carotid, external carotid, or maxillary arteries, it is important to identify the source of bleeding before therapy, particularly if surgical intervention is being considered.[1145] Care should be taken not to dislodge a thrombus and produce further hemorrhage. If dysphagia is apparent, food and saliva may be identified during endoscopy of the pharynx and nasal passages.[1109]

In guttural pouch mycotic infections, radiographs are of limited value because only minimum suppuration is associated with mycotic infections[1153]; however, the lateral view may allow assessment of the degree of fibrous reaction and loss of normal air space.[1153] Radiography may also aid in diagnosing some of the long-term sequelae such as fibrous deposits in the pouch and associated bony changes.[1156]

Serum titers to *A. fumigatus* are not diagnostic; however, reactivity to 22-kd and 26-kd serum antigens measured by immunoblot analysis may be diagnostic for guttural pouch mycosis.[1157]

31.38.4 Pathophysiology

The pathogenesis and predisposing factors leading to guttural pouch mycosis and arterial erosion are unknown, but it is believed that the disease is initiated by some stress to the soft tissues where the mycotic plaques are generally found.[1148] Potential stresses include inflammation, trauma, and vascular insult.[1133] Aneurysm

formation is not well correlated with the severity of the plaque formation. Although the nature of the initiating lesion remains unclear, it is generally agreed that the later stages are associated with deep fungal infections.[1148] *A. nidulans* and other *Aspergillus* species have been isolated and may be the causative agents.[1148–1156] *A. nidulans* is rarely pathogenic, but in the warm humid environment of the guttural pouch it may grow as an opportunist under certain circumstances.[1148] The mycotic lesions show no predilection for either the right or the left guttural pouch.[1147] Fungal infection of the pouch, erosion of major blood vessels, and involvement of nerves (IX, X, XI, XII, cranial cervical ganglion, and postganglionic sympathetic fibers) that traverse the area explain the epistaxis, local pain, and neurologic signs associated with guttural pouch mycosis.[1147,1148]

31.38.5 Epidemiology

No apparent age, sex, breed, or geographic predispositions have been observed. Guttural pouch mycosis is a sporadic disease that tends to arise during the warmer months of the year and rarely affects more than one horse in a particular stable.[1147] Affected horses are afebrile; infection is diagnosed when clinical signs such as epistaxis and dysphagia occur.[1147]

586

587

31.38.6 Necropsy Findings

At postmortem examination, lesions are confined to the pharyngeal muscles, guttural pouch, and bones of the skull.[1146] Gross findings may include large blood clots in the nasal passages and at the pharyngeal opening of the guttural pouch.[1156] Unilateral denervation atrophy of the ipsilateral pharyngeal or laryngeal muscles may occur if there is involvement of the pharyngeal and recurrent laryngeal branches of the vagus.[1146] Examination of the guttural pouch generally reveals clotted blood and a diphtheritic plaque in the dorsocaudal aspect of the medial compartment that is firmly adherent to the underlying tissue and is clearly demarcated from surrounding tissue.[1148,1156] The lesion may be localized or may affect the entire roof of the pouch. If hemorrhage has occurred, the lesion may be obscured by clotted blood, pus, or mucus.[1148] An intense inflammatory reaction may be evident in response to acute fungal infection, whereas the inflammation may subside with chronic healing lesions so that scar tissue is evident.[1148,1153] Active inflammation may also predispose to osseous lesions of the petrous temporal and stylohyoid bones.[1146,1148,1152] Some cases of guttural pouch mycosis may remain asymptomatic and may be diagnosed only at routine postmortem examination.[1147]

31.38.7 Treatment and Prognosis

Without treatment a poor prognosis is warranted, because horses affected with guttural pouch mycosis are at risk for a fatal episode of epistaxis. Both medical and surgical treatments have been advocated for horses affected with guttural pouch mycosis with variable results; however, surgical treatment by an intraarterial occlusion technique is generally considered to provide the best prognosis.[1158–1161] Spontaneous regression of guttural pouch mycosis may occur, and this must be considered when evaluating the various medical or surgical treatments for this disease.[1109,1147]

Medical treatment is generally aimed at topical therapy of the mycotic lesion through the pharyngeal opening of the guttural pouch by means of a catheter.[1109] Bathing of the lesion may be facilitated by anesthetizing the horse and placing it in dorsal recumbency.[1146] Instilling fungicidal and fungistatic drugs, topical enzymes, and organic

iodine compounds into the guttural pouch has been attempted with variable success.[1162,1163] The necessity and efficacy of these treatments are unknown, and systematic treatment is hampered by a lack of knowledge of the pathogenesis of guttural pouch mycosis.[1164] Parenteral administration of antibiotics, corticosteroids, thiabendazole, ketoconazole, and iodine compounds also has questionable efficacy.[1156,1158,1164] The response of guttural pouch mycosis to local and parenteral treatment is protracted; thus the risk of fatal hemorrhage exists long after treatment has commenced.[1165,1166]

Surgical treatment of guttural pouch mycosis appears to offer the best prognosis for eventual cure. The internal carotid artery is not an end artery, and blood may enter this vessel from the bifurcation of the common carotid or may return from the cerebral arterial circle. Various surgical techniques have been described, and use of a balloon-tipped catheter inserted into the distal internal carotid artery combined with proximal ligation of the internal carotid artery [1156,1165–1167] or transarterial coil embolization[1160,1168] induces thrombus formation and prevents hemorrhage from normal and retrograde blood flow. Thrombosis sufficient to prevent hemorrhage may develop in the distal internal carotid artery within 10 days of catheter placement.[1167] Mucosal healing and complete regression of the fungal plaque have been reported to occur as early as 5 weeks after arterial catheterization[1165] and as early as 15 days after coil embolization.[1160] In a series of 13 cases the insertion of the balloon-tipped catheter successfully prevented fatal epistaxis in all horses.[1165] Topical or systemic treatment of the mycotic plaque is believed to be unnecessary after arterial catheterization.[1165] Intraarterial insertion of latex balloons or embolization coils also results in lesion resolution,[1169–1171] although progression of a mycotic plaque after coil embolization and subsequent development of neurologic signs has been reported in one horse.[1172]

31.39 DISEASES OF THE PARANASAL SINUSES

31.39.1 SINUSITIS

JOHN R. PASCOE

31.39.1.1 Definition and Etiology

Sinusitis refers to inflammation of the paranasal sinuses, from primary microbial infection or secondary bacterial infection associated with dental disease or other sinus disease. Lined by respiratory mucosa, the paranasal sinuses are at risk for developing diseases affecting the respiratory tract.[1173] Sinus empyema, accumulation of pus within a sinus cavity, may result from bacterial or viral infection.

Incidence of sinusitis is relatively low, likely less than 0.5% of disease in equine practice.[1174] In 256 horses with sinonasal disease, primary sinusitis (24%) and dental disease—associated sinusitis (22%) occurred with similar frequency and were the most common cause of sinusitis, whereas sinus cysts (13%), sinonasal neoplasia (8%), ethmoid hematoma (8%), sinonasal trauma (6%), mycosis (5%), and rostral maxillary tooth infection (4%) were the other more common causes.[1175] The frontal and maxillary sinuses are more commonly involved, with the corresponding conchal sinuses and the sphenopalatine sinus affected less often. Median age of horses affected with sinonasal disease is 7 to 11 years.[1175]

Acute or chronic upper respiratory tract infections of viral or bacterial origin can result in primary sinusitis; *Streptococcus* species infection is the most common. Maxillary sinusitis caused by disease of the third (caudal

roots) through sixth cheek teeth (modified Triadian numbers 109 to 111, 209 to 211) often results from alveolar periostitis, patent infundibula, or fractured or split teeth.[1173] Dental defects permit access of food material or bacteria to the tooth root and sinus cavity, with extension to the frontal sinus likely through the frontomaxillary opening. Reported neoplasms include osteoma, osteosarcoma, adenocarcinoma, lymphosarcoma, squamous cell carcinoma, and fibroma.[1176–1179]

31.39.1.2 Clinical Signs and Differential Diagnosis

Signs vary depending on cause, location, and extent of sinus involvement, with unilateral nasal discharge (serous, mucoid, mucopurulent, purulent) being the most frequent sign.[1175,1180] Physical examination of a horse with sinusitis should include observation for epiphora, facial asymmetry, altered nasal airflow, abnormal breath odor, mandibular lymphadenopathy, and sinocutaneous fistula.

Nasal discharge is typically unilateral because the nasomaxillary opening is located rostral to the caudal edge of the nasal septum. Intermittent or continuous, nasal discharge need not be related to a previous upper respiratory infection. Malodorous discharge is commonly associated with dental sinusitis and sinonasal mycosis, whereas mucopurulent discharge is more commonly associated with sinus cysts.[1175] Sanguineous discharge is common with ethmoid hematoma and sinonasal trauma; however, guttural pouch mycosis, pulmonary hemorrhage, nasal turbinate necrosis, and neoplastic or granulomatous lesions should also be considered. Other differential diagnoses of nasal discharge should include guttural pouch empyema or mycosis; acute pharyngitis (strangles, rhinopneumonitis, and influenza); neoplasia or necrosis of the turbinates; ethmoid hematoma; and pulmonary disease.

587

588

After nasal discharge, submandibular lymphadenopathy is the most common sign, particularly when microbial infection is a component of sinusitis. Facial swelling occurs with frequency similar to that of lymphadenopathy, typically when sinus drainage is obstructed or there is an expansile mass within the sinus, or as an acute sign after facial trauma. Occasionally exophthalmos can occur with marked sinus distortion.

Patency of the nasomaxillary opening generally precludes facial distortion. Loss of patency occurs when inspissated exudate accumulates or mucosal lining tissue reaction obstructs the opening. Expansion of the sinus may result in reduced nasal airflow, particularly ipsilaterally, caused by distortion of the architecture of the nasal passages, and in such instances abnormal respiratory noise rather than nasal discharge may be the primary presenting sign.[1178]

Epiphora occurs if there is nasolacrimal duct involvement from trauma, or compression or destruction of the duct from underlying sinus disease. Approximately one third to one half of horses with dental sinusitis, sinus cyst, and sinonasal trauma have epiphora as a presenting sign.[1175]

Percussion of the affected sinus may reveal dullness or pain, although normal resonance does not preclude the possibility of sinusitis. If there is bone thinning over gas above a fluid line (as can occur with some maxillary sinus cysts), percussion may elicit increased resonance.

Careful examination of the oral cavity for signs of dental or periodontal disease should be performed when any of these signs are present. Particular attention should be paid to examination of the occlusal surface of the teeth with a very fine dental pick (e.g., 22-gauge needle); however, it should be recognized that periapical abscess formation can occur without defects in the occlusal surface. Accuracy of diagnosis of dental disease is substantially enhanced by use of intraoral endoscopy and CT.

31.39.1.3

Clinical Pathology

The hemogram in animals with sinusitis generally remains within the normal range, although acute sinusitis of infectious origin may be associated with neutrophilia. With chronic sinusitis there may be concurrent hyperfibrinogenemia. Sinus fluid obtained by percutaneous centesis should be examined cytologically (including a Gram stain) and submitted for microbial culture and susceptibility testing to differentiate among bacterial, fungal, and neoplastic disease. Flecks of feed material indicate sinusitis secondary to dental abnormalities.

31.39.1.4

Laboratory Aids and Definitive Diagnostic Tests

A presumptive diagnosis of sinusitis can be made from the physical examination and associated clinical signs.[1175,1181] Procedures most helpful in establishing a diagnosis of sinus disease in 85 horses were radiography (92%), endoscopy (38%), percutaneous centesis (21%), and examination of the oral cavity (20%).[1177]

Endoscopic examination of the nasal cavity may permit identification of exudate draining from the nasomaxillary opening or in advanced cases may reveal distortion of the nasal cavity secondary to sinus enlargement. Middle meatus examination is an important component of endoscopic examination. Diagnosis beyond recognition of the potential source of the nasal discharge is limited unless there is an obvious mass or abnormal tissue is observed. Sinoscopy can be accomplished by using an arthroscope[1182] or flexible endoscope[1183] inserted through small trephine holes in either the maxillary or the frontal sinus. Examination of the rostral compartment of the maxillary sinus requires a separate portal unless the bony septum between the rostral and caudal compartments has been destroyed. Observation may be limited by fluid or tissue especially in the rostral compartment of the maxillary sinus but can potentially be enhanced after sinus lavage and aspiration.

Standard radiographic projections include the standing lateral, dorsoventral, and right and left oblique views.[1184,1185] Radiographic findings include fluid lines within the sinus, space-occupying soft-tissue densities, areas of decreased bone density, fractures, or dental abnormalities. Dental root disease is identified radiographically by a loss of continuity of the lamina dura and lysis of the tooth root or surrounding bone, combined with new bone formation and cement deposition.[1184] Anatomy of normal equine skulls as demonstrated by CT and MRI has been described.[1186–1188] Diagnostic accuracy, especially determination of the extent of involvement of structures within the skull, can be enhanced by CT.[1189,1190] CT imaging enhances diagnostic accuracy of tooth involvement.[1190] Findings associated with dental caries include hypoattenuation of cementum, destruction of enamel, and filling of the infundibular cavity with gas, whereas with dental decay there is gas accumulation in the root area or fragmentation of the root, and sinus mucosal thickening. Additional changes with sinusitis typically involve the maxilla with endosteal sclerosis, thickening, periosteal reaction, and deformation, especially involving the facial crest.[1190] Scintigraphic examination may improve specificity in identification of dental involvement in sinusitis.[1191,1192]

Percutaneous sinus centesis may provide a definitive diagnosis and allow an avenue for subsequent therapy. Cytologic evaluation, with concurrent microbial culture and antibiotic susceptibility testing, may elucidate the cause of the sinusitis.[1177] Isolation of a single organism such as *Streptococcus* species generally indicates a primary sinusitis, whereas polymicrobial infection is more compatible with sinusitis of dental origin. Visual

examination of the oral cavity, especially intraoral endoscopy, and careful probing of the occlusal surfaces with a dental pick may identify dental abnormalities.

31.39.1.5 Necropsy Findings

Affected sinuses contain fluid or tissue of variable color and consistency. Fluid character ranges from clear and odorless with cystic sinus disease to white, yellow, or green purulent fluid with a variable, but often putrid, odor in sinusitis resulting from other causes. Sinusitis of dental origin has a characteristically pungent and unpleasant odor. Granulomatous lesions have been reported to appear as large lobular gelatinous masses filling the sinus cavity. The gross appearance of neoplastic lesions within the sinus cavity depends on the type of neoplasm. Neoplasia may cause surrounding soft-tissue and bony destruction, whereas large, benign space-occupying lesions may result in distortion of the nasal turbinates and nasal septum, as well as external facial bone distortion.

31.39.1.6 Treatment and Prognosis

588

Not infrequently, horses with a chronic mucopurulent nasal discharge from sinusitis have a history of response 589 to antimicrobial therapy, followed by recurrence of the discharge after antibiotic therapy ceases. Definitive diagnosis of sinusitis can be accomplished using the techniques described earlier. Sinoscopy permits examination of the paranasal sinuses and in some instances facilitates treatment.[1184,1193]

Suggested treatment for primary sinusitis or empyema involves daily lavage of the sinus through a percutaneous centesis site with 1 L of saline, to which a broad-spectrum antibiotic or antiseptic has been added. Once the results of culture and susceptibility testing are available, the appropriate antibiotic should be administered locally in the flush solution, as well as systemically, for 14 days. Resolution or reduction in the volume of nasal discharge is an indication of successful therapy. If little progress is made after 10 to 14 days or if drainage recurs, sinusotomy (trephination or bone flap technique, standing or recumbent anesthetized) may be required to resolve the condition.[1194] The prognosis is generally favorable if primary sinusitis is not chronic and if the mucous membrane is not markedly thickened.[1195] Chronic sinus disease (longer than 6 months) carries a poor prognosis, and, for resolution to occur, surgical removal of the thickened, infected mucous membrane is required; creation of sinonasal drainage by sinus fenestration is also recommended. Isolation of *Pseudomonas* species from a sinus aspirate generally indicates an unfavorable prognosis.[1180]

Sinusitis that results from secondary factors is generally not responsive to medical management. Such conditions include diseased teeth, granulomas, or neoplasia; surgical removal of the inciting cause is required, and adjunctive treatment may be required. The prognosis for sinusitis associated with dental abnormalities is usually favorable once the diseased tooth has been removed.[1195,1196] If the periodontal ligament is intact, endodontic therapy can be used to save the tooth. This is accomplished by surgical apicoectomy and retrograde occlusion of the root canal after debridement of the pulp. In geriatric horses with dental-associated sinusitis, when economic constraints limit surgical options, sinusotomy and periodic sinus lavage and antibiotic therapy have been used successfully to manage nasal discharge.

The prognosis for resolution of granulomatous lesions is generally guarded and depends on surgical access and extent of the lesion. Neoplastic lesions are often well established and have metastasized, either locally or regionally, by the time they become clinically apparent; the prognosis for resolution is generally guarded to poor.[1176] In a series of 16 horses with sinus neoplasia, 11 were euthanized because of the extent of the lesion,

four lesions recurred after surgical removal, and one horse with squamous cell carcinoma was successfully treated and had no recurrence at a 2-year follow-up evaluation.[1177]

31.39.1.7 Prevention and Control

Prevention of sinusitis in horses is difficult because of the variety of causes. Isolation of horses from those with upper respiratory bacterial or viral diseases may be of benefit in preventing primary sinusitis. Regular dental care and a proper diet may help circumvent sinusitis caused by dental abnormalities, although many cases most likely result from a variety of causes not yet defined or over which the owner or veterinarian has no control.

31.39.2 ETHMOID HEMATOMA

JOHN R. PASCOE

31.39.2.1 Definition and Etiology

Also termed *progressive ethmoidal hematoma*[1197] and *hemorrhagic nasal polyps*,[1198] ethmoid hematomas are slowly expanding angiomatous masses that appear to originate principally from the mucosal lining of the ethmoid conchae. Smaller hemangiomas arising from the mucosal lining of the frontal, maxillary, and sphenopalatine sinuses have been recognized, but the relationship between these benign endothelial tumors and ethmoid hematoma is uncertain. A relationship between paranasal sinus cysts and ethmoid hematoma has been suggested,[1199] but distinctly different histologic features characterize each disorder,[1200] seemingly arguing against a common cause and the likelihood that these lesions are variants of each other. The cause of ethmoid hematoma is unknown, and it remains a relatively uncommon condition.[1201–1205] Although reported in a 4-week-old foal and in 3-year-old horses, most affected horses are older than 8 years—generally thoroughbred, Arabian, or warmblood horses.[1201–1207]

31.39.2.2 Clinical Signs

A blood-tinged nasal discharge with intermittent epistaxis from one or both nostrils is the most common clinical sign.[1208] Unilateral or bilateral, epistaxis varies from blood-tinged mucoid or mucopurulent discharge to blood spots or a trickle of blood. Fulminant or fatal epistaxis as can occur with guttural pouch mycosis is uncommon. If the hematoma occupies the choana(e) or nasal cavity, a mucopurulent, occasionally malodorous nasal discharge with some blood discoloration is more commonly seen. Typically these horses have a history of abnormal respiratory noise, both inspiratory and expiratory, especially during exercise. With nasal cavity involvement, airflow is usually reduced or may be absent on the affected side. Facial distortion or asymmetry is uncommon and is more likely to occur when the hematoma occupies the frontal and maxillary sinuses. Less commonly there may be an associated history of coughing, choking, ptyalism, increased respiratory effort during resting breathing, and either head shyness or head shaking.[1197] If the hematoma has expanded into the paranasal sinuses, percussion yields a dull sound.

31.39.2.3 Laboratory Aids and Definitive Diagnostic Tests

Confirmation requires endoscopy of the ethmoid conchae and skull radiography (Figs. 31-45 and 31-46); however, the origin and extent of the mass can be delineated more accurately by computed tomographic examination of the skull. Sinoscopy may be of diagnostic value in horses with ethmoid hematoma involving the paranasal sinuses without protrusion into the nasal cavity. Rarely, ethmoid hematoma infiltrates the nasal conchae; these lesions, identifiable by CT, may be missed by sinoscopy. Because ethmoid hematoma is bilateral in approximately 30% of affected horses, it is prudent to examine both the left and right ethmoidal conchae. The ethmoidal labyrinth is visible approximately 25 cm from the nares, with the endoscope positioned in the ventral nasal meatus and the viewing tip deflected dorsally. The rostral surface of the ethmoidal concha does not protrude beyond the caudal nasal cavity and has a bulbous shape and a moist pink to pale red mucosal covering.

Beyond the rostral surface the numerous pillars that form the ethmoidal conchae and separate the ethmoidal spaces (cellulae ethmoidales) are visible. Ethmoidal hematomas that project into the ventral meatus or through the choana into the nasopharynx often obscure the ethmoidal concha. Occasionally, unilateral ethmoid hematomas that have expanded into the nasopharynx may protrude into the contralateral ventral meatus, obscuring the view of the ethmoidal labyrinth on that side. The origin of hematomas that expand dorsally into the frontal sinus may not be visible on endoscopy, but hemorrhage that originates deep to the visible portion of the ethmoidal conchae may be evident or may be noticed from the region of the nasomaxillary opening in the middle meatus. Visible ethmoid hematomas can vary in color from deep red to red-purple or may have a yellow-brown or yellow-green-brown to bronze color. The surface is irregularly rounded, with small punctate hemorrhages or erosions, and may be partially covered in yellow-white mucopurulent material that may be admixed with blood. Often the floor of the ventral meatus and the regions of contact with the nasal cavity have pooled exudate of blood and mucopurulent matter. Manipulation of the visible surface of the hematoma with the tip of the endoscope may elicit bleeding or oozing.

589 590

Fig. 31-45 Endoscopic view of left ethmoturbinate. **A**, Normal appearance. **B**, Ethmoturbinate obscured by an ethmoid hematoma.

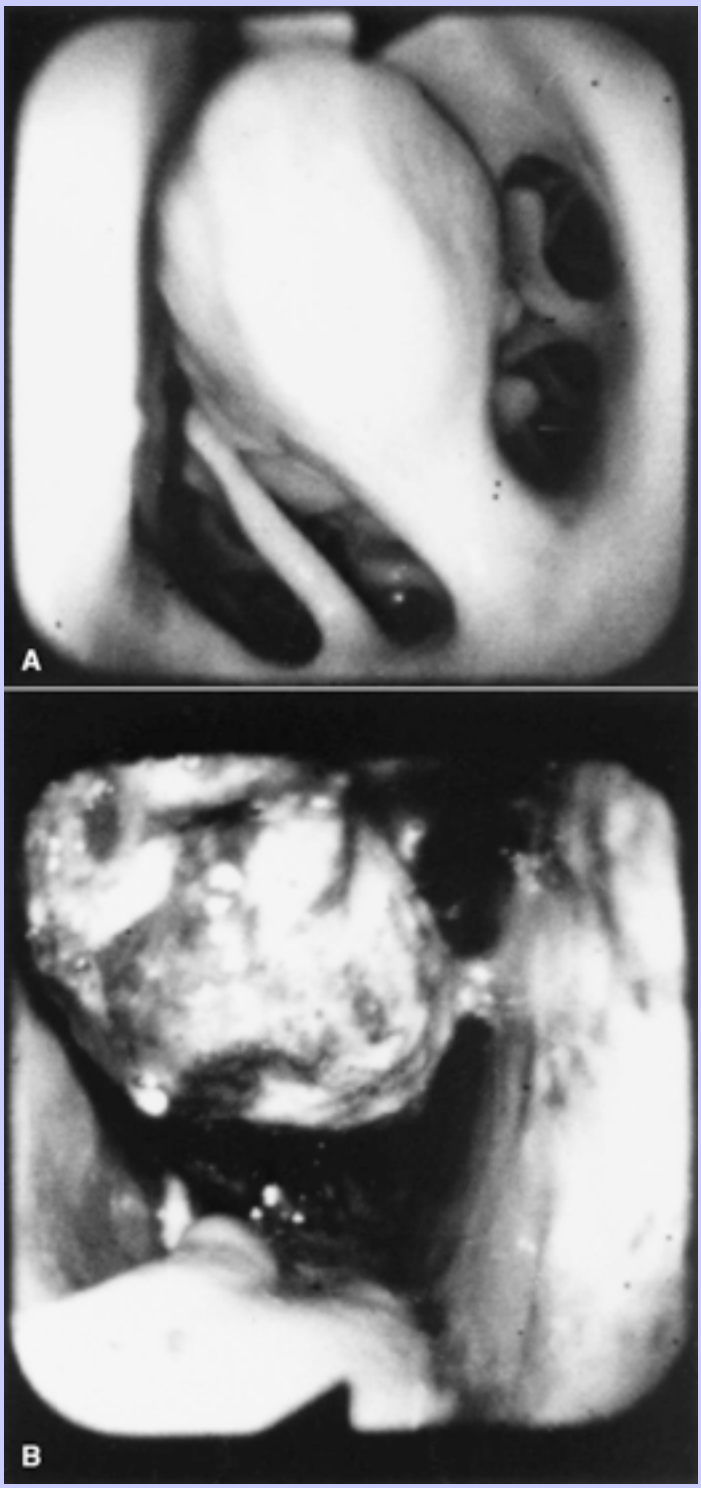


Fig. 31-46 Lateral radiograph demonstrating an ethmoid hematoma.

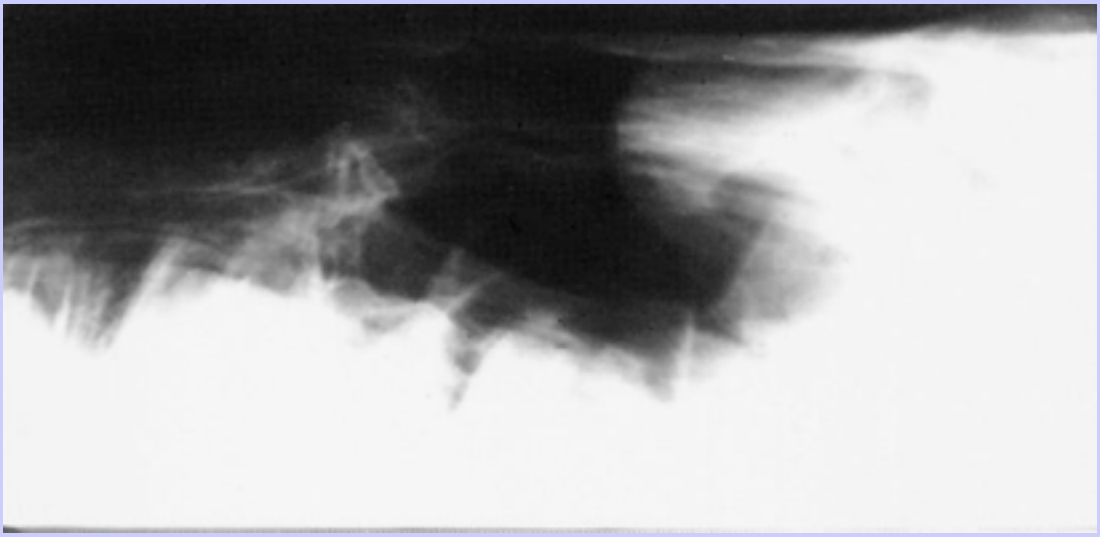

Recognition of a discrete, often smooth-surfaced homogeneous radiodensity originating from the ethmoidal conchae and extending into the frontal, maxillary, or sphenopalatine sinuses or into the pharynx or nasal cavity is suggestive of an ethmoid hematoma. Radiography is beneficial in determining the extent of the hematoma and in identifying suspected ethmoid hematomas that are not visible by endoscopy; however, precise definition of the origin of any hematoma is difficult from radiographic projections. Small hematomas contained within the ethmoid labyrinth may not be visible on radiographs. Computed tomographic examination of the skull allows more accurate assessment of the origin of the ethmoid hematoma,[1207,1209] allows determination of the extent of involvement of the paranasal sinuses and conchae, and facilitates surgical planning.

31.39.2.4

Necropsy Findings

Most of the morphologic features have been described from surgical specimens; few skulls with intact ethmoid hematomas have been examined.[1198] Except in regions with necrosis or secondary infection associated with contact with the sinus or nasal cavity walls, the hematoma is a smooth-surfaced saclike structure containing blood in various stages of organization. The sac lining is generally healthy respiratory mucosa originating from a pedunculated region of the mucosal covering of the ethmoturbinal or sinus wall. On section the contents are amorphous red-black to chocolate brown, and in larger masses some evidence of irregular compartmentalization by fibrous tissue exists, especially on the inner surface of the sac.

Morphologic features include an outer covering of respiratory epithelium (flattened columnar or cuboidal ciliated epithelium containing glands, and occasionally stratified squamous epithelium[1200]) overlying an irregular zone of submucosal fibrous tissue, containing hemosiderophages, occasional plasma cells, and lymphocytes, less commonly neutrophils, that forms a pseudocapsule around hemorrhage in varying states of organization. There is typically variable organization of the fibrous tissue components. Endothelial cells do not show evidence of neoplasia. Thin endothelium-lined sinuses are often present within the myxomatous stroma. The respiratory epithelium is sometimes focally ulcerated and infiltrated with neutrophils, and

occasionally there are squamous metaplastic changes. Ethmoid adenocarcinoma with a similar gross appearance to ethmoid hematoma has been reported in one horse.[1210]

31.39.2.5 Treatment and Prognosis

Because these masses slowly and progressively increase in size and can cause distortion of skull architecture if the paranasal sinuses are involved, removal is recommended. Treatment method depends on the location and size. Surgical ablation has been the preferred method; however, destruction of the hematoma by intralesional injection of formaldehyde solution is associated with less morbidity, although recurrence rates are similar to those with other methods.[1204–1212] Surgical access is usually achieved by sinusotomy and then hematoma ablation by curettage, cryosurgery, or use of an Nd:YAG laser[1213–1215]; photoablation can also be accomplished through the biopsy channel of an endoscope. After sinusotomy, the pedunculated origin of the hematoma is identified by digital palpation and then dissected, frozen, or photoablated, and the hematoma removed. If the hematoma is friable, intact removal may not be possible, and hemorrhage may make observation of the origin of the mass difficult. After removal the paranasal sinuses and nasal cavity are packed with gauze to control postoperative hemorrhage.

590

591

Surgical curettage can have the disadvantage of being associated with marked intraoperative blood loss typically from the turbinates or sinus mucosa rather than the hematoma. Temporary occlusion of both carotid arteries[1214] can substantially decrease blood loss until the sinus cavity is packed with gauze. Blood loss is minimized by cryosurgical extirpation and photoablation techniques, but these approaches are not always practical when initially dealing with large hematomas. There is also minimum blood loss with transnasal photoablation; however, this technique requires multiple procedures to destroy large masses but can be performed in the standing sedated horse. Photoablation (Nd:YAG laser, 100 W in noncontact technique) is effective in controlling remnants after surgical extirpation or subsequent regrowth.[1215,1216]

Destruction of ethmoid hematomas by endoscopically guided intralesional injection of formalin in standing sedated horses may reduce the need for surgical ablation in many horses.[1211,1217] A catheter passed through the endoscope biopsy channel is advanced through the rostral surface of the mass toward its origin, then 10% formalin (4% formaldehyde solution) is injected intralesionally. Commercially available catheters with a beveled needle tip have been used, but relatively stiff plastic tubing that will slide through the biopsy channel works will penetrate the capsule of the ethmoid hematoma. Sufficient volume (from 10 to 100 mL) is injected until fluid leaks back alongside the catheter or leaks from the mass. For visibly pedunculated masses, it is best to inject the formalin at the origin or neck of the mass. Tissue necrosis and slough occur in 5 to 10 days and may be associated with nasal discharge. Repeat injections, typically at no longer than 10- to 14-day intervals may be necessary to destroy the mass. Removal of necrotic tissue can be facilitated by use of long grasping forceps and hydropulsion. Mycotic plaques may cover the treated site during healing but typically resolve without treatment; endoscopically delivered topical natamycin has been used if mycotic plaque is extensive and associated with malodorous, purulent discharge.[1218]

Occasionally progression of the ethmoid hematoma may result in weakening or loss of the cribriform plate or roof of the sphenopalatine sinus.[1218] During mass removal, loss of this protective bony covering may result in intraoperative or postoperative neurologic complications. Recognition of loss of the integrity of these bony plates may not occur until sinus lavage. In a rare complication death occurred after intralesional formalin injection in a horse where the cribriform plate had been eroded by the ethmoid hematoma.[1219] Erosion of

calvarial bone is rare, but careful computed tomographic evaluation of these regions in horses with extensive hematoma formation involving the frontal or sphenopalatine sinuses is warranted.

Irrespective of treatment method, recurrence of the hematoma occurs in 30% to 50% of cases from several months to years after the initial surgery.[1198,1203–1206,1211,1212]

AMELIA R. WOOLUMS

JOHN C. BAKER

JOHN A. SMITH

31.39.5 DISEASES OF THE NASAL CAVITY

AMELIA R. WOOLUMS

JOHN C. BAKER

JOHN A. SMITH

31.39.5.1 Mycotic or Bacterial Nasal Granuloma

Infectious granulomas in the nasal cavity of ruminants are not common. Documented causes include the fungal organisms *Rhinosporidium seeberi* and other *Rhinosporidium* species (which cause rhinosporidiosis), *Helminthosporium* species (which cause maduromycosis), *Drechslera rostrata, Aspergillus* species, *Phycomycetes* species, *Stachybotrys* species, and *Bipolaris* species. Phycomycosis is discussed in the dermatology section in Chapter 40. Nasal granuloma caused by *Nocardia* species bacteria has also been reported.[1] There is no apparent age, breed, or seasonal predilection, and cases are sporadic. The major clinical signs are upper respiratory noise (stridor), dyspnea, and mucopurulent nasal discharge, sometimes with epistaxis. Affected animals may rub the nose, suggesting pruritus or irritation.[2–3] Nasal airflow may be reduced, and open-mouth breathing may occur in advanced cases. Hot or dusty weather may accentuate the signs, giving the appearance of seasonal exacerbation, but the lesions are progressive. The granulomas may be single or multiple, unilateral or bilateral, and located anywhere in the nasal cavity. They consist of 0.5- to 5-cm yellow to yellow-green or red nodules or polyps, which may be sessile or pedunculated. Rhinosporidiosis tends to be a single unilateral polyp in the posterior nasal cavity, and maduromycosis tends to occur in the anterior cavity, but these distinctions are not consistent. Red and black spots (spores) may occur on the masses, and some may become secondarily infected with bacteria and ulcerate. Differential diagnoses include allergic rhinitis, foreign bodies, tumors, nasal actinobacillosis, nasal actinomycosis, and *Oestrus ovis* infection in small ruminants.

Endoscopy, biopsy, and culture of the lesions aid in the diagnosis. Histopathologic analysis reveals granulation tissue containing eosinophils, mononuclear cells, round sporangia, and sometimes hyphae or filamentous bacteria.[1,2] The pathogenesis of the disease involves inoculation of eroded nasal mucosa with fungal spores or filamentous bacteria from the environment. The infectious agent causes a chronic delayed (type IV) hypersensitivity reaction, which eventually leads to the formation of a granuloma. Fungal granulomas can be more common in warm, wet climates. The granulomas can be difficult to treat, and although rarely fatal the disease is chronically debilitating, with salvage often being the most practical solution.

Recommended treatments include surgical removal of the granulomas when possible and long-term sodium iodide (NaI) therapy. NaI can be administered at a dose of 66 mg/kg IV as a 20% solution, repeated at 10- to 14-day intervals until remission or iodism occurs. Iodism is characterized by lacrimation, cough, and scaling of the skin. The use of antifungal drugs to treat this condition in ruminants has not been reported.

31.39.5.2 Allergic Rhinitis and Enzootic Nasal Granuloma

Allergic rhinitis occurs in cattle and in its chronic stages may lead to the formation of granulomas. A similar condition may occur in sheep.[4] The inciting antigen is frequently a plant pollen or more likely a fungal spore.[5] Once homocytotropic antibody (immunoglobulin E or possibly other classes in cattle) to the allergen has developed, subsequent exposure results in a localized, ongoing, immediate (type I) hypersensitivity reaction.[5–7] If recurrent exposure to the allergen occurs, repeated tissue damage by mast cell factors results in chronic epithelial, duct, and goblet cell hyperplasia and metaplasia, as well as mucous hypersecretion and granulomatous inflammation, suggesting that a type IV hypersensitivity reaction contributes to the chronic lesion.[5,6,8]

Any breed may be affected, but Channel Island breeds and Friesians seem most susceptible.[5] The disease occurs sporadically in the United States. A familial predisposition has been reported.[9] Most affected animals are between 6 months and 2 years of age. The signs are initially seasonal, usually occurring in warm, moist conditions; they include rhinorrhea, sneezing, nasal pruritus, a sudden onset of dyspnea, and stertorous inspiration.[9,10] There is a profuse bilateral nasal discharge. Intense pruritus is characteristic and associated with sneezing, head shaking, and nose rubbing.[10] In severe cases facial swelling, tachypnea, hyperpnea, and ulceration of the nasal mucosa may occur.[6,10] Nasal foreign objects may result from the animal's attempts to scratch the nasal mucosa. Lacrimation, chemosis, and blepharitis may also be present. In the chronic stages (the “enzootic nasal granuloma”), the signs are more constant, with seasonal exacerbations.[6,8,10] The granulomas tend to be multiple, firm, white, raised nodules 1 to 2 mm in diameter with an intact mucosa, or pale pink flat plaques scattered throughout the nasal cavity. Differential diagnoses include fungal granulomas, foreign bodies, respiratory viruses, nasal actinomycosis or actinobacillosis, tumors, *O. ovis* infection (small ruminants), and irritation caused by inhalation of hot or irritant gases.

Endoscopy, biopsies, cultures, antigen detection tests for viruses, bacteria, or fungi, and serologic analysis can be used to rule out these differential diagnoses. Eosinophil counts in nasal secretions correlate with the susceptibility of the animal and activity of the disease, but no absolute level is diagnostic.[5] Intradermal allergen testing has been suggested to aid in diagnosis, but interpretation of results needs to be done in conjunction with historical and clinical findings.[7] This condition should be differentiated from fungal or bacterial granuloma because the therapy is different.

Treatment and control entail removal of the allergen, or removal of the animal from the allergen, and therapy to block the hypersensitivity reaction. Recommended drugs include various antihistamines, meclofenamic acid, and corticosteroids at standard antiinflammatory doses (0.05 to 0.2 mg of dexamethasone per kilogram IM or IV or 1 to 2.2 mg of prednisolone per kilogram IM or IV daily). Topical corticosteroid therapy can be considered in severe, acute occurrences of the disease. The adverse effects of corticosteroids on milk production and their potential to induce abortion or parturition should be considered before their use. Antihistamine therapy has had equivocal results.[7]

31.39.5.3 Nasal Foreign Bodies

Cattle are more prone than small ruminants to the acquisition of nasal foreign bodies. Foreign objects may be acquired as a result of attempts to scratch the nose in cases of allergic rhinitis, or because of the cow's aggressive eating habits. Depending on the size and duration of residence of the object, signs may include head shaking, stridor, sneezing, snorting, frequent nose licking, unilateral decreases in airflow, foul odors, and serous, mucopurulent, or hemorrhagic discharges. Differential diagnoses include fungal granulomas, allergic rhinitis, tumors, nasal actinomycosis or actinobacillosis, and *O. ovis* (small ruminants). Many objects can be visualized on careful examination of the nasal cavity with an adequate light source, whereas some may require endoscopy for diagnosis and removal.

31.39.5.4 Nasal Trauma and Fractures

Trauma to the facial bones, sinuses, and turbinates may result from fighting, accidents caused by improper restraint, farm machinery accidents, human maliciousness, and passage of excessively large NGTs. Severe fractures can lead to facial swelling, SC emphysema, obstruction of airflow, stertor, and epistaxis. Secondary infection causes foul odors and mucopurulent nasal discharge. Differential diagnoses for the acute external swelling of the head with stertor include snakebite, actinobacillosis, actinomycosis, and phlegmon (*Fusobacterium, Clostridium* species). Unless the development of severe depression fractures, formation of sequestra, or severe obstruction of airflow occurs, surgery is usually not indicated. Radiographs confirm the diagnosis and help determine the need for surgical removal of potential sequestra or elevation and fixation of large displaced segments. Prophylactic antibiotics (typically penicillin, 22,000 U/kg IM or SC q12-24h) are recommended to prevent fracture infection and sinusitis, and NSAIDs (aspirin, 100 mg/kg PO twice; flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help relieve pain, swelling, and stridor. The prognosis is usually good.

31.39.5.5 Nasal Tumors and Polyps

Tumors and polyps of the nasal cavity and sinuses are rare in ruminants. Nasal tumors reported in cattle include osteomas and osteosarcomas of the sinuses, squamous cell carcinomas,[11] neuroblastomas, and adenocarcinomas of the ethmoid mucosa. Ethmoid adenocarcinomas are speculated to be caused by viruses on the basis of an endemic pattern in some cases.[12] They tend to occur in cattle 6 to 9 years of age and are frequently unilateral. Metastasis occurs to the lymph nodes and lungs. There is a report of a hemangiosarcoma involving the external naris of a cow.[13] Signs common to all nasal tumors include mixed or inspiratory dyspnea, stridor, nasal discharge, epistaxis, foul breath odors, unilateral decreases in airflow, open-mouth breathing, and distortion of the facial bones. Differential diagnoses include fungal granulomas, atopic

granulomas, foreign bodies, sinusitis, fractures, and nasal actinobacillosis and actinomycosis. Treatment has not been investigated.

The majority of nasal neoplasms in sheep and goats are adenopapillomas, adenomas, or adenocarcinomas.[14] Squamous cell carcinoma[15] and osteoma[16] have also been reported. Nasal adenocarcinomas have also been described in goats.[17]

An enzootic form of nasal adenocarcinoma occurs in both sheep and goats and is associated with ovine nasal adenocarcinoma virus (ONAV)[18,19] or caprine nasal adenocarcinoma virus (CNAV),[20] respectively. These agents are β retroviruses that are closely related to, but distinct from, jaagsiekte sheep retrovirus (JSRV), the cause of ovine pulmonary adenocarcinoma (OPA).[20,21] Although nasal adenocarcinoma has been difficult to consistently reproduce experimentally, inoculation of kids with concentrated cell-free and bacteria-free filtrate containing virus from naturally infected goats has resulted in disease.[22] Neoplastic transformation is limited to secretory epithelial cells of the nasal turbinates, but CNAV appears to have a wider tissue tropism than ONAV; in one study viral provirus incorporated into host DNA was found in many tissues of infected goats but was largely confined to tumor tissue of infected sheep.[20] There is no breed or sex predisposition for enzootic nasal adenocarcinoma; affected animals are most commonly young adults, but the tumor has been identified as early as 4 months of age.[18] Signs include progressive inspiratory dyspnea; stridor; exercise intolerance; mouth breathing; serous, mucoid, or mucopurulent nasal discharge, which is typically profuse; tachypnea; decreased airflow; head shaking; sneezing; exophthalmos; and facial asymmetry.[14,17,18,21] The lesions may be unilateral or bilateral, originating in the olfactory region of the ethmoid turbinates. The neoplasia arises either from Bowman's glands[18] or serous glands of the nasal mucosa.[17] The tumor begins as a small nodule that can grossly resemble the mucoid polyps that occur in animals with chronic rhinitis. Over time the adenocarcinoma grows into a soft, gray to grayish pink, mucoid, nodular, cystic mass. The tumor is benign but locally expansive, often entering the sinuses and eroding overlying bone.[17] Histologically the tumor is typically classified as a low-grade adenocarcinoma, but it may also be identified as an adenopapilloma or adenoma.[17] Initially affected animals eat and drink normally and maintain body condition, but as the tumor expands the animal begins to lose condition, and death eventually occurs as a result of inanition, asphyxia, or aspiration pneumonia. Necrosis or secondary bacterial infection of the tumor can occur and may lead to the production of foul-smelling, purulent discharge and systemic signs related to bacterial infection, such as fever, depression, and hyperemic mucous membranes.

Differential diagnoses for nasal neoplasia in small ruminants include nasal fungal or bacterial granuloma, actinobacillosis, actinomycosis, *O. ovis* infection, and sinusitis. Endoscopy and radiology are helpful in establishing an initial diagnosis of a nasal mass. Preoperative or antemortem pinch biopsies and exfoliative cytologic analysis frequently are nondiagnostic, and findings may be misleading.[14,15] Identification of tumors in multiple animals in a herd or flock supports a diagnosis of enzootic nasal adenocarcinoma. Definitive identification of infection with ONAV or CNAV can be difficult. Serologic tests are not reliable because animals do not consistently produce antibody to the viruses,[23] possibly because of the presence of endogenous retroviruses[24] that share epitopes with ONAV and CNAV and induce the development of immunologic tolerance. Recently PCR has been used to specifically identify and differentiate ONAV, CNAV, and JSRV in tissues of affected animals.[25] Surgical management of nasal adenocarcinoma in sheep has been described.[26]

31.39.6 *OESTRUS OVIS* INFESTATION

AMELIA R. WOOLUMS

31.39.6.1 Definition and Etiology

O. ovis is parasite of the nasal passages and sinuses of sheep and, less commonly, goats. Goats are relatively resistant to infection and, even when housed with sheep, tend to have a lower prevalence of infection.[27] Occasionally humans and other animals are accidentally infected, with conjunctival infection the most common form of disease in humans.[28,29] The pathogenic stage of the parasite is the larval stage. The first instar larvae are deposited near the nostrils of sheep by the adult female fly and migrate into the nasal and ethmoid turbinates; in the ethmoids the larvae molt to second instars, which migrate to the sinuses before molting again and becoming third instar larvae. Third instar larvae, which are yellow-white in color and have a dark dorsal stripe with rows of spines on the ventrum of each segment, return to the nasal passages and are sneezed out onto the ground, where they pupate and eventually develop into adult flies.[30,31] The adult is active during warm months, and the parasite may overwinter either as a first instar larva in the host or as a pupa in the ground. Larvae can persist in the upper airways for weeks to months, and appear to be able to arrest development for a period of time if necessary to avoid climate extremes.[32] Adult flies have a rudimentary mouthpiece and are not able to feed; thus the larvae must ingest adequate nutrients while in the host to support the life of the adult fly.[33]

31.39.6.2 Clinical Signs

The larvae cause irritation of the nasal passages and sinuses, leading to mucoid to mucopurulent and sometimes blood-tinged nasal discharge, sneezing, nose rubbing, and inspiratory stridor. Adults flies cause annoyance by flying around the heads of animals; thus both stages can lead to decreased productivity by decreasing the time spent grazing by affected animals. Occasionally the larvae may cause sinusitis or pneumonia owing to secondary bacterial infection associated with irritation caused by the larval infestation. Differential diagnoses to consider include nasal foreign bodies, allergic rhinitis, nasal adenocarcinoma, fungal rhinitis, trauma, sinusitis, actinobacillosis, or actinomycosis.

31.39.6.3 Pathogenesis

The larvae cause direct irritation to the nasal passages and sinuses, and this irritation may predispose animals to the development of secondary bacterial rhinitis, sinusitis, and/or pneumonia. Interstitial pneumonia has also been seen on occasion in affected sheep, presumably induced by inhalation of parasite antigens and inflammatory mediators from the upper respiratory tract.[34]

31.39.6.4 Epidemiology

Infection is more common in warm climates. Recent European surveys have identified *O. ovis* in 35% to 91% of sheep surveyed,[35,36] with seroprevalences of 46% to 69%.[27,36,37] A majority of flocks surveyed had at least one infected animal.[27,35] No North American reports describing the prevalence of *O. ovis* infestation have been published in recent decades.

31.39.6.5 Diagnosis

Diagnosis is usually presumptive, based on typical clinical signs. The larvae can also be identified via radiographs of the head or by endoscopy, but these tests may not be practical for field use. Serologic diagnosis has been used for research studies of the epidemiology of *O. ovis* infection, but these tests are unlikely to be available at most diagnostic laboratories.

593
594

31.39.6.6 Treatment and Prevention

The larvae are susceptible to ivermectin at 200 µg/kg PO.[38] Moxidectin at 0.2 mg/kg as a 0.1% oral drench was not effective against *O. ovis*[39]; these investigators found that the same dose given as a 1% injectable solution was effective, but this route is not approved in the United States. Pour-on eprinomectin at 0.5 mg/kg (applied immediately after shearing)[40] and injectable doramectin at 200 µg/kg IM[41] have also been shown to be effective in sheep, but these treatments are also not approved for use in sheep or goats in the United States. Because the adult fly should be killed by freezing weather, in areas with a season of freezing weather it is logical to treat after the first hard freeze, when sheep will no longer be susceptible to infection until warm weather returns. Prevention is aimed at regular strategic treatment with effective anthelmintics to prevent long-term infection with the larvae.

31.39.7 CONGENITAL CYSTIC NASAL TURBINATES IN CATTLE

An apparently developmental anomaly that results in signs of nasal obstruction has been reported in cattle.[42] The nasal conchae lack the normal communication with the nasal cavity and become filled with a thick white fluid, which may account for the enlargement. Signs are evident at or near birth and include progressive stridor, tachypnea, decreased airflow, exercise intolerance, mouth breathing, and short, convex nasal bones. Digital, radiographic, and endoscopic examinations of the nasal cavity reveal large, smooth, bilateral cystic ventral nasal conchae, often bilobate. Differential diagnoses include foreign bodies, trauma, and tumors. Surgical removal of the conchae with bilateral dorsolateral nasal bone flaps relieves the obstruction. Transnasal removal using obstetric wire has been described.[43]

31.39.8 DISEASES OF THE SINUSES

JOHN R. PASCOE

31.39.9 SINUSITIS

31.39.9.1 Definition and Etiology

Inflammation of the paranasal sinuses is most common in cattle and occurs infrequently in sheep and goats. Typically the frontal or maxillary sinuses are involved, and a variety of bacteria may be isolated. The proximate cause for infection is usually dehorning (frontal sinusitis) or infected teeth (maxillary sinusitis). Other causes include extension of actinomycosis or nasal neoplasia into the sinus, injuries to the horn, facial fractures, respiratory viruses (including malignant catarrhal fever [MCF], IBR, and parainfluenza viruses), sinus cysts,[44,45] lymphosarcoma,[46] and *O. ovis* (in sheep).[47–50]

31.39.9.2

Clinical Signs and Differential Diagnosis

Sinusitis associated with dehorning may be acute or may occur weeks to months later; typically only one sinus is affected. Nonspecific clinical signs include anorexia, lethargy, reluctance to move, and fever. When sinusitis occurs acutely after dehorning, the portal of entry is frequently open and discharging pus, and the animal is often febrile (39.5° C to 40.5° C). In chronic sinusitis, signs may include unilateral or bilateral nasal discharge, mild stridor, changes in airflow, and foul breath odors that are frequently unilateral; fever is not common. The animal may hold its head at an odd angle (extended up or down, tilted) and may squint the eyelids as if in pain. [49,51] With chronicity, frontal bone distortion, exophthalmos, and neurologic signs may occur.[51,52] In one report of 12 cattle with frontal sinusitis, four cattle had abnormal posture, with an extended head and neck, partially closed eyes, and a tendency to head-press or to rest the head on a stationary object; the other 8 cattle were apprehensive and intolerant of head manipulation.[51] Extension of infection may involve the CNS.

Occasionally sinusitis irritates the animal sufficiently that it may rub its head on the ground, driving more debris into the sinus.[50] Maxillary sinus cysts have been observed in cattle.[44] Typical signs included unilateral facial swelling over the affected sinus; mucopurulent, nonfetid nasal discharge; and radiographic evidence of septal deviation. One cow had stertorous respiration with diminished airflow. Differential diagnoses for sinusitis include facial fractures, nasal tumors, actinomycosis, actinobacillosis, retrobulbar abscess, and lymphosarcoma.

31.39.9.3

Diagnosis

Diagnosis can usually be made based on clinical signs. Diagnostic aids may be useful in selected cases, particularly when there is no recent history of dehorning, or in cases of maxillary sinusitis. The hemogram is quite variable and is of little assistance in diagnosis. Percussion of the sinus may reveal a dull, full sound and may elicit pain. If the bone has been greatly thinned and has gas underlying it, percussion may produce a hyperresonant sound. Fractures, soft-tissue masses, dental disease, fluid in the frontal sinus, or lysis of bony septa may be evident on radiographs.[51] Sinus centesis may yield purulent material, which should be cultured and examined cytologically. A small area over the affected sinus is clipped and surgically prepared, and local anesthetic is infiltrated subcutaneously. Then a small stab incision is made through the skin and periosteum, and a Steinmann pin is used to drill a small hole. Polyethylene tubing is inserted, and attempts are made to aspirate material. A small amount of sterile isotonic fluid can be injected and aspirated to obtain a washing. The stab incision is closed unless sinusitis is confirmed.

31.39.9.4

Treatment and Prognosis

Trephine sites for sinusotomy (Fig. 31-47) are as follows:

1 Dorsal frontal sinus

2 Postorbital diverticulum

3 Rostral frontal sinus

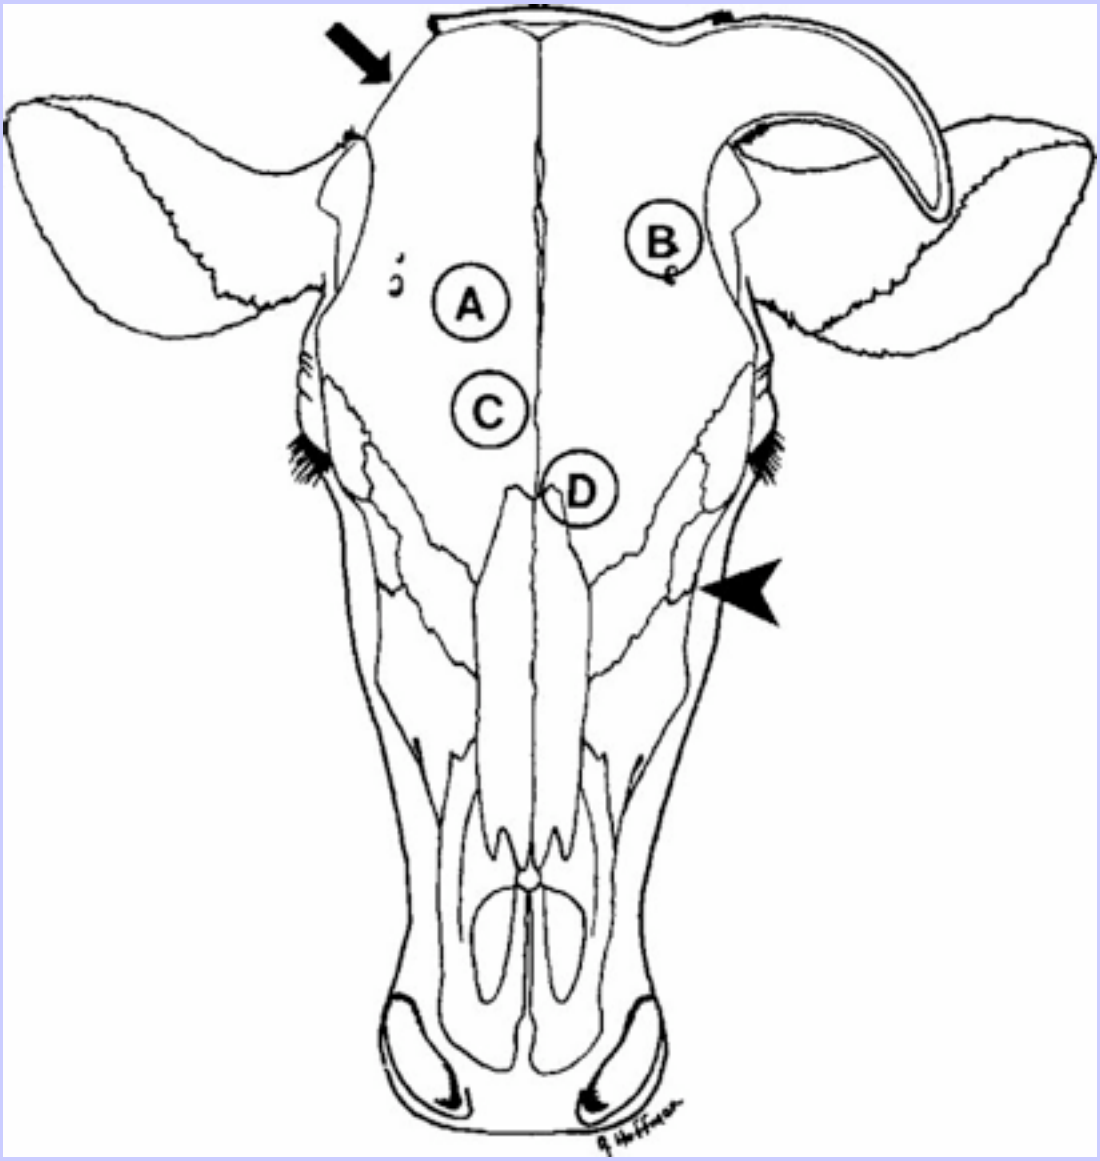
4 Turbinate portion of the frontal sinus

5 Maxillary sinus

Cattle that have frontal sinusitis after dehorning should be treated by sinusotomy and drainage of the sinus.[53] Sinusotomy sites should be based on anatomic landmarks[51] and modified as needed to accommodate any frontal bone distortion or wounds related to dehorning.[51] Sinusotomy should be performed 3 to 4 cm from midline, intersecting a line drawn between the caudal aspect of the orbits. If draining tracts are present at the poll, an additional sinusotomy can be made in the cornual portion of the frontal sinus.[51] Sinusotomy is performed after sedation and local anesthetic infiltration of the centesis site(s). A 2-cm—diameter circular piece of skin is excised, and a 19-mm (¾-inch) trephine used to create an opening into the sinus, through which purulent fluid should be evacuated and the sinus lavaged.

Additional trephine sites that permit access to other regions of the frontal sinus include the postorbital diverticulum, which is trephined approximately 4 cm caudal to the dorsal rim of the orbit, just above the temporal crest of the frontal bone; the rostral frontal sinus, which is trephined just caudal to a line between the centers of the orbits and to either side of the midline; and the turbinate portion of the frontal sinus, which is trephined just rostral to the line described and to either side of the midline.

Fig. 31-47 Trephine sites for sinusotomy. *A*, Dorsal frontal sinus. *B*, Postorbital diverticulum. *C*, Rostral frontal sinus. *D*, Turbinate portion of frontal sinus. The maxillary sinus is trephined ventral to a line from the infraorbital foramen to the medial canthus *(arrowhead)*. If draining tracts are present at the poll, an additional sinusotomy can be made in the cornual portion of the frontal sinus *(arrowhead)*.



Access to the maxillary sinus is achieved by trephining ventral to a line from the infraorbital foramen to the medial canthus. If an infected tooth is the cause of maxillary sinusitis, a sinusotomy is created with a trephine over the affected tooth to repel it; otherwise, the hole is usually made just dorsal and caudal to the facial tuberosity. The trephine site should be higher in the sinus of younger animals because the tooth roots are longer.

If the frontomaxillary and nasomaxillary openings are still patent, one trephine site may be sufficient, with the natural opening providing ventral drainage. In more chronic cases, two trephine sites (for ingress and egress) are needed. Another alternative in chronic sinusitis is the use of a curved steel sinus probe (1 cm diameter × 55 cm long), which is forcefully driven through the septal plates of the frontal sinus into the nasal meatus for ventral drainage.[54] The frontal sinus is very compartmentalized in mature sheep and goats, and effective drainage is difficult. Therapy should therefore be aggressive in these species, even in early cases, and double trephination or bone flaps for exposure and curettage should be considered.

If a tooth has been repelled, a roll of gauze or dental impression material should be used to occlude the alveolar socket to prevent feed material from entering the sinus. A strip of umbilical tape tied around the gauze roll or a wire in the dental material is passed through socket, sinus, and trephine hole and secured to the face by tying around another roll of gauze as a stent. These gauze packs are replaced each time the sinus is flushed. The sinus is lavaged daily with dilute antiseptic solutions such as 0.1% povidone iodine or chlorhexidine in saline, or 1:1000 potassium permanganate. Lavage is continued until infection is resolved. Enzymes (papain or 200,000 U of streptokinase and 50,000 U of streptodornase in at least 10 mL of normal saline solution) may help remove thick exudate.

Parenteral antibiotics and NSAIDs (aspirin, 100 mg/kg PO twice daily or flunixin meglumine, 1.1 to 2.2 mg/kg IV daily or divided twice daily) are indicated if systemic signs are present. In the absence of microbial culture and susceptibility results, penicillin (22,000 U/kg IM or SC q12-24h) is recommended as the antibiotic of choice because *Arcanobacterium (Actinomyces) pyogenes* is the most common organism isolated from cattle with chronic frontal sinusitis resulting from dehorning. *Pasteurella multocida* is the most common organism isolated from infections of the frontal sinus not associated with dehorning.[51] Penicillin may be effective against some isolates of *P. multocida;* alternatively, oxytetracycline can be administered if *P. multocida* is suspected (11 mg/kg IV or SC q24h, or 20 mg of long-acting oxytetracycline per kilogram SC q72h). If bacterial culture and susceptibility results are available, antimicrobial therapy should be modified accordingly. Early cases often resolve in 10 to 14 days, with a good prognosis. Long-term therapy (weeks) is frequently needed in chronic cases; the prognosis is more guarded, and salvage is often the best option.

31.39.9.5

Prevention and Control

Dehorning ruminants as neonates, particularly if a “closed” method such as a dehorning iron is used, is the most effective way to prevent frontal sinusitis. In larger cattle surgical dehorning with primary skin closure achieved under aseptic conditions minimizes the likelihood of sinusitis.[55] When this is not practical, dehorning should be avoided in rainy, windy, or dusty conditions, and fly control must be used. The dehorning of mature sheep or goats leaves massive wounds that typically take 4 to 6 weeks to close by second intention and so are susceptible to infection; special care, such as bandaging for the initial 7 to 10 days, must be taken.[56] Sinusitis did not occur in goats aged 2 to 24 months dehorned with a technique in which primary skin closure was achieved.[57]

31.40 DISEASES OF THE PHARYNX, LARYNX, AND TRACHEA

AMELIA R. WOOLUMS

JOHN C. BAKER

JOHN A. SMITH

31.41 PHARYNGEAL TRAUMA, ABSCESSES, CELLULITIS, AND GRANULOMAS

31.41.1 Definition and Etiology

Pharyngeal trauma may result in hematomas, foreign body granulomas, cellulitis, or abscesses. Trauma usually results from careless use of balling guns, dose syringes, paste-type anthelmintics or calcium preparations, specula, and stomach tubes. Rough, stemmy feeds (especially when chopped), grass awns, briars, and foreign objects (e.g., nails, baling wire) may also cause punctures. Migrating foreign objects or medications (e.g., mineral oil, anthelmintics) may cause pharyngeal granulomas. Hematomas and puncture wounds often result in abscess formation. Diffuse cellulitis may also result. Common bacteria involved include *Arcanobacterium (Actinomyces) pyogenes, Actinobacillus* species, *Pasteurella* species, *Bordetella* species, *Fusobacterium necrophorum*, and *Streptococcus* species. In cases of particularly virulent bacterial invasion, the condition can become rapidly fatal. *C. pseudotuberculosis* (CLA) may localize in the pharyngeal nodes of sheep and especially goats. CLA is discussed further on p. 658 and also in relation to the hemolymphatic system in Chapter 37.

595

596

31.41.2 Clinical Signs and Differential Diagnosis

Signs of pharyngeal trauma vary with the severity of the resulting reaction (e.g., peracute cellulitis vs. chronic abscess or granuloma). Prominent signs include inspiratory dyspnea with stertorous inspiratory sounds and a prolonged inspiratory phase; extended head and neck; ptyalism, which is often profuse; quidding; evident pain on swallowing or reluctance to swallow solid feed but willingness to drink liquids; prolonged chewing of boluses; regurgitation of food or saliva through the nostrils caused by pharyngeal paresis; mucopurulent to bloody nasal discharge and fetid odors, usually bilateral; cough; bloat; and visible or palpable swelling in the pharyngeal area.[58,59] Megaesophagus has been reported subsequent to pharyngeal trauma.[60] Palpation of the pharynx may increase the stertor and cause pain. In severe cases, systemic signs of fever, anorexia, depression, dehydration, and forestomach stasis may be present. Aspiration pneumonia may be a secondary complication.

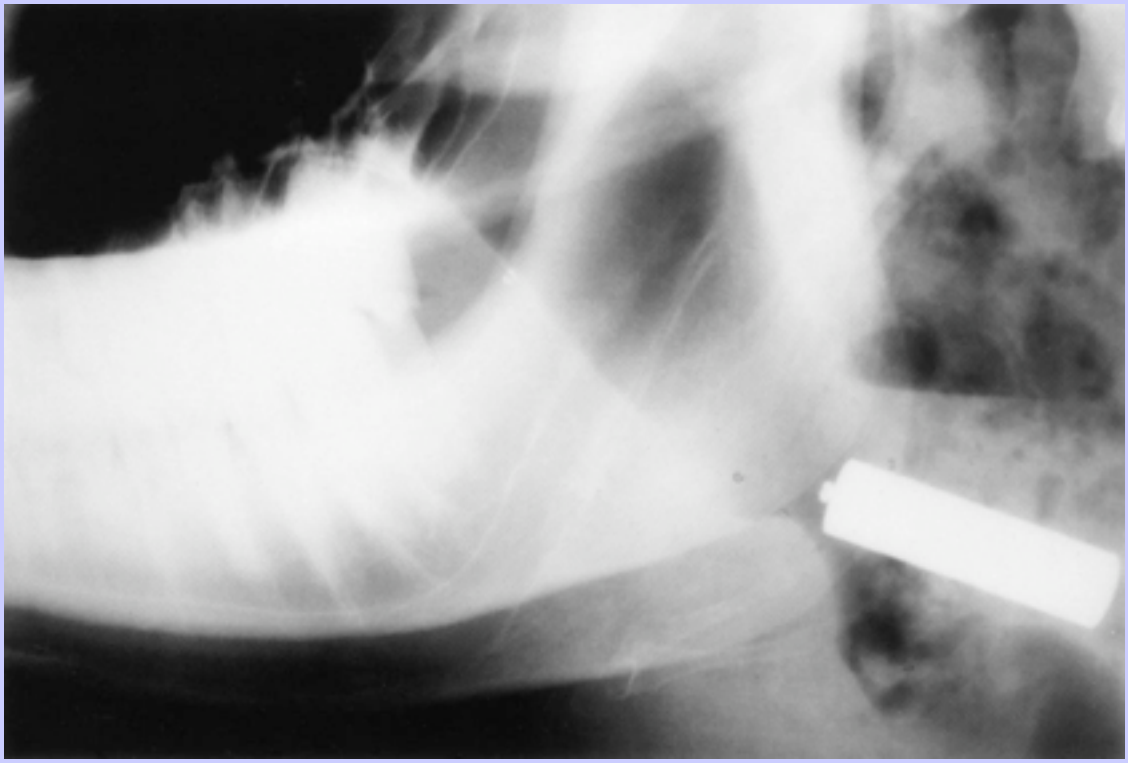
Differential diagnoses include pharyngeal tumors; lymphosarcoma; sialoliths; rabies; botulism; actinobacillosis; necrotic laryngitis; laryngeal abscesses, trauma, edema, or paralysis; and laryngeal tumors.

31.41.3 Diagnosis

A thorough manual examination of the oropharynx or a visual examination with an adequate speculum and light source usually confirms the diagnosis of a pharyngeal swelling and often reveals a puncture that is discharging pus. Cases in which the infection is diffuse can be more difficult to recognize, and endoscopy or radiography can be particularly helpful.[58] Restraining the jaws with a McAllum speculum allows a guarded needle attached to a length of tubing and a syringe to be inserted into the swelling for aspiration of any swelling identified. This helps

to differentiate localized abscesses from granulomas, hematomas, cellulitis, and tumors; allows culture and sensitivity determinations on abscesses; and may aid in cytologic diagnosis of granulomas or tumors. Radiographs may reveal foreign bodies (Fig. 31-48) or air densities (Fig. 31-49) in the pharyngeal tissues. The CBC usually reflects a chronic inflammatory process, with a neutrophilic leukocytosis and a left shift, or a neutrophil-lymphocyte reversal. Dehydration is frequently evident. If the animal is unable to swallow, large amounts of bicarbonate may be lost through the saliva, which may lead to evidence of metabolic acidosis on blood gas analysis or serum biochemical profile.

Fig. 31-48 Radiograph of the pharyngeal area of a cow. Note magnet located in the retropharyngeal tissue.



31.41.4 Treatment and Prognosis

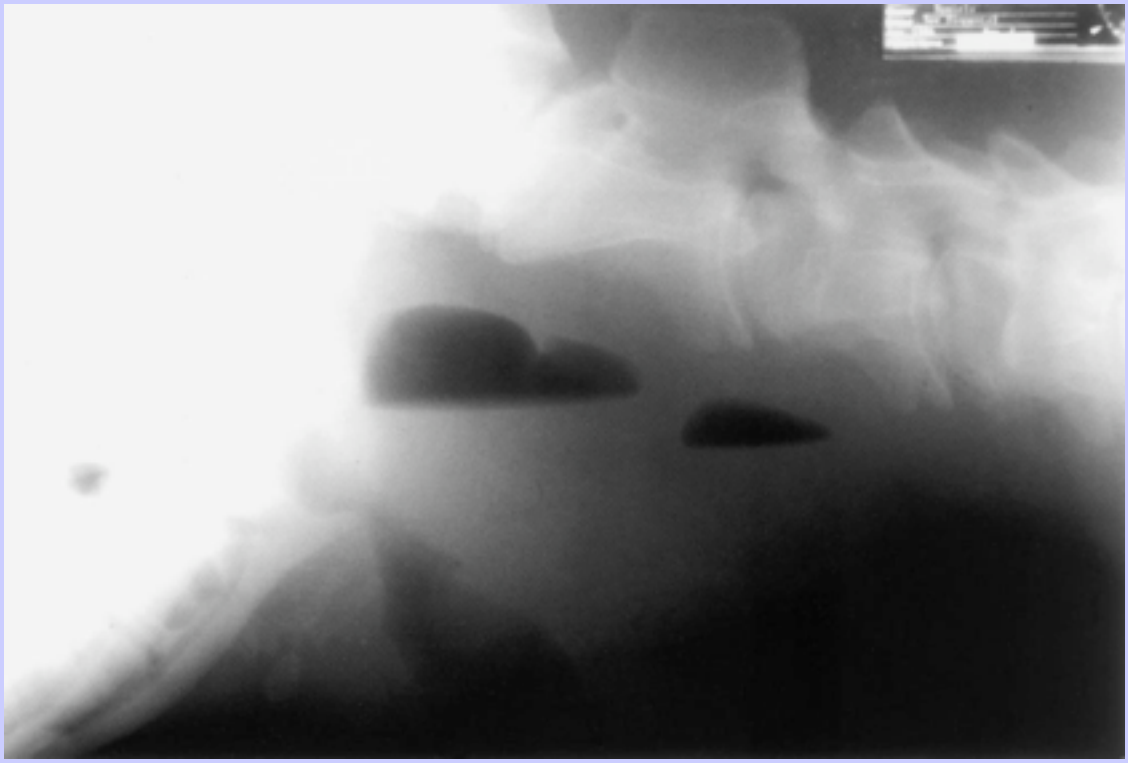
Discrete pharyngeal abscesses are usually best drained into the pharynx. Whenever possible the procedure should be done on the standing animal without sedation to preserve the cough reflex and prevent aspiration. A good oral speculum and excellent restraint are needed. The head should be kept lowered. A guarded blade such as a hook blade from a fetotomy set is introduced into the pharynx, and the abscess is lanced. The cavity is flushed with a mild antiseptic such as 0.2% povidone iodine in saline solution, again taking care to prevent aspiration. Other options include drainage to the exterior, drainage and flushing with a large-gauge needle and tubing, and extirpation.[59] Removal of a bacterial granuloma from the pharynx of a cow via electrocautery has been described.[61] Systemic antibiotics are administered in accordance with culture and sensitivity results, or, in their absence, procaine penicillin G (22,000 U/kg IM or SC q12-24h), tetracyclines (11 mg/kg IV or SC daily, or 20 mg/kg of long-acting oxytetracycline SC q72h), or sulfadimethoxine (55 mg/kg IV loading dose followed by

27.5 mg/kg IV q24h) are used. NSAIDs (aspirin, 100 mg/kg PO twice daily, or flunixin, 1.1 to 2.2 mg/kg IV daily or divided twice daily) help relieve pain, swelling, and stertor. In animals with severe persistent dyspnea, tracheostomy may be necessary. Granulomas and diffuse cellulitis are likewise treated medically with appropriate antimicrobials and antiinflammatory drugs. Supportive therapy such as IV fluids or feeding through a rumenostomy site may be necessary if the animal refuses to eat or drink. The prognosis for most pharyngeal abscesses, hematomas, cellulitis, and granulomas is usually good with appropriate therapy.

596

597

Fig. 31-49 Radiograph of the pharyngeal area of a cow. Note air densities in the tissue, suggestive of abscess formation.



31.42 DORSAL DISPLACEMENT OF THE SOFT PALATE

Although rare, dorsal displacement of the soft palate has been reported in cattle.[62] Respiratory noise is apparent on inspiration and expiration but is loudest on inspiration. Diagnosis can be made by endoscopic examination. Treatment is similar to that used in horses and can include conservative therapy, which consists of antiinflammatory drug therapy and rest, or the condition can be surgically corrected.

31.43 SUBEPIGLOTTIC CYST

Although rare, a subepiglottic pharyngeal cyst causing upper airway obstruction has been reported in cattle.[63] Surgical removal by a peroral approach has been described.[63]

31.44 NECROTIC LARYNGITIS (CALF DIPHTHERIA, LARYNGEAL NECROBACILLOSIS)

31.44.1 Definition, Etiology and Epidemiology

Acute to chronic infection of the laryngeal mucosa and cartilage of young cattle is very common, particularly in feedlots. Laryngeal contact ulcers[64] probably provide a damaged mucosal surface, which then allows invasion of the cartilage by *F. necrophorum*, which is the proximate cause of the lesions. It has also been suggested that *Histophilus somni* is the primary agent inducing a perilaryngeal vasculitis and that *F. necrophorum* represents a secondary bacterial invader.

The disease is most common where cattle are housed in dirty or crowded conditions and in feedlots. Most feedlot cases occur in animals on feed for longer than 30 days. The incidence is sporadic. Cases occur year round, but there appears to be a higher incidence in fall and winter. The disease has a worldwide distribution.

31.44.2 Clinical Signs and Differential Diagnosis

The problem occurs most commonly in calves from 3 to 18 months of age, up to about 24 months. It is characterized by an acute onset of a moist, painful cough, which the animal may attempt to suppress because of pain. Frequently a severe inspiratory dyspnea with a loud guttural stertor and open-mouth breathing with the head and neck extended are observed. The animal may salivate, make frequent painful swallowing movements, and stand and sip water continually. Signs of systemic disease including anorexia, depression, fever (as high as 106° F [41.1° C]), and hyperemic mucous membranes are present. There is often a bilateral nasal discharge and a fetid odor to the breath. The larynx may be visibly or palpably swollen, and palpation may elicit a cough, cause pain, and markedly increase the dyspnea and stertor. If untreated, many calves will die in 2 to 7 days as a result of systemic effects of bacterial toxins and upper airway obstruction. Recovered cases may have a chronic roaring respiration and a harsh, dry cough because of the misshapen larynx. Aspiration pneumonia and chronic “poor doers” are common sequelae. Differential diagnoses include pharyngeal trauma (abscess, cellulitis), severe viral laryngitis (e.g., IBR), actinobacillosis, and laryngeal edema, abscesses, trauma, paralysis, and tumors.

31.44.3 Diagnosis

The diagnosis is usually made presumptively based on clinical signs alone. A laryngoscopic or endoscopic examination can help confirm the diagnosis, but care must be taken to prevent further stress and respiratory embarrassment. Acute cases show changes in the CBC consistent with any acute septic condition: leukopenia caused by neutropenia with a left shift. In chronic or ongoing cases, leukocytosis with neutrophilia, monocytosis, and hyperfibrinogenemia may be present.

31.44.4 Pathophysiology

F. necrophorum normally does not penetrate intact mucous membranes. Laryngeal contact ulcers are thought to provide the portal of entry for *F. necrophorum*, which is ubiquitous. Laryngeal contact ulcers are also very common in slaughter cattle and are speculated to be caused by the following combination of factors: (1) an acute mucositis from mixed upper respiratory infections (such as IBR virus, bovine respiratory syncytial virus [BRSV], parainfluenza virus 3 [PI3], mycoplasma, and bacteria, including *Mannheimia, Pasteurella*, and *Histophilus* species); (2) reflex coughing and swallowing, which accelerate the rate of laryngeal closure; and (3)

resulting erosion of the swollen membranes over the vocal processes and medial angles of the arytenoid cartilages.[65] It has also been proposed that necrotic laryngitis results from a perilaryngeal vasculitis initiated by *H. somni* with secondary invasion by *F. necrophorum*.[66] Necrotic laryngitis can alter pulmonary function such that the growth rate is impeded, and also predisposes to secondary bacterial pneumonia.[67]

31.44.5 Necropsy Lesions

The lesions are typically located over the vocal processes and medial angles of the arytenoid cartilages. Acute lesions consist of marked edema, hyperemia, and swelling of the mucous membrane around a necrotic ulcer, with accumulated exudate. The lesions spread along the vocal processes and vocal folds and may extend into the cricoarytenoideus dorsalis muscles. In chronic cases the lesions consist of a focus of necrotic cartilage surrounded by purulent exudate, with a tract extending to the mucosal surface (Fig. 31-50). The tract opening is surrounded by granulation tissue and may drain pus. The arytenoid cartilage may be rotated into the lumen or may contain mucosal cavities lined with thin, hyperemic epithelium.[65]

31.44.6 Treatment, Prognosis, Prevention, and Control

Oxytetracycline (11 mg/kg IV or SC q24h, or 20 mg/kg of long-acting oxytetracycline SC q72h) or procaine penicillin G (22,000 U/kg IM or SC q12-24h) is appropriate; a sulfonamide, streptomycin, or tylosin is also usually effective. NSAIDs (aspirin, 100 mg/kg PO twice daily, or flunixin, 1.1 to 2.2 mg/kg IV once daily or divided twice daily) reduce swelling, inflammation, and fever. Cases with severe respiratory distress may benefit from one or two doses of steroids (dexamethasone 0.5 to 0.2 mg/kg IV or IM once or twice), but repeated doses of steroids are not recommended. A tracheostomy may be necessary in severe cases to relieve dyspnea and rest the larynx. Good nursing and supportive care are also important, including shelter, adequate ventilation, easy access to feed and water, and oral or IV fluids if needed. The prognosis is good when the condition is detected very early and treated vigorously; when extensive cartilage necrosis occurs, a fatal outcome or chronic ill-thrift with stertorous breathing is expected. There are no specific control measures. The proposed pathogenesis would suggest that measures to control other respiratory diseases may reduce the incidence of necrotic laryngitis.

Fig. 31-50 Postmortem photograph of necrotic laryngitis. Note the purulent material medial to the arytenoid cartilages. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

31.45 LARYNGEAL GRANULOMAS

Laryngeal granulomas have been described in cattle.[68] They may originate from laryngeal contact ulcers that have been described in feedlot cattle at slaughter (see the previous section on necrotic laryngitis for more information).[64]

31.46 LARYNGEAL PAPILLOMATOSIS

Papillomas of the larynx are common in feedlot cattle. They are caused by a papovavirus, which is thought to enter laryngeal contact ulcers (see the previous section on necrotic laryngitis).[64] Characteristic signs of laryngeal papillomatosis are stertorous respiration and cough. Differential diagnoses include necrotic laryngitis, pharyngeal trauma, abscess, or granuloma; actinobacillosis; and laryngeal abscesses, trauma, edema, paralysis, and tumors. The lesions are sessile to pedunculated, yellow, frondlike, 1- to 10-mm growths over the vocal processes of the arytenoid cartilages.[69] Treatment usually is not indicated but involves surgical removal. Measures to decrease other respiratory infections and thereby decrease contact ulcers may lower the incidence of papillomas.

31.47 LARYNGEAL ABSCESSES

Abscessation of the arytenoid cartilages caused by *Arcanobacterium (Actinomyces) pyogenes* has been reported in calves[70] and sheep.[71] Clinical signs include tachypnea, extension of the head and neck, cyanosis, and a severe progressive dyspnea with marked stertor that can be localized to the larynx. Many affected animals remain alert and afebrile and continue to eat until the terminal stages of severe dyspnea. Endoscopy reveals generalized edema and hyperemia of the laryngeal mucosa and obstruction of the rima glottidis by swelling of one or both arytenoids. Radiographs may demonstrate soft-tissue swelling of the larynx. The condition has been speculated to be initiated by grass awns, trauma, hereditary predisposition, or congenital cavitations in the cartilages. In sheep, rams appear to be more commonly affected than ewes, and two reports found a breed predisposition in Texels and Southdowns, although other reports have indicated that various breeds are affected.[71] The necropsy lesions consist of encapsulated abscesses containing pus and necrotic debris in the arytenoid cartilage, usually in the vicinity of the vocal cord. A tract from the abscess typically opens in an area of granulation tissue in the laryngeal mucosa. Treatment consists of tracheostomy, antibiotics (usually penicillin at 22,000 U/kg IM or SC q12-24h), and antiinflammatory drugs (aspirin, 100 mg/kg PO twice daily, or flunixin, 1.1 to 2.2 mg/kg IV daily or divided twice daily). The prognosis for recovery is considered guarded unless the condition is detected in the earliest stages and treated vigorously; however, one affected heifer lived for at least 1 year and was bred successfully after permanent surgical tracheostomy for chronic arytenoid abscessation.[72]

31.48 OTHER LARYNGEAL OBSTRUCTIONS (LARYNGEAL TRAUMA, EDEMA, PARALYSIS, AND FOREIGN OBJECTS)

Other laryngeal obstructions are all sporadic and may manifest with similar signs. Trauma to the larynx may result from roping or injury in restraint devices. Inappropriate placement of an endotracheal tube can potentially damage the larynx. The respiratory system is the main target organ for anaphylaxis in ruminants, and laryngeal edema can be a prominent component of this syndrome, which is discussed fully in this chapter on p. 652. Inhalation of smoke or other noxious gases also may cause laryngeal edema. Paralysis of the larynx was reported in a sheep with a false carotid aneurysm[73]; presumably other lesions of the neck or anterior mediastinum could cause laryngeal paralysis through involvement of the recurrent laryngeal nerves. Laryngeal hemiplegia has been reported in association with *Sarcocystis* species infection of the muscles of the larynx and pharynx in a ram.[74] Foreign objects more commonly lodge in the pharynx, but sharp objects and food materials may be aspirated and lodge in the larynx. Signs common to these laryngeal obstructions include inspiratory dyspnea, prolongation of the inspiratory phase, mouth breathing, stertor, cyanosis, salivation, and extension of the head and neck. Palpation of the larynx may reveal swelling and may exaggerate the dyspnea and stertor. Differential diagnoses include necrotic laryngitis, laryngeal abscesses, severe viral laryngitis, actinobacillosis, and tumors. Endoscopy and radiology are required in most cases to differentiate these conditions. Hematologic analysis may give some indication of the presence of bacterial infection; a stress leukogram may also be seen. Tracheostomy is indicated in all severe cases. Surgical correction of laryngeal obstruction by tracheolaryngostomy has been described in cattle.[75]

598
599

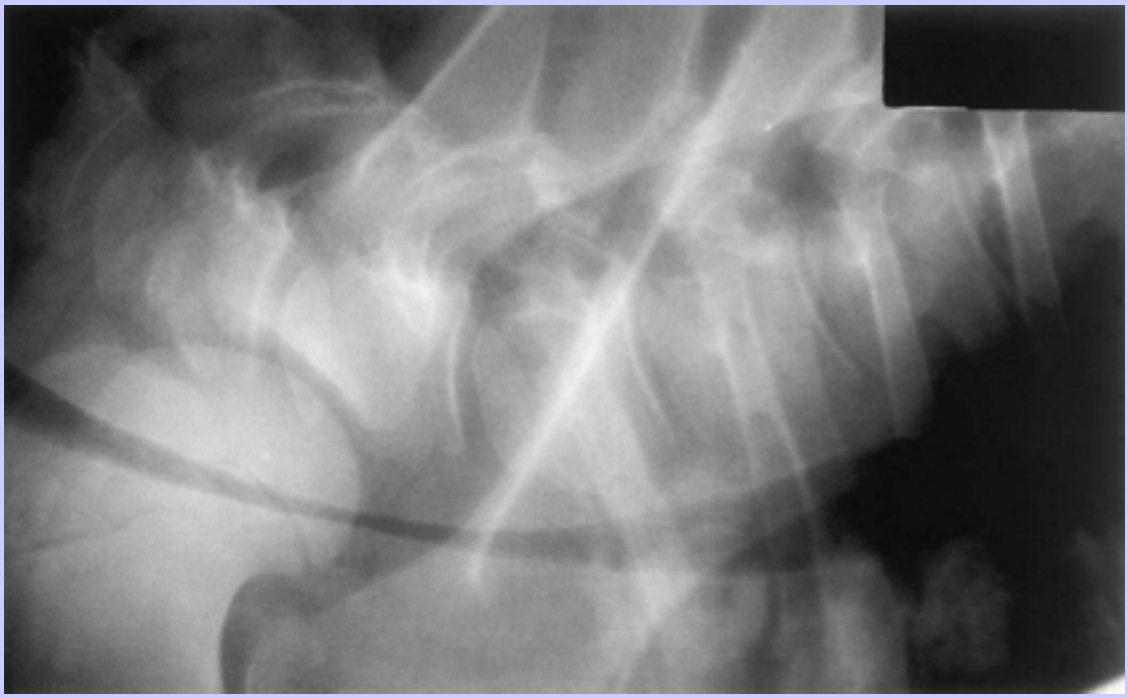
Laryngeal trauma and paralysis may resolve spontaneously or may require reconstructive surgery. The therapy of anaphylaxis is discussed on p. 652. Foreign objects should be removed surgically or endoscopically. NSAIDs (aspirin, 100 mg/kg PO twice daily, or flunixin, 1.1 to 2.2 mg/kg IV daily or divided twice daily) may help reduce swelling, edema, and respiratory embarrassment in all forms of obstruction.

31.49 TRACHEAL COLLAPSE AND STENOSIS

31.49.1 Definition and Etiology

Tracheal collapse or stenosis is infrequently reported in cattle and goats.[76–81] The cause is usually unknown, but the problem may result from cranial thoracic trauma, roping, tracheostomies, or possibly congenital defects. In cattle the majority of reports have described tracheal collapse in calves in which signs were usually first evident at several weeks of age.[76–79] The majority of these cases also involved the thoracic trachea (Fig. 31-51), suggesting a congenital lesion. However, in most calves with tracheal collapse the condition has been a result of dystocia at birth, especially breech presentations, which suggests a traumatic cause.[82] In contrast to reports in cattle, tracheal collapse has been reported in a mature goat that showed no previous signs of respiratory abnormality.[81]

Fig. 31-51 Radiograph demonstrating collapse of the thoracic trachea in a calf.



Tracheal collapse has also been reported in Texel-cross lambs with inherited chondrodysplasia[83]; affected lambs were normal at birth but developed exercise intolerance as early as 1 week of age. Severely affected lambs developed fatal respiratory compromise when exercised. Tracheal stenosis can also occur in lambs born to ewes that ingest *Veratrum californicum* root and rhizome material at days 31 through 33 of gestation.[84]

31.49.2 Clinical Signs and Differential Diagnosis

Clinical signs of tracheal collapse may include fever, tachycardia, tachypnea, cyanosis, and mucosal hyperemia with vessel engorgement, but affected animals may have normal vital signs and are otherwise alert and in good condition. Dyspnea is usually induced or exacerbated by excitement or exercise or may be severe at rest. Stertorous respiration is usually evident, is frequently worse on inspiration, and can often be localized to the trachea on auscultation. The inspiratory phase is prolonged, and a "honking" cough is characteristic, especially with intrathoracic collapse. Palpation may reveal or induce the collapse when the cervical trachea is involved. Tracheal palpation or elevation of the head may increase the stertor or induce the honking cough. In some cases there may be other evidence of trauma (fractured ribs, sternebrae), and in some animals pneumonia may be present. There is no response to antibiotics, steroids, or tracheostomy.

Texel-cross lambs with tracheal collapse resulting from inherited chondrodysplasia also exhibited retarded growth, forelimb varus, and reluctance to walk. Severity of signs varied among affected individuals; some died or were euthanized within weeks because of respiratory compromise, whereas others survived to breeding age.[83] Animals that survived for several months often developed arthritis characterized by severe erosive lesions of the articular cartilage of major joints including the shoulder, hip, and stifle. Lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* died within 5 minutes of birth after signs of severe respiratory distress.

599

600

Other possible disorders with signs similar to those seen in animals with tracheal collapse or stenosis are tracheal foreign bodies, tracheal actinobacillosis, neoplasms, bronchopneumonia, necrotic laryngitis, and extratracheal compressive lesions (e.g., abscesses, tuberculosis, hematomas).

31.49.3 Diagnosis

Any deviation of the hemogram from normal is probably a reflection of associated pneumonia or stress. Endoscopy and radiography are the most helpful ancillary aids. Care must be taken when restraining, sedating, and passing the endoscope in these animals; oxygen should be available. In cattle with idiopathic tracheal collapse, radiography (see Fig. 31-51) and endoscopy usually reveal a dorsoventral flattening, most typically in the caudal cervical and cranial thoracic trachea, although lateral collapse and collapse in other locations (cranial cervical, intrathoracic) are occasionally encountered.

31.49.4 Pathophysiology

Proposed causes of tracheal collapse in other species include congenital malformations, genetic or nutritionally induced weakness of cartilage, deficient innervation of the trachealis muscles, trauma, ischemic lesions from endotracheal tube cuffs, and primary pulmonary disease. No histologic differences were noted in tracheal rings from collapsed and normal segments in calves in one report.[76]

As previously mentioned, most calves with tracheal collapse have a history of dystocia at birth. During delivery, compression of the chest wall with fracture of the first pair of ribs may cause injury at the thoracic inlet.[85] However, signs of tracheal collapse are not immediately evident at birth, but develop over time.

Lambs with tracheal collapse associated with inherited chondrodysplasia had clinical signs most similar to a condition in humans that results from a mutation in the diastrophic dysplasia sulphate transporter gene,[86] but the

causative mutation in sheep has not yet been reported. Preliminary data indicated that the chondrodysplasia was inherited via a recessive mode of inheritance.[83] Tracheal stenosis in lambs born to ewes fed *V. californicum* was presumed to be caused by cyclopamine, a steroidal alkaloid which is the toxic principle in highest concentration in *V. californicum*. It was notable that lambs developed tracheal stenosis when ewes were fed *V. californicum* at 31 to 33 days of gestation, whereas craniofacial defects typically recognized in lambs born to exposed dams are seen when the ewe ingests the toxic plant by day 14 of gestation.[84]

31.49.5 Necropsy Lesions

At necropsy, affected animals may have either a laterally[78] or dorsally[77,81] compressed trachea; typically several centimeters of the trachea are affected. Necropsy of sheep with inherited chondrodysplasia reveals a trachea that is flaccid, flattened, and sometimes irregularly kinked. Tracheal rings are markedly thickened, and the lumen is narrow, possibly extremely so. Diffuse pulmonary congestion and edema, with epidcardial ecchymoses, may occur as a result of terminal anoxia and respiratory distress. Other lesions include exaggerated convex curvature of the ribs, anglular limb deformities, and erosive arthritis with exposure of the subchondral bone in one or more joints. Histologically, hyaline cartilage in affected organs is hypercellular and disorganized, with foci of apparent chondrolysis. Chondrocytes are larger than normal, although shrunken, apparently necrotic chondrocytes are also seen.[83] Necropsy of lambs with congenital tracheal stenosis resulting from maternal ingestion of *V. californicum* reveals pronounced lateral flattening of the trachea. Tracheal rings are reduced in number, with abnormal size and shape and irregular spacing. Histologically the cartilage rings in affected lambs were flattened and thin and had a thinner zone of proliferating chondrocytes on their outer surface compared with normal age-matched controls.[84]

31.49.6 Treatment and Prognosis

Mild cases may respond to confinement sufficiently to be fed out for slaughter. A number of surgical treatments have been proposed in other species, including anastomosis, bisection of tracheal rings, internal and external prostheses, and plication of the dorsal membrane.[76] External prostheses have been used successfully in calves,[76,82,85] adult cattle,[80] and a goat.[87] A favorable prognosis for surgical correction is estimated at approximately 30%.[82] A detailed description of surgical repair in calves by external prostheses has been published.[82] Successful management of lambs with congenital tracheal collapse or stenosis has not been reported, although mildly affected lambs with congenital chondrodysplasia survived into adulthood. Because of the apparent genetic basis for the disease, breeding of affected animals should not be recommended.

31.50 TRACHEAL FOREIGN BODIES AND MASSES

Ruminants may occasionally inhale foreign objects that lodge in the trachea. There are also two reports of tracheal actinomycosis that resulted in signs of tracheal obstruction.[88] Signs include a chronic cough, inspiratory dyspnea, audible stridor that can be localized to the trachea, extension of the head and neck, open-mouth breathing, and salivation. Differential diagnoses should include pharyngeal trauma, necrotic laryngitis, laryngeal abscesses, trauma, edema, or paralysis, tracheal collapse, and extratracheal compressive lesions. Endoscopy and radiology are important aids to diagnosis. Care must be exercised in restraint and in passage of the endoscope. Some small objects may be retrieved by a snare passed through an endoscope; others may require tracheostomy. When possible, the tracheostomy should be performed below the object. The actinomycotic masses are soft, pedunculated lesions with a granular surface containing small yellow foci. Of the two reported cases of tracheal actinomycosis, one died

of asphyxiation and the other responded initially to partial surgical removal of the masses, tracheostomy, and therapy with sodium iodide, penicillin, and streptomycin but relapsed some months later.[88a]

31.51 TRACHEAL EDEMA SYNDROME OF FEEDLOT CATTLE

Tracheal edema syndrome has also been referred to as *tracheal stenosis* in feedlot cattle. In this condition extensive edema and hemorrhage in the dorsal wall of the trachea result in coughing, dyspnea, and stertor, which has given rise to the term "honker cattle."[89] Tracheal edema syndrome occurs in two forms, characterized by either acute dyspnea or a chronic cough. It is not known whether the two forms are related. Although the syndrome has been recognized for years, no controlled research has been undertaken to determine the cause or risk factors of this syndrome, and the cause is unknown. Theories regarding possible causes include infections with upper respiratory viruses or bacteria such as *P. multocida* or *H. somni*, trauma to the trachea from feedbunks, passive congestion and edema from excessive fat accumulation in the thoracic inlet, hypersensitivity reactions, and mycotoxins.[90]

600

601

The acute dyspnea syndrome occurs mainly in heavy feedlot cattle in the latter two thirds of the feeding period and is most common in southern plains feedlots. It is sporadic and more common in summer, possibly because of exacerbation by hot weather. At one extreme, sudden deaths without the onset of noticeable clinical signs have been reported, and at the other extreme subclinical disease was evidenced by lesions in animals at slaughter that did not have clinical signs. Other factors that increase respirations also may cause signs to appear. Signs include an acute onset of dyspnea and loud guttural inspiratory sounds that can be localized to the lower trachea. Open-mouth breathing, extension of the head and neck, and cyanosis, leading to recumbency and death by asphyxiation, are present. Differential diagnoses for this form include pharyngeal trauma or abscess; necrotic laryngitis; IBR; laryngeal abscess, tumor, foreign object, edema, or paralysis; tracheal foreign object, mass, or collapse; and AIP.

The chronic form occurs in lighter cattle (135 to 400 kg [300 to 900 lb]) and is more common in western plains feedlots. It is also sporadic but less seasonal. Affected animals may have a history of IBR or pneumonia. The main sign is a continuous, frequent, deep, hacking, nonproductive cough. The animal may be unthrifty but is otherwise normal in appearance. The main differential diagnoses are necrotic laryngitis or mild, chronic suppurative pneumonia. Endoscopy and visualization of the lesions subsequently described aid in the diagnosis. Necropsy of the acute form reveals an edematous thickening of the submucosa and mucosa of the dorsal trachea (Fig. 31-52), as much as 5 cm thick and extending 20 to 30 cm from the midcervical area to the thoracic inlet or tracheal bifurcation. There is also extensive mucosal, submucosal, and peritracheal edema and/or hemorrhage, possibly related at least in part to agonal breathing. There may be no other lesions of the airway or lungs,[90] or abnormalities (e.g., pulmonary edema, bronchitis, interlobular edema and emphysema, alveolar hemorrhage) may be seen.[89] Lesions in the chronic form consist of hyperemia of the mucosa of the caudal third of the trachea, with a thin layer of mucopurulent exudate. The mucosa may have a cobblestone appearance or even large, fiber-like projections and polyps. No effective treatment exists for the chronic form. Corticosteroids (dexamethasone, 0.05 to 0.2 mg/kg IM or IV; prednisolone, 1 to 2.2 mg/kg IM or IV daily) are recommended for the acute form, as well as such practices as preventing stress, providing shade, and cooling with water sprays and fans. Broad-spectrum antibiotics have been recommended by some,[89,90] whereas others have not found them to be necessary.[91] However, because animals with tracheal edema syndrome may be difficult to distinguish clinically from animals with conditions that could respond to antimicrobials (such as necrotic laryngitis), antimicrobials are often administered. Because withdrawal times associated with antimicrobial administration could delay shipment of affected animals to slaughter, drugs with a short withdrawal time should be used if salvage is an option. Tracheostomy may not be helpful if placed proximal to the obstruction, and relief of dyspnea via tracheostomy may require insertion of an endotracheal tube to the tracheal bifurcation. Oxygen administration could be beneficial if available. Recovered patients tend to relapse and should be salvaged.

Fig. 31-52 Postmortem photograph of tracheal edema syndrome. Note severe mucosal and submucosal thickening, which has obstructed the trachea by approximately 50%. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

JOHN C. BAKER

31.53 CLINICAL CLASSIFICATION OF PNEUMONIA

AMELIA R. WOOLUMS

TREVOR R. AMES

JOHN C. BAKER

In an effort to simplify the differential diagnosis of the bewildering array of lower respiratory diseases of cattle, a classification system based on pathophysiology and clinical signs has been suggested.[92] Three classifications were proposed:

1 Bronchial pneumonia is characterized pathophysiologically by invasion of pathogenic organisms that gain access to the lung through the pulmonary tree. It is characterized clinically by depression, fever, and other signs of sepsis such as hyperemic mucous membranes or scleral injection, and an anterior-ventral distribution of abnormal lung sounds and lesions (see the following section). Bronchial pneumonia is the final outcome of the respiratory disease complex of ruminants, and because viruses play an important role in this disease complex, viral causes of respiratory tract disease in ruminants are placed in this category.

2 The interstitial pneumonias are a very diverse group of (usually) noninfectious diseases. Although it is difficult to make generalizations, these diseases are characterized pathophysiologically by an interstitial reaction that usually results from ingestion or inhalation of toxins or allergens. Clinically affected animals tend not to be as depressed and septic, the abnormal lung sounds and lesions are diffusely distributed, and there is little or no response to antibiotic therapy.

3 Metastatic pneumonia is characterized pathophysiologically by septic embolization of the lungs from other foci in the body, classically liver abscesses and postcaval thrombi. Clinically, cases of metastatic pneumonia exhibit signs of sepsis as with bronchopneumonia, but with widespread pulmonary lesions and abnormal lung sounds, and the eventual development of hemoptysis (see descriptions of vena caval thrombosis and metastatic pneumonia in this chapter).

601

602

31.54 THE BRONCHOPNEUMONIAS (RESPIRATORY DISEASE COMPLEX OF CATTLE, SHEEP, AND GOATS)

AMELIA R. WOOLUMS

TREVOR R. AMES

JOHN C. BAKER

The respiratory disease complex of ruminants consists of the single clinical entity of bronchopneumonia but is caused by numerous combinations of infectious agents, compromised host defenses, and environmental conditions. Bronchopneumonia causes greater economic losses than any other disease of feedlot cattle or lambs and is one of the most common causes of dairy calf mortality.

In dairy calves, bronchopneumonia, often called *enzootic pneumonia*, is most common in housed calves. It is called *shipping fever* in beef calves because the greatest incidence of bronchopneumonia occurs after shipment to stocker operations or feedlots; the term *bovine respiratory disease* (BRD) is also used to describe feedlot bronchopneumonia. Bronchopneumonia also occurs in nursing beef calves and in mature beef or dairy cows, sometimes in outbreaks that can have significant morbidity or mortality. Little is known about which factors are specifically the most important for putting these populations at risk for bronchopneumonia, but they are likely similar to risk factors described for housed dairy calves or feedlot cattle. The infectious agents and risk factors of bronchopneumonia of sheep and goats are very similar to those of calves.

Bronchopneumonia of ruminants is a disease of multifactorial causation that occurs when a certain combination of host, environment, and infectious agent characteristics (risk factors) is active. The numerous infectious agents (Boxes 31-3 and 31-4) that are associated with bronchopneumonia are ubiquitous in ruminant populations, and the bacteria most often associated with pneumonic lesions are part of the normal resident flora of the ruminant nasopharynx. In addition to recognition of the microbial agents that contribute to the development of bronchopneumonia in ruminants, understanding of the management practices that also play a role is necessary for developing successful programs of prevention.

31.54.1 Box 31-3 Viral Agents Associated with Respiratory Tract Diseases in Ruminants

31.54.1.1 BOVINE

31.54.1.1.1 Viruses of Major Importance (Commonly Isolated or Generally Accepted to be Important Contributors to Ruminant Respiratory Disease)

Bovine herpesvirus type 1 (IBR)

Bovine respiratory syncytial virus (BRSV)

Bovine viral diarrhea virus (BVDV)

Bovine parainfluenza virus type 3 (PI3)

Bovine respiratory coronavirus

Alcelaphine herpesvirus 1 and 2/ovine herpesvirus 2 (malignant catarrhal fever)

31.54.1.1.2 Viruses of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Bovine herpesvirus type 4 (DN-599, Movar 33/63, FTC-2)

Bovine adenovirus

Bovine rhinovirus

Bovine reovirus

Bovine enterovirus

Calicivirus

Influenza virus

31.54.1.2 OVINE AND CAPRINE

Ovine or bovine respiratory syncytial virus (ORSV, BRSV)

Parainfluenza virus type 3 (PI3)

Adenovirus

Bluetongue virus

Ovine progressive pneumonia (maedi-visna) virus of sheep*

Pulmonary carcinoma of sheep*

* Progressive pneumonias, capable of causing severe chronic respiratory disease.

31.54.2 Box 31-4 Bacteria, *Mycoplasma, Ureaplasma*, and *Chlamydia* Species Associated with Bronchopneumonia of Cattle, Sheep, and Goats

31.54.2.1 Bacteria of Major Importance (Commonly Isolated or Generally Accepted to be Important Contributors to Ruminant Respiratory Disease)

Mannheimia haemolytica

Pasteurella multocida

Histophilus somni

Mycoplasma bovis

Mycoplasma dispar

Ureaplasma species

Mycoplasma ovipneumonia (sheep and goats only)

Mycoplasma mycoides subsp. *mycoides*, large colony variant (goats)

Arcanobacterium (Actinomyces) pyogenes (secondary opportunistic pathogen)

31.54.2.2 Bacteria of Minor Importance (Uncommonly Isolated or of Uncertain Importance in Ruminant Respiratory Disease)

Pseudomonas aeruginosa

Escherichia coli

Streptococcus species

Staphylococcus species

Moraxella species

Salmonella species

Bacteroides species (anaerobe)

Peptococcus indolicus (anaerobe)

Fusobacterium species (anaerobe)

Chlamydia species

31.55 INFECTIOUS AGENTS ASSOCIATED WITH THE RESPIRATORY COMPLEX OF CATTLE, SHEEP, AND GOATS

31.55.1 Etiology

Numerous infectious agents have been isolated from cases of bronchopneumonia in ruminants (see Boxes 31-3 and 31-4). Although infectious bronchopneumonia of ruminants is usually caused by two or more infectious agents acting together, some agents can also cause significant disease alone. Therefore the clinical and epidemiologic characteristics, means of diagnosis, and treatment and prevention of the infectious agents will be

first considered individually. A description of epidemiology, diagnosis, and treatment of "undifferentiated" bronchopneumonia (bronchopneumonia with no specific causative diagnosis attempted) will then follow. The clinical signs, gross pathologic lesions, and recommended methods of diagnosis for the major infectious causes of ruminant respiratory disease are listed in Table 31-9.

31.56 VIRAL AGENTS

31.56.1 Bovine Herpesvirus Type 1 (Infectious Bovine Rhinotracheitis Virus)

31.56.1.1 Definition and Etiology

602

604

Bovine herpesvirus 1 (BHV-1) is an enveloped DNA virus that is classified as an alphaherpesvirus in the family Herpesviridae. It is associated with multiple, distinct disease syndromes of cattle that include IBR, conjunctivitis (see Chapter 39), infectious pustular vulvovaginitis (IPV), balanoposthitis, abortion (see Chapter 43, encephalomyelitis (see Chapter 35), and mastitis.[93,94] Although only a single serotype of BHV-1 is currently recognized, three subtypes have been identified on the basis of restriction endonuclease cleavage patterns. These subtypes are referred to as BHV-1.1 (respiratory infections), BHV-1.2 (respiratory and genital infections), and BHV-1.3 (neurologic infections). BHV-1.3 has been reclassified as a distinct herpesvirus and is designated as BHV type 5.[93] Only the respiratory manifestations of infection with BHV-1 are discussed here. The respiratory form is characterized by rhinitis, tracheitis, and pyrexia and is referred to as IBR. BHV-1 can also cause pneumonia as part of a severe generalized infection in newborn calves.[95] The virus is also of great importance in the bovine respiratory disease complex because of its role in enhancing secondary bacterial bronchopneumonia by causing respiratory injury and immunosuppression,[96] as discussed later.

Table 31-9 Clinical and Gross Pathologic Characteristics of Common Infectious Agents That Cause Respiratory Disease in Ruminants

Agent	Species	Clinical Signs*	Gross Pathology*	Diagnosis
VIRUSES				
BHV-1 (IBR)	Cattle	Fever, depression, anorexia, serous to mucopurulent nasal discharge, muzzle hyperemia, nasal plaques, coughing, inspiratory stridor (conjunctivitis ± keratitis, abortion)	Congestion; fibrinopurulent exudate of nasal passages, larynx, trachea; in young calves, pneumonia and involvement with other organs	VI or IFA nasal swabs, conjunctival scrapings PS VI, IFA, or IHC of tissue from upper airways or lungs collected at necropsy
BRSV†	Cattle, sheep, goats	Fever, depression, anorexia, tachypnea, nasal discharge (±), coughing, expiratory dyspnea, harsh bronchovesicular sounds over cranioventral lung, crackles and wheezes rarely, quiet lung sounds caused by pneumothorax, subcutaneous emphysema	Lobules in cranioventral lung collapsed, firm, dark red; caudodorsal lung fails to collapse, rubbery texture (suggestive of acute interstitial pneumonia); dorsocaudal emphysema	IFA or RT-PCR of nasal swabs (VI unreliable) PS IFA or IHC of lung at necropsy (most reliable in acute stage of disease)
PI3	Cattle, sheep, goats	Like BRSV but more mild, commonly asymptomatic; contributes with other agents to enzootic calf pneumonia or shipping fever	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI or IFA of nasal swabs PS VI, IFA, or IHC of lung at necropsy

BVDV	Cattle	Fever, depression, anorexia, nasal discharge, tachypnea, coughing (±); contributes with other agents to enzootic calf pneumonia or shipping fever (diarrhea, abortion, congenital defects, PI calves, hemorrhagic syndrome)	Scattered lobules of cranioventral lung collapsed, firm, dark red	VI, ELISA or PCR of peripheral blood buffy coat PS VI, IFA, or IHC of lung at necropsy
Respiratory coronavirus[†]	Cattle	Contributes with other agents to enzootic calf pneumonia or shipping fever	Not yet well characterized, probably as for PI3	VI (need special cells) or RT-PCR of nasal swabs PS VI or IFA of lung at necropsy
BACTERIA				
Mannheimia haemolytica	Cattle, sheep, goats	Fever, depression, anorexia, signs of endotoxemia, tachypnea, evidence of pleural pain, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles (coughing not prominent)	Cranioventral lung lobes firm, dark red to gray-brown; fibrin on pleura; yellow pleural fluid that may be gelatinous; infarct-like (wedge-shaped) lesions sometimes seen	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy
Pasteurella multocida	Cattle, sheep, goats	Fever, tachypnea, cough, depression, mucoid to mucopurulent nasal discharge, harsh bronchovesicular sounds over cranioventral lung ± crackles	Cranioventral lobules (sometimes lobes) firm, dark red to purple; purulent exudate in airways; fibrin on pleura not expected	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) Culture from characteristic lesions at necropsy

Histophilus somni†	Cattle, (uncommon in sheep, goats)	As for *P. multocida*; possibly also evidence of pleural pain (joint effusion, infertility or abortion, otitis, conjunctivitis, neurologic signs)	As for *M. haemolytica*, although fibrinous pleuritis not as consistent; fibrinopurulent arthritis, myocarditis often seen in respiratory cases	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret) culture from characteristic lesions at necropsy
Mycoplasma bovis‡	Cattle	Fever, anorexia, tachypnea, cough, nasal discharge; chronic or ongoing pneumonia that fails to respond as expected to therapy (joint or tendon sheath effusion, otitis, conjunctivitis)	Cranioventral lobules collapsed, firm, dark red; multiple grossly visible raised nodules filled with caseous material (abscesses or caseous necrosis); (fibrinopurulent arthritis, tenosynovitis, or otitis common in respiratory cases; myocarditis or pericarditis)	Culture from aseptic TTA from animal with signs of disease (nasal swabs difficult to interpret; more meaningful if several in group have positive culture from characteristic lesions at necropsy)

BVDV, Bovine viral diarrhea virus; *BHV-1*, bovine herpesvirus type 1; *ELISA*, enzyme-linked immunosorbent assay; *IBR*, infectious bovine rhinotracheitis; *IFA*, immunofluorescent assay; *IHC*, immunohistochemistry, most commonly used on formalin fixed lung tissue collected at necropsy; *PCR*, polymerase chain reaction; *PI3*, parainfluenza type 3; *PS*, paired serology; *RT-PCR*, reverse transcriptase—PCR; *TTA*, transtracheal aspirate; *VI*, virus isolation.

* Clinical signs not related to the respiratory system but possibly also prevalent are listed in parentheses. Note that respiratory disease is often caused by two or more agents, so clinical signs and gross pathology in an individual or herd may be any combination of those listed for individual agents.

† Agent does not survive transport well or can be difficult to isolate; requires special handling or culture techniques to maximize likelihood of isolation.

‡ Usually need to specifically request tests to isolate mycoplasmas and to specifically identify the species *M. bovis*.

31.56.2 Clinical Signs

Clinical signs vary and range from mild to severe. Genetic factors also appear to be an important determinant of the severity of BHV-1 infection, specifically the type-I interferon genotype.[97] Clinical signs include pyrexia, anorexia, dramatic drop in milk production in dairy cattle, increased respiratory rate, a slight degree of hyperexcitability, ptyalism, coughing, and nasal discharge that progresses from serous to mucopurulent. Dyspnea characterized by open-mouth breathing may appear if the larynx or trachea becomes partially blocked with mucopurulent material. Auscultation of the lungs reveals harsh bronchovesicular sounds and referred tracheal

sounds. Clinical signs of lower respiratory tract infection may be exacerbated by secondary bacterial pneumonia, which is a common sequela to BHV-1 infection. Severe hyperemia and reddening of the muzzle can occur, which is the reason for the common name of "red nose" to describe BHV-1 infection. Pustules may develop on the nasal mucosa and later form diphtheritic plaques. Conjunctivitis with excessive ocular discharge may be present. Conjunctivitis with corneal opacity can also occur as the principal manifestation of BHV-1 infection and may be misdiagnosed as infectious bovine keratoconjunctivitis (pinkeye). Abortions may occur concurrently with respiratory disease, but they can also occur as late as 100 days after infection.[93,94] Abortions may also occur in cattle that escape serious respiratory disease.

On rare occasions, neonatal calves may suffer from both an acute respiratory and a systemic form of BHV-1 infection. The infection is characterized by rhinitis, marked lacrimation, inflammation and necrosis of the soft palate, laryngotracheitis, and ulceration of the GI tract.[95] Vaccination of calves within 3 days of age with modified live viral vaccines has also been associated with severe fatal systemic BHV-1 infection.[98] The severity of disease in vaccinated calves was suspected to be caused by lack of maternal antibody and resultant widespread multiplication of the vaccine virus.

31.56.3 Pathogenesis

The route of infection is by direct contact with infected cattle or aerosol; apparent transmission by aerosol has been recognized among calves separated by as little as 4 m.[99] At least three of the surface glycoproteins of BHV-1, gC, gD, and gB, mediate host cell attachment and entry through interaction with heparan sulfate proteoglycans and other host cell proteins.[100,101] Epithelial cells of the respiratory tract are the initial target of infection after respiratory exposure, and after initial infection the virus can spread intracellularly to neighboring epithelial cells via intracellular bridges. Lymphocytes and monocytes are also susceptible to infection; although infection with these cells produces little virus, they appear to be a means by which the virus reaches extrarespiratory sites after respiratory infection. In severe field cases of BHV-1 infection the virus can be found in multiple organs including the esophagus, spleen, and liver.[102,103]

Respiratory disease caused by BHV-1 is mediated by two major mechanisms: (1) direct injury and destruction of infected epithelial cells in the upper respiratory tract and bronchi, with resultant inflammation and increased susceptibility to infection with secondary opportunistic pathogens; and (2) immunosuppression resulting from dysfunction of neutrophils, lymphocytes, and macrophages. Immunosuppressive actions of BHV-1 include decreased neutrophil chemotaxis and mitogen-induced blastogenesis of lymphocytes,[104] decreased expression of MHC class I molecules,[105] and induction of apoptotic death of lymphocytes and monocytes.[106] BHV-1 infection modifies expression and activity of cell surface receptors in ways that can be harmful; binding of the adhesion molecule ICAM-1 (CD18/CD11a) on bovine leukocytes to *Mannheimia haemolytica* leukotoxin was increased after BHV-1 infection of cattle, leading to enhanced leukocyte death.[107]

604 605

Another important mechanism of pathogenesis of BHV-1 is the ability to establish latent infection in neural tissue.[101] After acute infection, BHV-1 can be found in a latent state in the trigeminal ganglia; recent research indicates that the virus may also persist latently in the tonsil.[108] During latent BHV-1 infection, virus is not actively produced in infected cells; thus latently infected cattle do not shed virus. However, an RNA molecule termed the *latency related transcript* (LRT) is abundantly produced in latently infected cells. Research indicates that the LRT prevents apoptosis in cells receiving signals that should trigger apoptosis, suggesting that the LRT functions at least in part to promote survival of infected cells.[101] One or more proteins encoded by the LRT

appear to be required for the virus to reactivate from latency.[109] Stress or administration of glucocorticoids causes reactivation of the latent virus, leading to shedding of virus and the possibility of infection of in-contact susceptible animals. Latency appears to occur in effectively all cattle that are infected with BHV-1, thus ensuring that the virus can be spread during times of stress by animals that have been free of clinical disease from BHV-1 infection for months to years. Calves that are exposed to BHV-1 when they have moderate levels of circulating maternal antibody can develop latent infection while never showing signs of clinical disease.[110] Latency of BHV-1 is thus an important mechanism by which the virus can persist and spread in a group of cattle.

31.56.4 Epidemiology

Studies of antibody prevalence to BHV-1 indicate that infection is widely distributed in the cattle population.[93,94] Adult cattle are thought to be the principal reservoirs of infection.[93,94] Infections of the respiratory tract by BHV-1 are prevalent when large concentrations of beef or dairy cattle are assembled, although BHV-1 does not appear to have an important role in enzootic pneumonia of calves.[111–113] Feedlot cattle appear to have higher attack rates, more severe disease, and higher case fatality rates than do range or dairy cattle. This is likely because of the stressful conditions experienced by feeder calves at the time of entry into feedlots. Entry into feedlots may also coincide with decline of passive immunity. The case fatality rate is generally low unless complicated with secondary bacterial pneumonia. Historically, disease caused by BHV-1 infection was most commonly recognized within the first few weeks after feedlot entry. However, since the 1990s, disease resulting from BHV-1 has sporadically been recognized in cattle that have been in feedlots for several months; these “late breaks” of disease are noteworthy in that they often occur in cattle that have been previously vaccinated against BHV-1.[114,115] Although BHV-1 is a relatively genetically stable virus, there is evidence that mutations are occurring in BHV-1 isolates currently circulating in cattle populations, which may help the virus escape host immunity.[115] Studies have shown that, although commercially available vaccines can still prevent disease resulting from experimental challenge with modern BHV-1 isolates, viral shedding is increased relative to cattle challenged with older BHV-1 isolates that are more similar to the strains of virus included in vaccines.[115,116] Repeat vaccination later in the feeding period has been recommended to decrease risk of late BHV-1 breaks,[114] although the efficacy of this practice has not been confirmed in clinical trials.

The fact that BHV-1 is capable of establishing latent infections in neural tissue is undoubtedly important in the epidemiology of disease caused by the virus. Under periods of stress, latent infections can become reactivated, resulting in viral shedding. Modified live BHV-1 vaccines are also capable of causing latent infections.[93,117]

Fig. 31-53 Postmortem photograph of opened trachea from animal infected with BHV-1. Note multiple white fibrinonecrotic plaques and, distal to plaques, yellow fibrinopurulent material on tracheal mucosa. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

31.56.5

Necropsy Findings

IBR is rarely fatal in mature cattle unless it occurs during periods of severe stress or is complicated by secondary bacterial infection of the lung. Lesions caused by BHV-1 infection include rhinitis, laryngitis, and tracheobronchitis. The mucosa of the nasal passages and trachea can be congested or hemorrhagic. Pustular lesions (sometimes referred to as *plaques*) may be observed, and these lesions may coalesce to form adherent necrotic material on respiratory (Fig. 31-53), ocular, and reproductive mucosa.[103] Usually the inflammatory lesions induced by BHV-1 do not extend into airways contained within the lung, but secondary bacterial bronchopneumonia with the expected pathology is common. Conjunctivitis and, less commonly, keratitis may be present. Esophageal erosions have been identified in severe natural outbreaks.[102] Perinatal infection of calves can lead to fatal systemic disease, with necrotic foci found in the liver, adrenal glands, kidneys, and other organs.[98] Although intranuclear inclusion bodies are a feature of herpesvirus infections, they are not a common histologic feature of BHV-1.

31.56.6 Diagnosis

BHV-1 can be diagnosed by virus isolation or immunofluorescent antibody (IFA) testing to identify virus in nasal swabs or conjunctival scrapings antemortem, or from samples collected postmortem. Infection can also be diagnosed by paired serology, with tests for serum neutralizing antibody (SN) most commonly done.

31.56.7 Treatment and Prevention

Cattle infected with BHV-1 should receive supportive care. Administration of antimicrobials appropriate to prevent infection with bacteria likely to cause secondary bronchopneumonia is appropriate (Table 31-10). Good-quality feed and water should be made easily available, and additional stressors such as movement or mixing should be avoided or postponed. NSAIDs such as aspirin or flunixin meglumine (1.1 to 2.2 mg/kg IV daily or divided twice daily) may help severely affected individuals maintain water and feed consumption. Steroids should not be administered. Because protective immunity develops rapidly after either intranasal or IM vaccination (see later), BHV-1 vaccination in the face of an outbreak may help limit disease, although the efficacy of this practice has not been tested in a controlled study.

605

606

Table 31-10 Antimicrobials Approved by the FDA for Treatment of Bronchopneumonia of Beef Cattle

Antimicrobial	Label Dose	Route of Administration	Treatment Interval (hr)	Slaughter/MilkWithdrawal	Approved for Sheep and Goats?
STANDARD PREPARATIONS					
Amoxicillin	11 mg/kg	IM, SC	24	25 days/96 hours	No
Ampicillin	2–5 mg/kg (22 mg/kg)*	IM	24	6 days/48 hours	No
Ceftiofur (sodium)	1.1–2.2 mg/kg	IM, SC (cattle) IM (sheep and goats)	24	4 days/0 days	Sheep and goats
Ceftiofur (HCl)	1.1 mg/kg	IM, SC	24	3 days/0 days	No
Enrofloxacin†	2.5–5.5 mg/kg multiday therapy	SC	24 or once	28 days/not approved	No
Erythromycin	1.1–2.2 mg/kg (11–22 mg/kg)*	IM	24	14 days/72 hours	Sheep
Oxytetracycline	11 mg/kg	IV‡, IM‡, SC‡	24	15–22 days‡/not approved	Not for injection§
Procaine penicillin G	6600 U/kg (22,000 U/kg)*	IM	24	10 days (cattle), 9 days (sheep) /48 hours	Sheep
Spectinomycin	10–15 mg/kg	SC	24	11 days/not approved	No
Sulfadimethoxine	55 mg/kg, initial treatment 27.5 mg/kg thereafter	IV, PO	24	7 days/60 hours	No
Tylosin	17 mg/kg	IM	24	21 days/not approved	No
LONG-ACTING PREPARATIONS					
Ceftiofur crystalline free acid (Excede)	6.6 mg ceftiofur equivalent per kg (1.5 mL/45 kg)	SC in the ear	Once (7-day duration)	13 days/0 days	No
Danofloxacin†	6 mg/kg	SC	48	4 days/not approved	No
Enrofloxacin†	7.5–12.5 mg/kg	SC	Once	28 days/not approved	No
Florfenicol	20 mg/kg	IM	48	28 days/not approved	No
	40 mg/kg	SC	Once (4-day duration)	38 days/not approved	No
Oxytetracycline	20 mg/kg	IM, IV, SC	48–72	28 days/96 hours	No

Oxytetracycline (Tetradure)	30 mg/kg	IM, SC	Once (7-day duration)	28 days/not approved	No
Sulfadimethoxine (sustained release bolus)	138 mg/kg	PO	7 days	21 days/not approved	No
Tilmicosin	10 mg/kg	SC	72	28 days/not approved	Sheep Toxic to goats
Tulathromycin	2.5 mg/kg	SC	Once (7- to 14-day duration)	18 days/not approved	No

IM, Intramuscular; *IV*, intravenous; *PO*, oral; *SC*, subcutaneous.

* Author-suggested dose that has been shown to be more effective than label-approved dose. Higher dose can be given by the same route of administration and with the same treatment interval, but use of extralabel dosages must comply with the Animal Medicinal Drug Use Clarification Act (AMDUCA), and withdrawal times must be significantly extended.

† Extralabel use in food animals prohibited by law.

‡ Varies with preparation.

§ Oxytetracycline is labeled for administration to sheep in feed; not a recommended route for treatment of respiratory disease.

Note: Many of the drugs listed in this table are not approved for use in veal calves.

Efforts to prevent BHV-1 infection should include practices that optimize host immunity and avoiding management practices that put cattle at risk, such as mixing newly introduced cattle with established populations. Many brands of inactivated and attenuated BHV-1 vaccines for SC or IM administration are commercially available; products are available that contain BHV-1 alone or in combination with other pathogens. Temperature-sensitive, modified live vaccines are also available for intranasal administration; intranasal vaccines also include parainfluenza type 3 (PI3). Numerous reports confirm that either parenteral or intranasal BHV-1 vaccines can protect cattle from disease after experimental challenge with virulent BHV-1[118–122] or BHV-1 followed by *M. haemolytica*[123]; only a few are referenced here. Unfortunately there are few studies of BHV-1 vaccine efficacy in field trials, which better reflect the impact of vaccination in the "real-life" setting. In one older trial, vaccinated feedlot cattle were actually more likely to develop respiratory disease than unvaccinated cattle[124]; in a more recent trial there was no difference in respiratory disease between vaccinated and unvaccinated cattle, but vaccinated cattle had improved feed efficiency over the first 28 days after entering the feedlot.[125] The lack of field trials confirming vaccine efficacy may result in part from reluctance on the part of veterinarians or producers who perceive the vaccines to be useful to allow the inclusion of control groups of animals that are not vaccinated; researchers have admitted to being thwarted by this obstacle when organizing a field trial of BHV-1 vaccine efficacy.[126] In spite of the lack of published field trials supporting efficacy of BHV-1 vaccines to prevent respiratory disease, they are widely used; over 90% of feedlot cattle are reported to receive BHV-1 vaccines.[127] Historically it was thought that vaccination with modified live BHV-1 leads to protective immunity for years, or perhaps even the life of the animal, but recent evidence of infection and disease in feedlot animals within months of vaccination[114,115] indicates that this is not the case.

606
607

While both modified live and inactivated BHV-1 vaccines are available, modified live vaccines are preferable when it is safe to use them because they are more likely to stimulate a cell-mediated immune response similar to that induced by infection.[128] Few studies to date have compared modified live to inactivated vaccines in the same trial. When this comparison has been made it has been to compare protection against experimental BHV-1 infection, with modified live vaccines providing superior protection in some[129] but not other[130] studies. Improved efficacy of inactivated vaccines in more recent studies[130] may be a result of inclusion of more advanced adjuvants, which can greatly improve the immune response to inactivated vaccines. Modified live BHV-1 vaccines are capable of causing latent infections, which could theoretically lead to shedding and spread of the vaccine strain of virus to in-contact naïve animals.[94,117] Because modified live BHV-1 vaccines can induce abortion, the manufacturer's recommendations regarding administration should be closely followed. Modified live vaccines may also lead to severe disease if administered to calves within a few days of birth[98]; intranasal modified live BHV-1 vaccines may be safer than parenterally administered modified live virus vaccines in very young calves.[131]

If a modified live vaccine is to be used, the veterinarian must then decide whether to use a product for intranasal or for parenteral administration. Both have been shown to provide protection rapidly; in one study, intranasal vaccination protected calves challenged within 48 hours of vaccination,[118] whereas other studies have shown that intramuscularly or subcutaneously administered modified live vaccine can protect cattle challenged 72 hours after vaccination.[119,122] Both types of vaccines can induce protection in cattle before serum neutralizing antibodies are evident,[121,122] indicating that cell-mediated rather then humoral immunity is responsible for protection soon after vaccination. In one trial that compared the protection afforded by intranasal versus parenteral BHV-1 vaccine, feedlot cattle that received intranasal vaccine had improved feed efficiency over cattle that received parenteral vaccine, but there was no difference in morbidity or mortality attributable to respiratory disease between the two groups.[125] Intranasally administered BHV-1/PI3 vaccines are theoretically preferable to parenteral vaccines because they induce a better mucosal immune response; they may also have an advantage when calves are vaccinated in the presence of passive immunity.[120,132] It appears that intranasal modified live vaccines are more likely to be spread to in-contact animals than are parenteral modified live vaccines; two studies confirmed BHV-1 shedding by nonvaccinated cattle in contact with cattle vaccinated intranasally with modified live BHV-1,[133,134] although two different studies could not identify evidence that modified live virus vaccine given intramuscularly spread to nonvaccinated cattle.[135,136]

Vaccines that have gene deletions have been developed and used in Europe.[137] These vaccines allow serologic differentiation of vaccinated from naturally infected animals and have application for BHV-1 control or eradication programs.

31.56.8 Herpesviruses in Sheep and Goats

Herpesviruses have been isolated from sheep and goats. It remains undetermined whether herpesviruses have a role, and if so, to what extent, in respiratory disease of small ruminants.

31.56.9 Respiratory Syncytial Viruses of Cattle, Sheep, and Goats

31.56.9.1 Definition and Etiology

BRSV is an enveloped RNA virus that is classified as a nonhemagglutinating pneumovirus of the family Paramyxoviridae. This virus was named for the characteristic cytopathic effect it produces in vitro and in vivo, which is the formation of syncytial cells. BRSV shares many similarities in its biology and epidemiology with the human respiratory syncytial virus (HRSV). HRSV is considered to be the most important respiratory tract pathogen of infancy and early childhood. Although BRSV and HRSV are closely related, they are distinct viruses.[138] RSV has also been isolated from sheep and goats with respiratory disease. Studies using RNAse mismatch cleavage analysis indicate that ovine RSV may be distinct from HRSV and BRSV, whereas caprine RSV may be more closely related to BRSV.[139,140] The possibility of interspecies transmission has not been well defined. However, a European serologic survey undertaken to determine whether nonbovine species were likely to harbor BRSV infection found that only goats, in addition to cattle, were commonly seropositive.[141] These results indicate either that goats are commonly infected with BRSV or that antigenic similarities between caprine RSV and BRSV led to production of cross-reactive antibodies in many goats. Although two major antigenic subtypes, A and B, of human RSV have been clearly defined, research has shown that BRSV is less variable than human RSV at the genetic level, as indicated by evaluation of nucleotide sequences in genes for viral proteins or by digestion of viral RNA with restriction enzymes.[142] However, in spite of minimal to moderate differences among BRSV isolates at the genetic level, isolates can differ notably in their reactivity with monoclonal antibodies directed against individual BRSV proteins[143,144]; this indicates that apparently minor genetic differences could lead to changes that allow the virus to evade host immunity. Differences in molecular weights of viral proteins also divide isolates into two major groups.[145] A study of genetic variability in BRSV isolates collected over several decades showed that genetic change occurred over time[146,147] and that BRSV isolates commonly included in commercial vaccines differed a relatively large amount from some isolates collected from recent natural outbreaks.[146] Studies have also shown that genetic differences in BRSV isolates can be grouped by geographical origin, with some European isolates differing to a notable degree from isolates from the United States or Japan.[146,147] Most important, European research identified genetic changes in a region of the BRSV G glycoprotein (the viral attachment protein) that was previously thought to be highly conserved and difficult or impossible for the virus to change.[146] These changes appear to be driven by vaccination, indicating that antigenic pressure induced in cattle by vaccination can lead BRSV to change in unexpected ways. These data indicate that commercial vaccines may need to be reformulated periodically to include isolates of the virus that are similar to isolates currently circulating in natural populations.

607

608

31.56.9.2 Clinical Signs

Clinical signs of BRSV infection can vary from inapparent to severe in an infected group of cattle.[148–151] Signs of disease are limited to the respiratory system. Infected animals may display elevated rectal temperature of 40° C to 42.2° C (104° F to 108° F), depression, decreased feed intake, elevated respiratory rates, ptyalism, cough, and nasal and lacrimal discharges. Signs of disease may progress rapidly, and early signs may be missed. Thoracic auscultation may reveal increased bronchial and bronchovesicular sounds; fine crackles or wheezes may be heard, particularly in the middle or dorsocaudal lung fields. Absence of

bronchovesicular sounds may be noticed in the dorsal or dorsocaudal lung fields if an emphysematous bulla is present, or if a bulla has ruptured, leading to pneumothorax. In later stages of the disease, dyspnea can become pronounced and is characterized by increased expiratory effort and mouth breathing. SC emphysema and intermandibular edema are sometimes noted. Dramatic reduction in milk production has been reported in dairy cattle. Duration of disease is variable (1 to 2 weeks). A biphasic clinical course has been described but does not appear to be a consistent finding. Experimental infections of lambs with ovine RSV caused a mild primary pneumonia and was also capable of causing lower respiratory tract lesions in calves and deer.[152]

31.56.9.3

Pathogenesis

The means of transmission appears to be contact with infected cattle and aerosols. The incubation period is 3 to 5 days. Infection with BRSV can cause bronchitis, bronchiolitis, alveolitis, and interstitial pneumonia.[148–151] After experimental infection, BRSV is found in cells of the nasal, tracheal, and bronchial epithelium by 2 days postinfection and in bronchiolar and alveolar epithelial cells by day 4 postinfection.[153] The virus causes epithelial cells to fuse, resulting in the characteristic multinucleated cells, or syncytia, which are seen in airways and alveoli. Epithelial cells, which may undergo apoptosis after BRSV infection,[153] slough into the lumen of airways and are phagocytized by neutrophils or alveolar macrophages.[153] Infection of alveolar macrophages and circulating peripheral blood mononuclear cells occasionally occurs,[154,155] and BRSV infection of macrophages decreases important functions of these cells including Fc receptor expression, phagocytosis, phagosome-lysosome fusion, and production of factors that induce neutrophil chemotaxis.[156,157] Infection leads to bronchitis, bronchiolitis, alveolitis, and sometimes AIP; these changes lead to clinical signs referable to small airway and alveolar disease (expiratory dyspnea, auscultable wheezing) and hypoxemia as evidenced by arterial blood gas analysis.[158]

The severity of disease after BRSV infection is related to host immunity. Both humoral and cell-mediated immunity contribute to protection. Clinical signs of infection are less severe in animals with moderate to high levels of serum antibody against BRSV,[159,160] and more extensive pathology is seen in calves depleted of $CD8^+$ T cells before infection.[161] Protection after intranasal vaccination is related to the rapidity in onset of nasal BRSV-specific IgA production,[162] indicating that mucosal immunity is likely also important in protection against naturally occurring disease. Host immunity after exposure to BRSV can minimize disease, and clinical signs are usually the most noticeable in calves under 6 months of age.[149,163] However, ruminants appear to be susceptible to reinfection with BRSV throughout their lives, and adult cattle can develop severe disease after BRSV infection.[149,150] Because genetic variability among BRSV isolates is not great, reinfection does not seem to be solely a result of viral strain variation. Although data investigating the duration of BRSV immunity after natural infection are limited, it appears that natural infection does not confer lifelong immunity, and some cattle may be reinfected annually,[164] although clinical signs are not always apparent.

While host immunity can protect ruminants from severe disease after BRSV infection, the host immune response can also contribute to disease. Evidence for BRSV immunopathogenesis comes from both natural outbreaks and experimental challenge studies. Cattle with severe disease after natural infection have a higher proportion of degranulated mast cells in their lungs than less severely affected cattle,[165,166] indicating that mast cell mediators contribute to physiologic and pathologic changes seen in severe cases. Serum tryptase, a preformed enzyme present in mast cell granules, was significantly increased in the serum of cattle experiencing severe naturally occurring BRSV infection,[166] also supporting a contribution of mast cells in

severe BRSV-induced disease. In experimentally challenged cattle, BRSV-specific IgE has sometimes been associated with disease severity.[167,168] Exposure to the fungus *Saccharopolyspora rectivirgula* (formerly *M. faeni*), the spores of which induce pulmonary hypersensitivity in cattle and other species, enhanced BRSV-specific IgE production in calves, indicating that environmental allergens can also affect the nature of the immune response to BRSV infection.[168] Recent research showed that calves infected with BRSV before infection with *Histophilus somni* developed higher levels of *H. somni*–specific serum IgE than did calves infected with *H. somni* alone.[169] Thus BRSV infection can lead to production of virus-specific IgE, which may be enhanced by coexposure to allergens, and BRSV infection may also increase IgE production in response to infection with other agents. In these cases, cross-linking of IgE bound to mast cells by binding of BRSV or other specific antigen is expected to lead to bronchoconstriction, pulmonary edema, and other signs of mast cell mediator release and immediate hypersensitivity.

Perhaps the most convincing evidence that BRSV can trigger immunopathogenesis is the fact that certain BRSV vaccines have on rare occasion been shown to cause enhanced disease when vaccinated animals are subsequently infected with BRSV. Vaccine-enhanced disease has been seen after both natural[170,171] and experimental[172,173] infection. Vaccine-enhanced disease has also occurred in human infants vaccinated with a formalin-inactivated RSV vaccine,[174] and formalin-inactivated BRSV vaccines have caused enhanced disease in some[172,174] but not all[158] studies. Inactivated BRSV vaccines have also been shown to prevent disease after infection[175,176]; therefore not all inactivated BRSV vaccines enhance disease. It appears that the dose of BRSV protein, the adjuvant included in the vaccine, and probably also other factors related to the formulation of the vaccine affect whether enhanced disease is likely after infection of cattle given a particular BRSV vaccine.[177] Apparent vaccine-enhanced disease has also been reported in cattle that received a modified live vaccine in the early stage of a natural BRSV outbreak.[170] It is important to note that BRSV vaccines are used very commonly, and vaccine-enhanced disease is very rare; thus vaccination is still recommended as part of any plan to control disease caused by BRSV. Many gaps exist in our understanding of what aspects of the immune response contribute to disease severity after BRSV infection or vaccination. Most research completed to date has focused on enhanced disease in calves that received formalin-inactivated BRSV. The data suggest that when enhanced disease occurs in calves vaccinated with formalin-inactivated BRSV, it is related to a relatively strong response by T helper type 2 (Th2) cells, as evidenced by decreased production of the Th1 prototype cytokine interferon gamma,[178] increased production of BRSV-specific IgE,[179] and pulmonary eosinophil infiltration.[173] The association of BRSV-specific IgE production with disease severity in some experimental studies indicates that at least some individual ruminants will produce IgE after BRSV vaccination or infection, which may contribute to severe disease in these individuals.

608

609

The presence of co-infection with other pathogens such as *M. haemolytica*[180] or bovine virus diarrhea (BVD) virus (BVDV)[181] can also increase the severity of disease after BRSV infection. Although genetic variation among BRSV isolates is not extensive, experimental challenge with certain isolates of BRSV can lead to serious disease,[158,182] whereas challenge with other isolates leads to only minimal disease.[183,184] This indicates that, in spite of limited differences among viral isolates at the genetic level, variation among BRSV isolates may still contribute to variations in disease severity.

31.56.9.4

Epidemiology

Prevalence of antibodies to BRSV in the cattle population of the United States ranges from approximately 60% to 80%.[151] The virus has been recognized in association with respiratory tract disease in nursing beef

calves, in dairy calves, and in cattle entering into feedlots. BRSV was demonstrated to be involved in 14% to 71% of respiratory disease outbreaks in North American and European studies of calf pneumonia outbreaks involving several farms.[185] Seroconversion to BRSV has been significantly associated with treatment for respiratory disease in feedlot cattle,[186,187] and cattle with low antibody titers to BRSV at feedlot entry have increased risk of developing disease.[186] Although feedlot cattle are commonly infected with BRSV after arrival, a recent survey of necropsy findings at 72 Canadian feedlots found BRSV at postmortem of only 11% of the cattle that died or were euthanized because of pneumonia.[188] The low rate of isolation at necropsy suggests that if the virus contributes to the development of pneumonia in feedlot cattle, it is often no longer present by the time the animal dies or is euthanized.

BRSV therefore represents an important virus in the bovine respiratory disease complex on the basis of its frequency of occurrence and predilection for causing infection of the lower respiratory tract. In general, morbidity rate tends to be high in outbreaks of BRSV, whereas case fatality rate is variable, ranging from none to as high as 20%.[185]

Cattle are most likely the principal reservoirs of infection, although a European serologic survey of different species found that goats were also often seropositive,[141] indicating that goats may be a source of BRSV infection for cattle, and vice versa. The mechanism by which BRSV persists in the cattle population is not known. Possibly a similar epidemiologic pattern to the one that has been described for HRSV also exists for BRSV. HRSV is capable of reinfecting the host throughout his or her life; however, severe lower respiratory tract disease occurs only in association with the initial exposure. Subsequent exposure results in mild upper respiratory tract disease. Similarly, adult cattle may periodically undergo subclinical to mild infections and serve as a source of infection for susceptible young stock. However, a recent study concluded that transmission among seropositive cattle was not a plausible mechanism of BRSV persistence in a dairy herd.[189] These authors suggested that persistent BRSV infection in individuals is a more plausible explanation of population persistence of BRSV. BRSV has been identified in B lymphocytes in tracheobronchial and mediastinal lymph nodes of calves 71 days after experimental infection,[190] so it may be that individual cattle harbor the virus long term and periodically begin shedding it, allowing it to periodically reappear in herds even if they are closed to new introductions. However, more research is needed before persistent infection is clearly proven to be a means by which BRSV remains established in herds.

31.56.9.5 Necropsy Findings

Grossly, BRSV infection can cause signs of AIP; therefore differential diagnoses for the typical gross lesions include other causes of AIP (see later discussion). Signs of AIP are most evident in the dorsocaudal lung; affected lung is heavy, with a rubbery texture, and fails to collapse when the thorax is opened. Individual lobules may appear dark, and interstitial or bullous emphysema is often present in the dorsocaudal lung in severe cases (Fig. 31-54). Pathologic emphysema must be differentiated from that sometimes caused by agonal breathing of cattle. Cranioventral lobes or lobules are often dark and collapsed because of atelectasis or consolidation (Fig. 31-55). Histologic lesions depend on the stage of infection. Neutrophilic and later mononuclear bronchitis, bronchiolitis, and alveolitis are present in infected animals. Syncytial cells may be seen in the airways or alveoli; intracytoplasmic inclusion bodies are rarely present.[149,160,182] Signs of AIP including alveolar epithelial hyperplasia, hyaline membrane formation, and interstitial inflammatory cell infiltrate, hemorrhage, and edema are seen in severe cases. Later, evidence of chronic bronchitis and bronchiolitis obliterans can be found.[149]

31.56.9.6

Diagnosis

Infection is diagnosed by identification of the virus in nasal secretions, tracheal aspirates, or lung lavage fluid from live calves or in lung tissue collected postmortem. BRSV is difficult to isolate as it does not survive transport well; thus methods of identification that do not require the virus to be alive (such as immunofluorescence, IHC, and RT-PCR) are preferable to virus isolation for the identification of BRSV. IHC of formalin-fixed tissue is convenient because the virus can be identified in tissue processed for histopathologic evaluation. If virus isolation is to be attempted from samples collected in the field, it is recommended that that veterinarian contact his or her diagnostic laboratory before collecting samples so that samples are collected and transported in ways that optimize likelihood of success. Although virus is readily identifiable in lung tissue of cattle early in the course of disease (within approximately 8 days of infection), virus is less likely to be found in lung tissue by 10 to 15 days postinfection, even when IHC is used.[153,172,182]

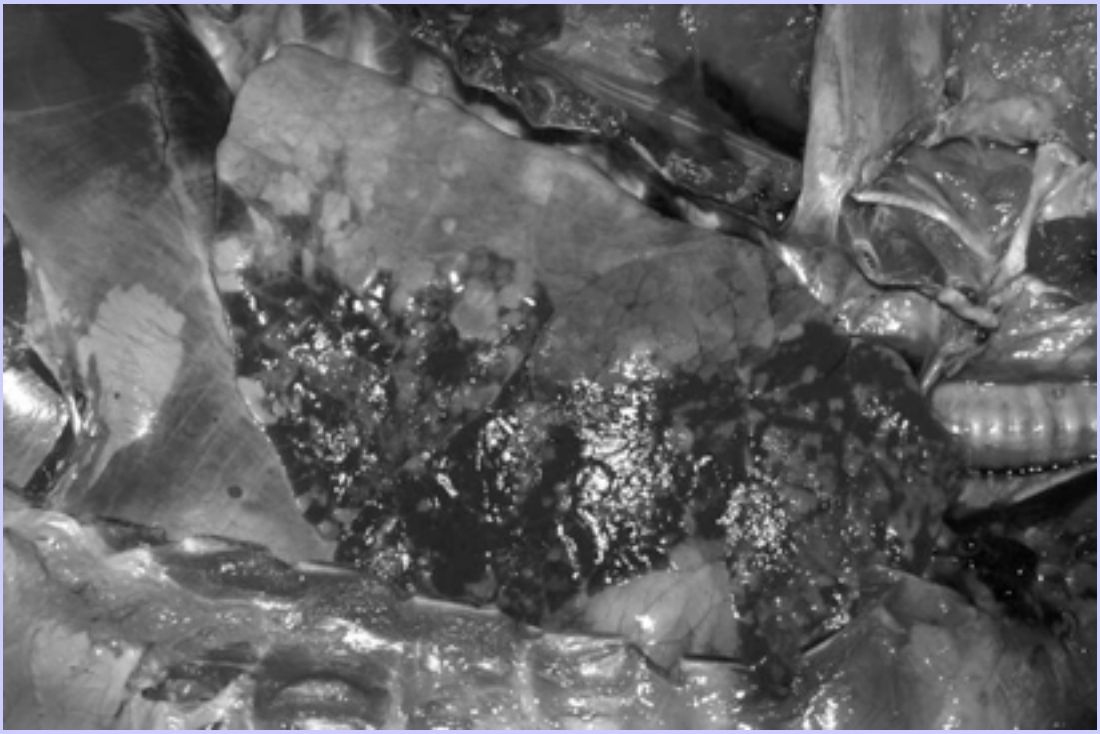
Fig. 31-55 Postmortem photograph of lungs from calf with severe BRSV infection. Photograph contributed by Dr. Laurel Gershwin, University of California, Davis, Calif.



Seroconversion as evidenced by paired serology also supports a diagnosis; virus neutralizing or ELISA assays are most commonly used to identify BRSV-specific antibody. Identification of BRSV-specific IgM in a single acute sample is also diagnostic,[191] but testing for BRSV-specific IgM may not be available at most diagnostic laboratories.

31.56.9.7

Treatment and Prevention

Treatment of BRSV is supportive and aimed at preventing secondary bacterial infection and limiting the inflammatory response in bronchioles and alveoli. Antimicrobial therapy appropriate for common secondary bacterial pathogens (see Table 31-10) is appropriate. Antiinflammatory therapy with NSAIDs (flunixin meglumine at 1.1 to 2.2 mg/kg IV daily or divided twice daily) is considered appropriate, but controlled studies of these drugs in animals with disease caused by BRSV are limited. Administration of one or two doses of steroid therapy (dexamethasone 0.05 to 0.2 mg/kg IV or IM once or twice) is appropriate in animals with severe respiratory distress or evidence of AIP. Intranasal oxygen insufflation is appropriate if available. Diuretic therapy with furosemide (0.5 to 1 mg/kg IM or IV once or twice daily) is warranted in animals suspected of having AIP. Although the prognosis for animals with uncomplicated BRSV infection is good, the prognosis for animals with AIP is guarded. Animals with severe respiratory distress should be handled with care, as even careful manipulation to administer treatment can lead to rapid respiratory decompensation and death.

Both modified live and inactivated BRSV vaccines for IM or SC administration are commercially available. Certain commercially available vaccines have been shown to protect calves against virulent experimental challenge.[175,176,192] Results of some well-designed trials of BRSV vaccine efficacy have also been published.[193–196] In some studies the effect of BRSV vaccination on all clinical respiratory disease (i.e., not only disease caused specifically by BRSV) was evaluated,[193,195,196] whereas in other studies protection against disease caused by BRSV was specifically evaluated by identification of clinical respiratory disease and simultaneous seroconversion to BRSV in vaccinated cattle.[194] Vaccination decreased all respiratory morbidity in some[195] but not other[193,195,196] groups of cattle evaluated. Vaccination decreased disease specifically caused by BRSV in large groups of calves if all calves in the group were vaccinated, but not if half of the calves in the group were vaccinated.[194] A recent large clinical trial evaluating the effect of vaccination of feedlot cattle with a modified live vaccine containing BHV-1, PI3, and BVDV, with or without BRSV, found that pens of cattle that received the vaccine including BRSV had lower overall morbidity and mortality and lower numbers of respiratory deaths than pens of cattle that received the vaccine that did not include BRSV.[196] There is no RSV vaccine licensed for use in small ruminants, and no controlled studies of the effects of extralabel administration of BRSV vaccines licensed for cattle on respiratory disease in sheep or goats have been published.

31.56.10 Bovine Virus Diarrhea Virus

BVDV is an enveloped RNA virus of the genus Pestivirus in the family Flaviviridae. A wide spectrum of disease has been associated with BVDV infection, including subclinical infection, bovine virus diarrhea and mucosal disease (see Chapter 32), immunosuppression, repeat breeding problems, abortion, fetal mummification (see Chapter 43), congenital defects, immunotolerance, and persistent infections. Only the contribution of this virus to respiratory disease is discussed here.

Historically the role of BVDV in the bovine respiratory disease complex has been controversial,[197–199] but more recent research provides good evidence that the virus contributes to bovine respiratory disease and related decreased productivity of cattle in the field in at least some cases.[200,201] Experimental challenge of cattle with BVDV alone leads to mild pneumonia,[202,203] and occasionally herd outbreaks of BVDV are first identified by the presence solely of signs that are likely to be interpreted as evidence of respiratory disease, such as fever, tachypnea, and loud bronchovesicular sounds.[204] Experimental infection studies have also shown that respiratory disease caused by *M. haemolytica*,[202] BHV-1,[205] or BRSV[181] is significantly more serious when cattle are co-infected with BVDV. This synergistic effect of BVDV with other respiratory pathogens is believed to be a result of immunosuppression caused by BVDV, which is discussed in detail in Chapter 32. The ability of BVDV to cause respiratory disease appears to depend in part on the strain of infecting virus.[203,206]

Although the results of experimental challenge studies show that BVDV can cause mild respiratory disease alone and can contribute to the development of more serious disease in combination with other pathogens, data from field cases of respiratory disease are generally considered of greatest relevance. Studies of naturally occurring bovine respiratory disease have shown that in some situations BVDV can be isolated from a majority of cattle affected with shipping fever pneumonia, particularly in association with *M. haemolytica*,[188,207] or in association with *Mycoplasma bovis* in animals with chronic pneumonia.[208,209] Seroepidemiologic studies have indicated an association of BVDV with respiratory disease in some but not all cases.[198,210] The most convincing data linking BVDV to respiratory disease has come from studies of calves purchased and assembled at sale barns for

shipment to feedyards across several states.[201] In 2 consecutive years BVDV was significantly more likely to be isolated from calves that were treated for respiratory disease than calves in the same group that were not treated; calves treated for respiratory disease were also significantly more likely to seroconvert to BVDV than penmates who were not treated for respiratory disease. The majority of BVDV isolates collected from calves in this study were BVDV type 1b. If this finding is representative of the BVDV isolates circulating in cattle throughout the United States, it could have important implications for the ability of vaccines to adequately protect cattle, as commercially available vaccines currently contain BVDV type 1a almost exclusively.[211] More research will be necessary to determine how frequently viral strains in BVDV vaccines will need to be updated so that they provide adequate protection from currently circulating strains.

In addition to contributing directly to bovine respiratory disease by infecting the respiratory tract and enhancing the pathogenicity of co-infecting bacteria or viruses, BVDV may also contribute to respiratory disease by impairing the ability of cattle to respond properly to vaccination against other respiratory pathogens. Calves infected with BVDV before BHV-1 vaccination shed BHV-1 longer after subsequent BHV-1 infection than calves that were not co-infected with BVDV.[212] In another study, calves persistently infected with BVDV failed to develop a serologic response to a *M. haemolytica* vaccine, in contrast to control animals not infected with BVDV.[213]

In summary, although the importance of BVDV in the bovine respiratory disease complex has previously been debated, recent research indicates that BVDV is significantly associated with the development of bovine respiratory disease in at least some cases. Whereas experimental challenge studies indicate that BVDV can cause at least mild respiratory disease when acting alone, the virus appears to contribute most importantly by impairing the host's ability to resist infection and limit disease caused by other pathogens that infect the animal at the same time or soon after BVDV infection occurs.

31.56.11 Parainfluenza Virus Type 3 of Cattle, Sheep, and Goats

31.56.11.1 Definition and Etiology

Parainfluenza virus type 3 (PI3) is an enveloped RNA virus classified in the family *Paramyxoviridae*. The virus has been associated with respiratory tract disease in cattle, sheep, and goats. It hemagglutinates and hemadsorbs red blood cells of certain species, which means that serum antibodies can be identified by hemagglutination inhibition assays. Variation in virulence among strains of PI3 has been reported.[214] Significant similarities between bovine PI3 and human PI3 have led to efforts to use bovine PI3 as a modified live intranasal vaccine for humans; bovine PI3 was found to be safe and immunogenic in a clinical trial in human infants.[215]

31.56.11.2 Clinical Signs

Uncomplicated PI3 infections result in subclinical to mild signs. Clinical signs, if present, may include fever, cough, nasal and ocular discharge, increased respiratory rate, increased bronchovesicular sounds, and wheezes.[216–218] The most important role of PI3 is in predisposing the respiratory tract to subsequent infection by other viruses and bacteria such as *Mannheimia (Pasteurella) haemolytica*.[219] Severity of signs increases with the development of secondary bacterial pneumonia, and if death occurs it is usually the result of secondary bacterial infection. Infection with PI3 is widespread in sheep and goats.[220–221] Only one serotype of ovine PI3

has been identified, and it is related to but distinct from the bovine strain. Most infections are inapparent to mild.

31.56.11.3 Pathogenesis

Infection with PI3 can lead to signs referable to both upper and lower respiratory tract infection. After experimental infection of calves, clinical signs are evident by 2 days postinfection, and signs peak 4 days postinfection. Virus is found in the nasal passages, trachea, and bronchiolar and alveolar epithelial cells. The virus damages the pulmonary mucociliary apparatus[222] and depresses several important functions of alveolar macrophages such as Fc receptor expression, phagocytosis, and microbicidal activity,[223] which are important in predisposing infected animals to secondary bacterial pneumonia.

31.56.11.4 Epidemiology

The widespread prevalence of antibodies to this virus indicates that it commonly circulates in ruminant populations.[191,221,224] This finding suggests the possibility of repeat infections or at least the persistence of antibodies after infection. Inapparent or subclinical infections with PI3 are common; in one report, 28 groups of calves seroconverted to PI3 over 8 months, but respiratory disease was seen in association with PI3 infection in only four of these groups.[225] Although infection can often be inapparent, if environmental and managerial practices are suboptimal, PI3 may become an important initiator of respiratory tract disease. Infection appears to spread rapidly in susceptible cattle housed at high population densities and in close contact. In seroepidemiologic surveys evaluating groups of calves in herds experiencing outbreaks of respiratory disease, seroconversion to PI3 has been associated with 14% to 38% of outbreaks evaluated.[111,112,226] In some surveys PI3 is the virus most commonly isolated from the lungs of calves that die or are euthanized because of pneumonia.[227] Feedlot cattle commonly seroconvert to PI3 soon after feedlot arrival, and seroconversion has been associated with treatment for respiratory disease in some[186] but not all[187] cases. In spite of the fact that feedlot cattle frequently become infected with PI3 after feedlot entry, a recent survey of necropsy findings at 72 Canadian feedlots found PI3 at postmortem examination of only 4% of the cases with pneumonia.[188] The low rate of isolation at necropsy suggests that if the virus contributes to the development of pneumonia, it may no longer be present by the time the animal dies or is euthanized.

31.56.11.5 Necropsy Findings

Lesions of PI3 infection alone are rarely seen during postmortem examination. Experimental PI3 infection results in congestion of the respiratory mucosa, swelling of lymph nodes associated with the respiratory tract, and lobular consolidation concentrated in the cranioventral lung.[218,219] Bronchiolitis and alveolitis are seen histologically with both proliferative and degenerative changes in the epithelial cells of the bronchioles and alveoli. Syncytia and intranuclear and intracytoplasmic inclusion bodies may be seen.[218,219] In many respects, pathologic features of PI3 infection are similar to those caused by BRSV, although the lesions produced by the latter are generally more extensive.

31.56.11.6 Diagnosis

PI3 can be isolated from nasal swabs of infected animals. Unlike BRSV, which is also in the paramyxovirus family, PI3 is not particularly difficult to isolate. Diagnosis can also be confirmed with paired serology, with hemagglutination inhibition or virus neutralizing assays most commonly used.

611

612

31.56.11.7 Treatment and Prevention

There is no specific treatment for infection with PI3; as for other respiratory viruses of ruminants, administration of appropriate antibiotics to prevent secondary infection with likely bacteria is recommended. As for any viral respiratory tract infection, supportive care is indicated, such as providing readily available good-quality feed and water and avoiding or postponing additional stressors such as movement or mixing of animals. Both inactivated and modified live PI3 vaccines are available for parenteral administration, and modified live PI3 vaccines are available in combination with BHV-1 for intranasal administration; these vaccines are labeled for use in cattle but not in sheep or goats. A univalent modified live intranasal PI3 vaccine is available in Europe.[218] Experimental challenge studies have shown that both parenteral and intranasal vaccines can decrease viral shedding and clinical signs after challenge.[216–218,228] No field trials have specifically evaluated the effect of PI3 vaccines to decrease respiratory disease. One study reported that a modified live BHV-1/PI3 vaccine licensed for use in cattle decreased clinical signs and viral shedding when administered before experimental challenge of sheep, but the vaccinated sheep also appeared to become latently infected with BHV-1.[228] The investigators noted that induction of latent BHV-1 infection could be an important negative side effect of vaccination, as sheep could theoretically spread BHV-1 to other in-contact ruminants, such as cattle. Although the practice appears to occur commonly, administration of BHV-1/PI3 vaccines to sheep or goats constitutes an extralabel use of these products.

31.56.12 Bovine Coronavirus

Coronaviruses are enveloped, single-stranded positive sense RNA viruses of the family Coronaviridae. Bovine coronavirus is a major cause of calf diarrhea and has also been implicated as a cause of winter dysentery in cattle. Although it has been known for some time that bovine coronavirus can infect the respiratory tract of calves,[229] the practical relevance of this agent as a respiratory pathogen has been debated. However, evidence is accumulating that bovine coronavirus may be an important contributor to outbreaks of respiratory disease in some cases.

One reason for the lack of awareness regarding a role for coronavirus in respiratory disease may be the fact that standard cell lines used for isolation of other respiratory viruses are often not permissive to bovine respiratory coronavirus infection. Thus, coronavirus may not be isolated if only standard cell lines are used to attempt to isolate viruses from cattle experiencing respiratory disease. Bovine respiratory coronavirus can readily be recovered by using human rectal tumor-18G cell lines.[230] An antigen-capture ELISA and a sensitive RT-PCR assay have also been developed for identification of the virus.[231] It is not yet clear whether the coronaviruses that have been associated with respiratory disease in cattle are different in important ways from the coronaviruses that cause enteric disease; studies comparing biologic and antigenic properties of enteric and respiratory isolates have yielded mixed results.[232,233]

An association of coronavirus with two naturally occurring outbreaks of shipping fever was described in a well-detailed report.[234] In these outbreaks, which were characterized by high morbidity and mortality, coronavirus was isolated from the nasal passages of over 80% of the cattle in the early stages of the outbreaks. No other respiratory viruses were identified in most of the cattle, but *M. haemolytica* was also isolated from a majority of cattle as the two epizootics progressed. A few cattle with high serum antibody titers against coronavirus at feedlot arrival did not shed the virus. However, a clear causative role for coronavirus was difficult to identify because so few cattle remained healthy that it was apparently not possible to find a difference in viral shedding or seroconversion in animals that had respiratory disease versus those that did not. In a separate report the researchers used Evans's criteria of causation, which have been suggested as more appropriate than Koch's postulates for evaluation of causative factors in complex diseases such as the bovine respiratory disease complex, to support a causative role for coronavirus in the outbreaks they studied.[235] Other researchers attempting to confirm or refute an important causative role for coronavirus in bovine respiratory disease have nearly always found the virus when calves are sampled soon after feedlot entry.[231,236,237] Moreover, it is very common for a majority of cattle to have antibody titers to the virus at feedlot arrival or to seroconvert soon after feedlot entry; therefore it is clear that cattle are often infected with the virus at times when respiratory disease is likely to occur.[231,236,238] However, the importance of the virus in causing respiratory disease has still been debated[238] because seroconversion has not been significantly associated with treatment for respiratory disease or with decreased weight gain during the feeding period.[238–240] One group did find that cattle shedding coronavirus from the respiratory tract soon after feedlot entry were significantly more likely to have pneumonia at slaughter as compared with cattle not shedding the virus.[240] Another group found that vaccinating calves intranasally with a modified live coronavirus and rotavirus vaccine commercially marketed to decrease diarrhea caused by these viruses (i.e., an extralabel use of the vaccine) significantly decreased the subsequent rate of treatment for respiratory disease in cattle that had relatively low serum antibody titers against coronavirus at arrival.[237] These studies provided direct or indirect evidence that coronavirus caused respiratory disease in the cattle under study.

In summary, some of the currently available data support an important role for coronavirus in contributing to the bovine respiratory disease complex, but other data do not. In this regard coronavirus is similar to other infectious agents, which can be identified as important players in some outbreaks studied but not identified at all in others. More research would be useful to better characterize the relevance of bovine respiratory coronavirus as a respiratory pathogen. Currently no vaccines are commercially marketed for the prevention or control of respiratory disease caused by bovine respiratory coronavirus infection.

31.56.13 Malignant Catarrhal Fever Virus

The African (wildebeest-associated) form of malignant catarrhal fever (MCF) is caused by alcelaphine herpesvirus types 1 and 2. A causative agent for the American (sheep-associated) form is believed to be ovine herpesvirus type 2. The occurrence of MCF in the cattle population is sporadic. There is multisystemic involvement, including involvement of the respiratory tract. MCF is discussed in detail in Chapter 32.

31.56.14 Bovine Herpesvirus Type 4

The bovine type 4 herpesviruses are serologically distinct from other herpes viruses such as BHV-1 and BHV-2 (bovine mammillitis).[94] Although the level of antibody prevalence to BHV type 4 (BHV-4) is high in the cattle population of the United States, the pathogenic role of this virus remains unclear. It has been implicated in several disease conditions of cattle, including respiratory tract disease, reproductive disorders (abortions and

metritis), mammillitis, and enteric disease.[241] It has also been isolated from apparently healthy cattle. Several of these viruses (DN-599, Movar 33/36, FTC-2) have been isolated from cattle with respiratory tract disease. Intranasal inoculation of DN-599 into calves produced respiratory disease, but the importance of this group of viruses in the bovine respiratory disease complex is poorly defined. Currently they are not thought to be important enough to warrant vaccine development.

31.56.15 Adenoviruses of Cattle, Sheep, and Goats

Adenoviruses are nonenveloped double-stranded DNA viruses of the family Adenoviridae. Ten serotypes of bovine adenovirus (BAV) are currently recognized.[242] BAV infection is widespread and is frequently subclinical[243,244]; adenoviruses are also often isolated in association with other viruses and bacteria,[94,243] making it difficult to assign causation in naturally occurring disease outbreaks. Adenoviruses have been associated with pneumonia, enteritis, conjunctivitis, keratoconjunctivitis, and "weak calf syndrome."[245] When calves develop pneumonia and enteritis at the same time ("pneumoenteritis"), adenoviral infection should particularly be considered as a possible cause.[94]

Six antigenic types of ovine adenovirus and two types of caprine adenovirus have been identified.[246] Little information concerning the incidence and distribution of adenovirus infection in the sheep and goat population is available; however, it appears likely that this virus causes widespread infection.[247] A study in Iowa reported that adenovirus infections were widespread in the sheep population and that the prevalence of active infection based on seroconversion rates was approximately 45%.[247] The majority of isolations of this virus have been from young lambs, and it has been isolated in association with respiratory and enteric disease. Experimental infections result in mild disease with anorexia, pyrexia, increased respiratory rates, coughing, and diarrhea. Gross lesions observed include atelectasis, edema, and consolidation of the lungs.[248] Ovine adenovirus serotype 6 has been shown under experimental conditions to act synergistically with *Mannheimia (Pasteurella) haemolytica* in the production of pneumonia in lambs.[249]

31.56.16 Bovine Rhinovirus

Bovine rhinovirus is a nonenveloped single-stranded RNA virus in the family Picornaviridae. Two serotypes of bovine rhinovirus are officially recognized.[94] Infection with this virus appears to be widespread in the cattle population. By 10 to 12 months of age virtually 100% of beef and dairy cattle in Missouri are seropositive to rhinovirus.[250] Clinical signs of rhinovirus infections range from inapparent signs to fever, depression, decreased appetite, increased respiratory rate, lacrimation, conjunctivitis, salivation, coughing, and nasal discharge. Little research is available that characterizes the relative importance of rhinovirus in the bovine respiratory disease complex.

31.56.17 Bovine Reovirus

Bovine reovirus is a nonenveloped, double-stranded segmented RNA virus in the family Reoviridae. Three mammalian serotypes are recognized. Reoviruses have been isolated from the respiratory and digestive tracts of apparently healthy cattle. Infections appear to be common in cattle, and bovine isolates are antigenically identical to human serotypes. The importance of reovirus infections in bovine respiratory tract disease is unclear. Subclinical infections appear to predominate under field conditions.

31.56.18 Bovine Enterovirus

Enteroviruses are nonenveloped single-stranded positive sense RNA viruses in the family Picornaviridae. Over 60 strains of bovine enterovirus have been isolated from the respiratory, reproductive, and digestive tracts of cattle. The majority of these isolates have been obtained from healthy animals, although isolations have been made from cattle in association with abortions, enteritis, and respiratory disease. In general, infections with enteroviruses are common and transient and usually not considered to be pathogenic.

31.56.19 Calicivirus

A calicivirus has been isolated from dairy calves from a herd with a persistent respiratory disease problem.[251] This virus caused only minimal disease in experimentally infected calves, but a persistent infection was produced.

31.56.20 Influenza

Influenza virus has not historically been considered to cause naturally occurring respiratory disease in ruminants in North America. However, it is possible to experimentally infect cattle with influenza,[252] and a report from England describes several cattle that seroconverted to human influenza A virus during outbreaks of clinical respiratory disease and decreased milk production in dairy cattle.[253] Antibodies from the cattle reacted most strongly with a human H1N1 virus (A/England/33/80) and a human H3N2 virus (A/England/427/88). Retrospective analysis of banked serum samples also identified measurable antibody titers to human influenza in 49% to 59% of samples tested, with several sets of paired sera taken from animals during respiratory disease outbreaks showing evidence of seroconversion, with relatively high virus neutralizing antibody titers.[253,254] Attempts were made to isolate influenza virus from cattle with signs of respiratory disease but were not successful.[254] It was not possible to rule out other more recognized causes of bovine respiratory disease in the outbreaks in which cattle seroconverted to influenza, so it has not been proven conclusively that influenza is a significant contributor to naturally occurring bovine respiratory disease. However, the relatively high rate of seropositivity seen in cattle in England suggests that the virus may commonly circulate among cattle in at least a subclinical form, and thus cattle may be a significant reservoir of virus that could infect other species. More research is necessary to determine the significance of influenza infection in cattle and other ruminants. More information about influenza virus is presented in the section on equine influenza on p. 543.

31.57 BACTERIAL AND CHLAMYDIAL AGENTS

31.57.1 Mannheimia Haemolytica

31.57.1.1 Definition and Etiology

M. haemolytica (formerly *Pasteurella haemolytica*) is a gram-negative aerobic bacteria of the family *Pasteurellaceae*. There are at least 12 serotypes of *M. haemolytica*, and some ruminant isolates are untypable with currently available laboratory tools. Five serovars previously classified as *M. haemolytica* have been determined to be separate species and have been reclassified as *Pasteurella trehalosi* or *Mannheimia*

glucosida.[255,256] *P. trehalosi* causes pneumonia or systemic disease with multiorgan infection in sheep,[257] whereas *M. glucosida* is a low virulence opportunistic pathogen of sheep.[258] Some serotypes of *M. haemolytica* are pathogenic, whereas others are nonpathogenic commensals of the ruminant nasopharynx, and the serotypes that are pathogenic for cattle are not the same as those that are pathogenic for sheep or goats.[259–261] Serotype A1 is the most common isolate from pneumonic lungs of cattle, and serotype A6 is the next most common[262,263]; serotype A2 is the most common isolate from the nasopharynx of normal cattle.[264] Serotype is also relevant to pathogenicity of isolates from sheep and goats; both *M. haemolytica* and *P. trehalosi* can be isolated from the nasopharynx of normal small ruminants,[265] but *M. haemolytica* serotype A2 is the most common isolate from sheep and goats with pneumonia, and serotypes A7, A9, and several others have also been associated with disease.[259,261,266]

613

614

31.57.1.2

Clinical Signs

Cattle, sheep, or goats infected with *M. haemolytica* display a dull or depressed attitude and lose interest in eating. Fever, tachypnea, and depression are often the only abnormal signs early in the course of infection[267–269]; coughing is not a prominent sign in the acute stage of disease[268,269] unless co-infection with another agent such as BHV-1 or BRSV is present. Animals may display evidence of thoracic pain, such as standing with elbows abducted or catching the breath before expiration; these signs are a result of the painful fibrinous pleuritis caused by *M. haemolytica*. Because *M. haemolytica* is a gram-negative organism, endotoxin (lipopolysaccharide) is produced by the agent, and thus cattle with mannheimiosis may show signs of endotoxemia, including fever, tachycardia, tachypnea, salivation, respiratory distress, pale or dark mucous membranes with prolonged capillary refill time, and cool extremities. Thoracic auscultation may reveal harsh or loud bronchovesicular sounds consistent with pulmonary consolidation,[268] particularly over the cranioventral lung. Disease after *M. haemolytica* infection can be fatal, particularly if it is not treated; it can also lead to chronic pneumonia associated with secondary invasion with agents such as *P. multocida, Mycoplasma bovis*, or *Arcanobacterium (Actinomyces) pyogenes*.

It is important to remember that naturally occurring disease caused by *M. haemolytica* is commonly preceded by infection with a viral agent such as BHV-1, BRSV, or BVD; therefore the clinical signs described previously for these and other respiratory viruses may also be present in animals infected with *M. haemolytica*.

31.57.1.3

Pathogenesis

M. haemolytica is a normal inhabitant of the nasal pharyngeal mucosa,[96,265] but not the lung, and is considered an opportunistic pathogens. Calves and lambs become infected at an early age and carry *Pasteurella* as a minor part of the upper respiratory tract flora. Only a small percentage of nasal swabs yields positive results for *M. haemolytica* serotype A1 in healthy, unstressed calves,[270] but if several areas of the nasal mucosa are cultured at necropsy, it is often possible to isolate *M. haemolytica* from animals that previously had negative findings on nasal swabs.[271] The stress of transportation or viral infection causes a breakdown of the defense mechanisms that hold the nasal mucosa infections in check, resulting in a rapid proliferation of virulent *M. haemolytica* serotype A1. A greater number of calves will yield positive nasal mucosa swab *M. haemolytica* results during and after transport, and there is a large increase in the numbers of *M. haemolytica* in positive samples.[270,272] BHV-1 and PI3 viruses have been shown to have the same effect as transportation on *Pasteurella* populations of the nasal mucosa. *M. haemolytica* has been demonstrated in the tracheal air of stressed, healthy calves harboring the organism on their nasal mucosa. Some of these inhaled

organisms are deposited deep within the lung and normally are cleared within hours. But under conditions of impaired pulmonary defenses caused by stress, nutritional deficiencies, or preexisting viral infection, *M. haemolytica* is able to proliferate rapidly within the lung and with the aid of its virulence factors and toxins to produce a severe lobar necrotizing fibrinous pleuropneumonia. Calves infected with respiratory viruses, including BHV-1, PI3, BVDV, and BRSV, or *Mycoplasma* species have increased susceptibility to severe bronchopneumonia when exposed to *M. haemolytica*.[96] Similarly, infection of lambs with PI3 or adenovirus followed in several days by *M. haemolytica* causes severe pneumonia.[220,273]

Once *M. haemolytica* becomes established in the lungs, interactions between the bacteria and the host defenses result in tissue damage and elimination of the invader. A major virulence factor of *M. haemolytica* is an exotoxin that is lethal to ruminant leukocytes, the leukotoxin. Leukotoxin, which is produced by *M. haemolytica* during the logarithmic phase of growth, causes cytolysis of ruminant platelets, lymphocytes, macrophages, and neutrophils.[274] There is diversity in the gene encoding the leukotoxin molecule among *M. haemolytica* serotypes, and genetic diversity is related to differences in toxicity. For example, the leukotoxin encoded by some pathogenic bovine serotype A1 strains differs from the leukotoxin encoded by ovine A1 strains by only one amino acid but is substantially more toxic for bovine leukocytes than for ovine leukocytes.[260] Leukotoxin binds to cells via CD18, the beta subunit of the β_2 integrins CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and CD11c/CD18 (CR-4)[275,276]; although leukotoxin can bind to cells from nonruminant species, only ruminant cells are killed by the toxin.[274] Contact with leukotoxin increases expression of LFA-1 on ruminant leukocytes, making the cells even more sensitive to injury by leukotoxin.[277] At low concentrations, leukotoxin induces leukocyte death by apoptosis, whereas at higher concentrations the toxin causes cell lysis.[278] *M. haemolytica* expressing a mutant nontoxic leukotoxin induced less lung pathology in calves as compared with *M. haemolytica* producing functional toxin, but clinical signs were not different between the two groups of calves, indicating that leukotoxin is not the only virulence factor of importance in causing disease.[279]

Another virulence factor that certainly contributes to disease resulting from *M. haemolytica* is lipopolysaccharide, or endotoxin. As in all species, exposure of ruminants to endotoxin from gram-negative bacteria induces a multitude of responses leading to inflammation, including initiation of the complement and coagulation cascades, activation of endothelial cells and recruitment of neutrophils, and activation of neutrophils and alveolar macrophages, leading to their production of proinflammatory cytokines, which further amplify the inflammatory response. The proinflammatory cytokines TNF-α, IL-1β, and IL-8 are expressed in the lungs of cattle within 48 hours of *M. haemolytica* infection.[280] Calves exposed to a preparation containing *M. haemolytica* endotoxin develop leukopenia, fever, tachypnea, diarrhea, and dyspnea as early as 2 hours after exposure.[281] Endotoxin potentiates the effects of leukotoxin by inducing increased expression of β_2-integrins on leukocytes, which contain CD18, the receptor for leukotoxin.[277,282] Bovine alveolar macrophages first exposed to endotoxin were susceptible to death induced by concentrations of leukotoxin too low to cause cell death alone; and macrophages exposed to both endotoxin and leukotoxin produced more of the proinflammatory cytokines IL-8 and TNF-α than did macrophages exposed only to leukotoxin.[282] These data indicate that leukotoxin and endotoxin work in synergy to cause disease in ruminants. The production of IL-8 is of particular importance, because IL-8 is a major inducer of neutrophil chemotaxis.[283] The massive influx of neutrophils induced by IL-8 and other inflammatory mediators is a key factor in lung tissue destruction caused by *M. haemolytica*. Calves experimentally depleted of neutrophils are completely protected from gross and microscopic lesions of the severe fibrinonecrotic bronchopneumonia that is induced by intratracheal inoculation of *M. haemolytica* in calves with normal neutrophil levels.[284] Lysis of

neutrophils results in the release of lysosomal products, including elastase, collagenase, and reactive oxygen intermediates. These chemicals are bactericidal but also capable of destroying the neutrophils themselves and surrounding tissues. Neutrophil-mediated damage to the endothelial cells results in exudation and thrombosis, which produce the classic lesions of necrosis and fibrinous exudation.[285]

In addition to leukotoxin and endotoxin, *M. haemolytica* possesses other factors that contribute to its virulence. The bacteria have a polysaccharide capsule that aids in attachment and prevents phagocytosis by neutrophils,[286] and iron-regulated outer membrane proteins (IROMPs) that bind transferrin and alter the function of neutrophils.[287,288] The bacteria produce adhesions that mediate attachment to host cells,[289] and neuraminidase produced by the bacteria may aid in host colonization by decreasing the viscosity of respiratory mucus[290] and decreasing the repellant negative charge on host cells by cleaving sialic acid residues.[291]

31.57.1.4

Epidemiology

In many studies over several decades, *M. haemolytica* has been found to be the most common bacterial isolate from feedlot cattle with fatal fibrinous bronchopneumonia.[188,292–296] *M. haemolytica* was isolated postmortem from 25% to 30% of cattle that died or were euthanized because of pneumonia in two studies evaluating causes of mortality in feedlot cattle.[188,296] Seroconversion to *M. haemolytica* or *M. haemolytica* leukotoxin has been significantly associated with treatment for respiratory disease or "undifferentiated fever" in feedlot cattle in some[186,297] although not all[298] studies. Booker and colleagues found that the odds of developing undifferentiated fever (case definition similar to that usually used for undifferentiated respiratory disease) was 2.8 times greater for cattle that developed a fourfold rise in antibody titer to *M. haemolytica* leukotoxin, as compared with cattle that did not seroconvert to leukotoxin.[297] And whereas O'Connor and co-workers found no association between seroconversion to *M. haemolytica* and treatment for undifferentiated respiratory disease, they did find that vaccination against *M. haemolytica* was significantly associated with protection against the development of undifferentiated respiratory disease in feedlot cattle in their study, which indirectly indicated a role for *M. haemolytica* in the development of respiratory disease.[298] Although *M. haemolytica* is recognized as the bacteria most commonly contributing to fibrinous pneumonia in feedlot cattle, one study that used BAL to identify bacteria present in the lungs of feedlot cattle before antimicrobial treatment for acute pneumonia found that *M. haemolytica* was not identified more frequently in the lungs of cattle with pneumonia than normal controls, whereas *P. multocida* was significantly associated with bronchopneumonia.[299] In the study by Allen and colleagues, none of the calves died or were euthanized because of the naturally occurring disease, indicating that disease was not severe. Because *M. haemolytica* is relatively more likely to cause acute fatal pneumonia than other bacterial pathogens of the ruminant lung, it may be overrepresented in necropsy surveys in which only fatal cases of disease are sampled.

In contrast to the situation in feedlot cattle, *M. haemolytica* is not commonly associated with outbreaks of pneumonia in calves. At postmortem examination of 43 calves from 34 outbreaks of respiratory disease, *M. haemolytica* was isolated from only two calves[111]; in another study, *M. haemolytica* was isolated from calves in 4 of 14 outbreaks of respiratory disease.[112] Although *M. haemolytica* is not as commonly isolated from calves as are other bacterial pathogens, it can be a cause of fatal disease; in one study, only *M. haemolytica* was significantly more often isolated from calves with fatal pneumonia as compared with calves with subclinical pneumonia.[300]

31.57.1.5

Necropsy Findings

Infection with *M. haemolytica* causes fibrinopurulent bronchopneumonia (Fig. 31-56). The infection is aerogenous, so disease occurs primarily in the cranioventral lung, but in severe cases, a majority of the lung may be affected. Affected areas of lung are dark red to purple or gray-brown (Fig. 31-57), firm, and heavy; discolored areas may be wedge-shaped owing to thrombosis of a vessel supplying the affected region during the severe inflammatory response (Fig. 31-58). The interlobular septa are expanded by clear to yellow gelatinous material that represents proteinaceous fluid that has leaked from blood vessels in the lung. The inflamed areas of lung are covered with yellow fibrin that may adhere to the pleura of the thoracic wall, and the pleural cavity usually contains straw-colored fluid, which may be voluminous.[267–269] In cases that have been ongoing for a few days, firm, gritty lumps that are dry and crumbly on sectioning may be identified; these represent areas of necrotic tissue.[269] Bronchial lymph nodes may be swollen, wet, and dark red. Histologically, alveoli are filled with edema and fibrin, and there is massive infiltration of neutrophils and macrophages. “Oat cells” can be seen, which are necrotic leukocytes with streaming of the chromatin.[188] Foci of coagulative necrosis are often found rimmed by a basophilic border of leukocytes; coagulative necrosis may expand to fill entire lobules. Hemorrhage is often present both within and between alveoli, and an occasional vessel may be found to contain a thrombus. Interlobular septa and lymphatics can be found dilated with edema and fibrin. Bronchioles are filled with leukocytes and may have foci of epithelial necrosis.[188,268,269] *M. haemolytica* may also produce pneumonia characterized by firm, dark red pulmonary consolidation without fibrinous pleuritis; this is especially common in dairy calves or sheep and goats. Animals that survive the acute stage of pneumonia caused by *M. haemolytica* may have multiple abscesses and pleural adhesions; in these cases other bacteria such as *P. multocida, Mycoplasma bovis*, or *Arcanobacterium (Actinomyces) pyogenes* may be contributing to pathology.

31.57.1.6

Diagnosis

Diagnosis of pneumonia due to *M. haemolytica* is most reliably made by culture of lungs with typical gross pathology at postmortem evaluation of animals that die or are euthanized as representative cases in outbreaks. Antemortem diagnosis in individual animals can be made by collecting fluid by transtracheal aspiration (TTA) or BAL and submitting the fluid for aerobic bacterial culture. These methods are not practical for widespread use in the field, but they may be warranted for valuable individual animals or to identify the cause of an outbreak of respiratory disease in several animals. Cytologic evaluation of TTA or BAL samples would be expected to reveal septic purulent inflammation characterized by large numbers of neutrophils that may be degenerate, exhibiting toxic change, and possibly containing intracellular bacteria. Thoracocentesis can be a useful diagnostic procedure to identify fluid accumulation in the thorax; fluid collected shows a high percentage of neutrophils with a high (>3 g/dL) total protein content if bacterial pleuropneumonia is the cause of fluid accumulation. Pleural fluid collected by thoracocentesis can also be submitted for aerobic bacterial culture to confirm infection with *M. haemolytica*. In a hospital with the necessary equipment, transthoracic ultrasound evaluation can be used to confirm the presence of consolidated lung tissue and pleural effusion with fibrin.[301] Thoracic radiography, if possible, is expected to show evidence of consolidation of the cranial lung and possibly pleural fluid accumulation.[302] Evidence of pneumonia identified by either radiography or transthoracic ultrasound evaluation has been shown to correlate strongly with findings on postmortem examination of calves with bacterial bronchopneumonia.[301,302]

Collecting bacteria by nasal swabs could be a reliable means of diagnosis if *M. haemolytica* isolated from swabs can be serotyped,[303] but because nonpathogenic *M. haemolytica* can be present in nasal passages of normal animals and can be distinguished only by serotyping, simple identification of the bacteria in nasal swabs as identified by culture is not diagnostic.

Serologic tests can be used to identify serum antibodies to *M. haemolytica*, and seroconversion identified by paired serologic testing could be used to confirm infection with *M. haemolytica* in one or more ruminants. However, these tests are most commonly used for research applications, and they may not be available at all diagnostic laboratories.

31.57.1.7

Treatment and Prevention

Treatment of *M. haemolytica* requires administration of an antimicrobial effective against the organism. Many antimicrobials are currently labeled for the treatment of *M. haemolytica* (see Table 31-10). The decision to choose any one of the many approved products is based on multiple factors including regional susceptibility of *M. haemolytica* isolates, the number of times it is possible to treat animals, withdrawal times, and cost. See the discussion on pp. 630–633 for further information on treatment of bacterial bronchopneumonia.

In addition to appropriate antimicrobial therapy, treatment to prevent the adverse effects of endotoxin should be considered for ruminants suspected or confirmed to have pneumonia caused by *M. haemolytica*. The NSAID flunixin meglumine can ameliorate the inflammatory response to endotoxin, and treatment with flunixin meglumine has been shown to improve outcome in individual animals infected with *M. haemolytica*. However, administration of NSAID drugs such as flunixin meglumine has not been shown to be reliably cost-effective in the treatment of large numbers of feedlot cattle with respiratory disease. Thus a consideration of the value of the animals treated may be necessary before NSAID therapy can be justified in an entire group of calves.

Prevention of infection and disease caused by *M. haemolytica* is approached by three avenues: administering antimicrobials prophylactically to animals at high risk of disease; increasing host immunity by ensuring adequate passive transfer and administering vaccines against *M. haemolytica*; and minimizing factors such as viral respiratory tract infection, mixing of animals from various sources, and long-distance shipment, which increase the susceptibility of animals to infection and disease caused by pathogenic serotypes of *M. haemolytica*.

Prophylactic or metaphylactic administration of antimicrobials effective against *M. haemolytica* is a reliable means of decreasing morbidity and mortality associated with respiratory disease in calves at high risk for disease because of recent weaning, uncertain immune status, mixing with cattle from a variety of sources, and long-distance shipment. Administration of tilmicosin to groups of such high-risk calves either before shipment or on arrival at feedlots decreased the proliferation of *M. haemolytica* serotype A1 in the nasopharynx of calves and was associated with decreased treatment for respiratory disease as compared with calves not treated with tilmicoson.[304] In a later study, administration of florfenicol at arrival decreased colonization of the nasopharynx with *M. haemolytica* A1 and delayed treatment for respiratory disease.[270] Further discussion of the role of metaphylactic administration of antimicrobials to control bovine respiratory disease can be found on p. 639.

616

617

Mixing recently weaned calves from multiple sources and shipping them long distances is a well-known precursor to outbreaks of fibrinous pneumonia[305]; and because *M. haemolytica* is the species of bacteria most

commonly associated with fatal fibrinous pneumonia, it follows that efforts to minimize stresses and improve immunity for calves moving through the marketing chain should lessen disease caused by *M. haemolytica*. Recent studies have indicated that preconditioning, wherein vaccination and stressful procedures such as weaning and castration are carried out well in advance of mixing and shipment, can decrease costs associated with fibrinous pneumonia in feedlot cattle.[306] However, preconditioning should not be considered a guarantee against all respiratory disease; disease that is sometimes severe can occur in preconditioned calves. Further discussion of the role of preconditioning to prevent bovine respiratory disease is continued on p. 638.

Vaccination can be used as part of a plan to decrease disease caused by *M. haemolytica*. Many experimental and commercially marketed vaccines have been tested for efficacy in preventing either disease resulting from experimental infection with *M. haemolytica* or naturally occurring respiratory disease, and the published literature is too extensive to describe in detail here. In summary, some research indicates that vaccination can lessen disease, other research shows that vaccination has no effect, and a few older reports show that *M. haemolytica* vaccination can enhance disease after infection.[307] Although commercially marketed vaccines are tested for safety, and no published reports exist that describe enhanced disease caused by currently available products, the fact that *M. haemolytica* bacterins historically caused enhanced disease is a reason to avoid the use of autogenous products that are not thoroughly tested for safety before administration. To induce protective immunity, a vaccine against *M. haemolytica* must contain leukotoxin; additional benefit may be gained by including other antigens associated with the bacterial cell wall.

Experimental challenge studies have shown that currently available commercial vaccines can lessen disease caused by infection with *M. haemolytica*.[308–310] However, data from well-designed field trials, which are a more relevant measure of the value of vaccination in the field, have reported mixed results. Most of the published field trials that have evaluated currently available (as of 2007) vaccines have evaluated a leukotoxin-rich bacterial culture supernatant vaccine (Presponse, Fort Dodge Animal Health, Fort Dodge, Ia). Of four trials carried out by different investigators in different regions, vaccinated calves had decreased respiratory morbidity (treatment for respiratory disease) in two trials,[311,312] but not in the other two trials.[313,314] Mortality resulting from respiratory disease was lower in vaccinated calves in two trials[312,313] but not in the other two trials.[311,314] Fewer vaccinated calves required a second treatment for respiratory disease (repulls) in three trials[312–314]; this variable was not examined in the fourth trial. Two trials found an economic advantage to vaccinating calves with this vaccine[312,313]; the other two trials did not measure costs related to vaccination. In all of these trials calves were vaccinated at feedlot arrival; in some cases subsets of calves also received a vaccination before arrival.[312,314]

Another recent trial evaluated a commercially available vaccine containing leukotoxin and cell-associated antigens (Pulmo-Guard, Boehringer Ingelheim, St. Joseph, Mo.), and found that vaccination of calves at feedlot arrival had no effect on respiratory morbidity or mortality or on the number of calves that required a second treatment for respiratory disease.[315] A trial testing an *M. haemolytica* vaccine currently available in Canada (Pneumo-Star, Biostar Inc., Saskatoon, Saskatchewan) found that vaccination at arrival was associated with decreased respiratory morbidity.[298]

This short summary of clinical trials testing the efficacy of *M. haemolytica* vaccines yields a clue to the reason for the ongoing debate regarding whether these vaccines are useful: about half the time field trials indicate that the vaccines decrease illness or death related to respiratory disease, and about half the time they do not. Therefore there is support for using *M. haemolytica* vaccines, and there is support for not using them. Note also that no large-scale clinical trial has compared two different *M. haemolytica* vaccines, so it is not possible

to give an evidence-based recommendation in favor of any vaccine over another. It must be remembered that in none of these clinical trials was the actual cause of respiratory disease determined, which is typical of large-scale field trials. Therefore vaccination was expected to decrease all respiratory disease, not just respiratory disease caused by *M. haemolytica*. This may be an unreasonable expectation for a vaccine from an immunologic perspective, but from a practical perspective, this is what producers expect. In general, if vaccination against *M. haemolytica* is used, evidence best supports its use in "lightweight" (300 to 600 lb) calves at high risk for disease. In one trial, vaccination decreased disease in calves with relatively high morbidity, but no effect was seen in a group of calves with low respiratory morbidity.[311] *M. haemolytica* vaccination is also recommended as part of many preconditioning programs, particularly if calves are to be sent directly to the feedlot without any backgrounding period.[316]

Vaccination of sheep or goats using commercially available vaccines labeled for use in cattle is not likely to provide reliable protection against disease, as serotypes of *M. haemolytica* that most commonly cause disease in sheep and goats are not included in vaccines for cattle. Moreover, although vaccination with sheep-associated serotypes can provide protection against infection, cross protection among different serotypes is not reliable,[261] indicating that an effective vaccine will likely need to contain antigens from multiple serotypes. There is a vaccine labeled for use in sheep and goats in the United States (*M. haemolytica–P. multocida* Bacterin, Colorado Serum Co., Denver, Colo.), but published clinical trials testing the efficacy of this product are lacking.

31.57.2 Pasteurella Multocida

31.57.2.1 Definition and Etiology

P. multocida is a gram-negative aerobic bacteria of the family Pasteurellaceae. Like *M. haemolytica, P. multocida* can be found in the nasopharynx of healthy ruminants. Although *P. multocida* is regularly isolated from the lungs of ruminants with bronchopneumonia, there has been debate over the years as to whether this species is a primary pathogen—that is, capable of causing disease alone—or whether some other primary stressor or insult is required to occur before this agent can participate in disease. As with *M. haemolytica*, experimental challenge of calves with *P. multocida* alone does cause clinical signs and pathologic change in the lung similar to that seen in natural outbreaks of disease (described later),[268,317,318] but large numbers of the bacteria must be administered in a way that bypasses the upper respiratory tract (most commonly by intratracheal instillation). Alternatively, prior administration of a viral respiratory pathogen makes animals more susceptible to disease caused by experimental *P. multocida* infection. These findings indicate that some insult that weakens the ability of the respiratory tract to resist advancement of these bacteria into the lower airways is necessary for most if not all cases of naturally occurring disease to occur. However, because *P. multocida* can cause lung lesions that can be severe,[317] and because the bacteria can exacerbate disease caused by primary viral infection, it is logical to consider this agent when planning strategies to treat and control ruminant respiratory disease.

P. multocida is a diverse species of bacteria that is classified into five serogroups (A, B, D, E, and F) based on antigenic differences in the bacterial capsule. Serogroups B and E cause hemorrhagic septicemia, a disease predominantly seen in Asia and Africa[319]; these serogroups are rarely isolated in the United States. Serogroup A is by far the predominant serogroup associated with ruminant respiratory disease,[263,320] although serogroups D and F may be common in some regions, particularly in sheep.[321] In addition to the alphabetic serogroup designation, isolates may also receive a numeric designation based on cell wall antigen types (for

example, *P. multocida* A3 has been commonly isolated from cases of bovine pneumonia).[318] A recent study characterized 153 *P. multocida* isolates from cases of pneumonia and mastitis in cattle in England and Wales based on the outer membrane proteins expressed by the bacteria. This research indicated that relatively few strains of *P. multocida* cause the majority of disease in cattle. Moreover, although a few strains isolated from cattle had also been associated with disease in swine and poultry, the majority of strains were uniquely associated with their host species of origin.[320] Other research indicated that certain strains of *P. multocida* had a predilection for the respiratory tract of sheep, whereas other strains were associated with the reproductive tract.[321] Taken together, these data suggest that differences among strains of *P. multocida* are related to the type of disease caused and the host likely to be affected. Therefore merely isolating *P. multocida* without further characterizing the isolate could make it difficult to know with confidence whether the type of bacteria isolated was actually contributing to disease. It has been suggested that strain variation is related to differences in severity of respiratory disease occurring in ruminants infected with *P. multocida*.[317]

31.57.2.2

Clinical Signs

Calves infected with *P. multocida* alone display clinical signs of fever, increased respiratory rate, and sometimes depression, coughing, and mucoid to mucopurulent nasal discharge.[268,317,318] Loud or harsh bronchovesicular sounds may be heard over the cranioventral lung fields owing to pulmonary consolidation, and coarse crackles may be heard as a result of air moving through exudate in large airways. Because *P. multocida* is a gram-negative organism that produces endotoxin, signs of endotoxemia (tachypnea, tachycardia, fever) may also contribute to signs that accompany infection with the organism. Compared with calves infected with *M. haemolytica*, calves infected with *P. multocida* tend to have less severe signs, and signs of disease last for a shorter time.[268,317]*P. multocida* is more commonly isolated from young calves with pneumonia[111,112] than with other bacterial respiratory pathogens such as *M. haemolytica*, but it is less commonly isolated from feedlot cattle with acute bronchopneumonia.[188] Thus *P. multocida* is considered to be of relatively greatest importance in contributing to calf pneumonia. *P. multocida* has been found to overgrow *M. haemolytica* in the lungs of calves experimentally challenged only with *M. haemolytica*[268]; therefore *P. multocida* may also be an important contributor to cases of subacute to chronic pneumonia in feedlot cattle initiated by other organisms.

31.57.2.3

Pathogenesis

Little is known regarding the pathogenesis of *P. multocida* in ruminant respiratory disease. In addition to lipopolysaccharide (LPS), the organism also has a capsule that allows it to resist phagocytosis. Outer membrane proteins, particularly iron-regulated outer membrane proteins, are likely to contribute to the ability of the bacteria to establish and proliferate within the host.[322,323] The prominent role of *P. multocida* in enzootic calf pneumonia (ECP) and rather minor role in acute bronchopneumonia of feedlot cattle suggests that prolonged impairment of the respiratory defense mechanisms is necessary for this organism to establish in the lungs in sufficient numbers to create bronchopneumonia. It is likely that the organism is chronically inhaled in small numbers into the lungs of calves with persistent damage to the respiratory defenses from infectious agents such as viruses or mycoplasmas and environmental damage from inadequate housing and ventilation, allowing it to colonize and produce an expanding lesion. This proposed pathogenesis agrees with the insidious onset that is commonly observed with ECP, and would also fit the association of *P. multocida* with chronic or ongoing pneumonia in feedlot cattle. It is important to remember that culture of *P. multocida* from pneumonic lung does not exclude the possibility of other bacteria such as *M. haemolytica* being the

primary pathogen, because *P. multocida* has been shown to overgrow *M. haemolytica* in challenge studies using large doses of pure cultures of *M. haemolytica*.[268]

31.57.2.4 Epidemiology

P. multocida is commonly isolated from the lungs of calves that die or are euthanized because of bronchopneumonia, with mycoplasmas being the only bacteria isolated more often in surveys involving multiple farms experiencing outbreaks of calf pneumonia.[111,112] In contrast, *M. haemolytica* is more frequently isolated postmortem from feedlot cattle with fibrinous pneumonia than is *P. multocida*.[188,296] However, one study of bacterial isolates from BAL of feedlot cattle found that *P. multocida* was the only species isolated more frequently from cattle with clinical signs attributed to acute pneumonia as compared with normal cattle.[299] A notable aspect of this study was that animals were sampled before treatment with antimicrobials; in surveys of bacteria identified postmortem, animals have usually received antimicrobial treatment before death, which may bias the microbiologic findings.

31.57.2.5 Necropsy Findings

P. multocida produces a purulent bronchopneumonia with plum-colored cranioventral consolidation and purulent exudate on cut section within the airways; when calves are experimentally infected with *P. multocida* alone, the lesion is usually not extensive and is typically confined to the cranioventral lung lobes.[268,317,318] Histologically, bronchopneumonia characterized by infiltration of neutrophils and macrophages into alveoli and airways is seen. Microscopic evidence of abscesses may be present. Fibrin deposition with expansion of lymphatics and interlobular septa with edema, and focal areas of coagulative necrosis, has been reported in calves infected with *P. multocida*,[317,318] but this lesion is more typical of infection with *M. haemolytica*.[268]

618

619

31.57.2.6 Diagnosis

Bronchopneumonia caused by *P. multocida* is diagnosed as described for *M. haemolytica*. The species is most commonly identified by culture of lung lesions identified at postmortem examination of affected animals. Because of the association of *P. multocida* with chronic or ongoing pneumonia, identification of this agent may indicate that the animal has been affected with bronchopneumonia for several days to weeks.

31.57.2.7 Treatment and Prevention

Treatment of *P. multocida* is as described for *M. haemolytica*. Several antimicrobials are labeled specifically for the treatment of *P. multocida*, and products labeled for the treatment of *M. haemolytica* are also likely to be effective against this organism (see Table 31-10). Because *P. multocida* seems to be associated with chronic or ongoing pneumonia, effective treatment of infection with this species may require longer therapy than the 3 to 5 days historically recommended for ruminants with bronchopneumonia, but this recommendation has not been tested in controlled studies and would be an extralabel use of some antimicrobials.

Because prior insult to respiratory defense mechanisms appears necessary for infection with *P. multocida* to cause disease, prevention of disease is likely to be aided by undertaking efforts to prevent other primary respiratory injury. This would include efforts to prevent infection with viral respiratory pathogens and to establish management practices that help minimize respiratory tract disease.

As compared with *M. haemolytica*, relatively little is known about protective immunity to *P. multocida*. Modified live vaccines can protect calves from disease caused by experimental challenge.[324,325] Antibody responses to several outer membrane proteins were associated with protection in one study, and these were induced by live but not killed vaccine.[325] Several commercial vaccines are marketed that contain *P. multocida* in combination with *M. haemolytica*; one such vaccine is approved for use in sheep and goats as well as cattle (*M. haemolytica–P. multocida* Bacterin, Colorado Serum, Denver, Colo.). There are currently no vaccines marketed that contain only *P. multocida*. No published large-scale trials have specifically evaluated the effect of vaccination against *P. multocida* on respiratory disease in the field.

31.57.3 Histophilus somni (Formerly Haemophilus somnus)

31.57.3.1 Definition and Etiology

H. somni is a gram-negative aerobic bacteria of the family *Pasteurellaceae*. The name of this organism was recently changed form the previous name, *Haemophilus somnus*.[326] *H. somni* can be found on the genital and upper respiratory mucosa of normal ruminants,[327–330] but it can also cause a variety of diseases, including septicemia, thrombotic meningoencephalitis (TEME), endometritis, abortion and infertility, pneumonia, pleuritis, laryngitis, otitis, conjunctivitis, myocarditis, mastitis, and polyarthritis.[331] Only pneumonia and pleuritis resulting from this organism are considered here. Two bacteria very similar to *H. somni, Haemophilus agni* and *Haemophilus ovis*, have been isolated from sheep with septicemia, meningitis, mastitis, and reproductive abnormalities; DNA hybridization studies have indicated that these three organisms should all be classified as *H. somni*.[332] Although specific serotypes of *H. somni* have not been associated with disease as is the case for *M. haemolytica* and *P. multocida*, differences in virulence among different strains have been demonstrated in experimental challenge studies.[333] Moreover, differences in expression of molecules considered to be virulence factors have been demonstrated when strains from healthy animals are compared with strains from diseased animals.[334] Thus it appears that some isolates of *H. somni* are more likely to cause disease than others, but more research is needed to confirm the characteristics that define a pathogenic isolate.

31.57.3.2 Clinical Signs

As mentioned earlier, *H. somni* can cause disease in a variety of organ systems, and the clinical signs of infection will depend on the organ system affected. The possibility of concurrent infection of multiple systems should be considered in patients suspected to have disease caused by *H. somnus*. In a Canadian retrospective study from the early 1990s, the majority of animals presented to a regional diagnostic laboratory for necropsy as a result of haemophilosis had disease in more than one organ system.[335] Signs of respiratory tract infection can range from mild to severe and can include fever, tachypnea, cough, nasal discharge, and depression. Severe cases of disease can be fatal.[333,336] Harsh or loud bronchovesicular sounds may be heard on thoracic auscultation because of pulmonary consolidation, particularly over the cranioventral lung fields. Affected animals may have signs of pain owing to fibrinous pleuritis,[336] including reluctance to move, standing with elbows abducted, and catching the breath before expiration. The cell wall of *H. somni* contains lipooligosaccharide (LOS), which induces inflammatory responses identical to those induced by LPS from *E. coli*[337]; therefore animals with pleuritis or pneumonia caused by *H. somni* could also have clinical signs referable to endotoxemia, including tachypnea, tachycardia, dark or pale mucous membranes with prolonged capillary refill time, salivation, or dyspnea.

31.57.3.3 Pathogenesis

H. somni can live on respiratory or genital mucous membranes without causing disease, and it is not entirely clear what factors related to the pathogen or host must change for disease to occur. The physical and immunologic barriers presented by the upper respiratory tract are apparently of major significance; calves exposed to *H. somni* by aerosol did not develop disease,[338] whereas instillation of the bacteria directly into the trachea or bronchi led to disease that could be severe.[333,336] As has been shown for *M. haemolytica* and *P. multocida*, primary infection by a viral respiratory pathogen is likely a predisposing factor that allows *H. somni* to advance and establish in the lower respiratory tract in many cases. Calves infected with BRSV before infection with *H. somni* had disease of greater severity than that seen in calves infected with either BRSV or *H. somni* alone.[169,336]

H. somni has many features that help the bacteria escape the immune response. The bacteria have outer membrane proteins that bind to the Fc region of antibody, allowing them to escape opsonization.[334] When the bacteria are ingested by neutrophils or macrophages, they are able to resist being killed.[339] The bacterial LOS induces inflammatory responses similar to the LPS of other gram-negative bacteria,[337] and *H. somni* is able to periodically change the structure and antigenicity of its LOS, which is likely to be important in evading the host immune response.[340]

An important aspect of the pathology caused by *H. somni* is the formation of vasculitis and vascular thrombi; this was first recognized in the context of the neurologic lesion caused by the bacteria, which is known as *thrombotic meningoencephalomyelitis* (TME), but vascular thrombi are also identified histologically in the lungs of animals with pneumonia caused by *H. somni*.[336] For some time the exact cause of the vascular thrombosis typical of *H. somni* infection was not known, but recent research indicates that the bacteria cause death of vascular endothelial cells by inducing apoptosis (programmed cell death).[341] Apoptotic death of endothelial cells is mediated in part through the bacterial LOS, which interacts with the P2X7 purinergic receptor on endothelial cells, inducing activation of certain caspases, enzymes that activate the apoptotic pathway and initiate a cell suicide program.[328] Although the entire pathway leading to vasculitis and thrombosis has not been completely elucidated, thrombosis is no doubt mediated in part by exposure of the vascular basement membrane on endothelial cell death, which leads to exposure of the basement membrane, activation of platelets and the coagulation cascade, and thrombosis.

619
620

Another important aspect of *H. somni* is the propensity of infection to induce IgE production by the host.[169,342] Infection with BRSV before infection with *H. somni* led to production of high levels of *H. somni*–specific IgE, which was associated with disease of increased severity as compared with control calves.[169] Cattle vaccinated with four different *H. somni* bacterins were all found to develop serum levels of *H. somni*—specific IgE that were significantly higher than levels seen in control unvaccinated cattle.[342] Because IgE mediates type I (immediate) hypersensitivity, animals that produce IgE against *H. somni* after vaccination or primary infection could have signs of an allergic or anaphylactic response on subsequent revaccination or reinfection. Such IgE-mediated hypersensitivity reactions have been proposed to contribute to the adverse reactions sometimes seen in cattle after vaccination for *H. somni*.[342] In addition to inducing IgE production, *H. somni* directly produces histamine,[343] which could further contribute to the development of hypersensitivity-like signs during *H. somni* infection. Among other actions, histamine increases permeability of bronchial epithelium; this may aid the bacteria in moving out of the airway and into the lung parenchyma.

31.57.3.4

Epidemiology

Exposure to *H. somni* is common, with 25% to 100% of cattle in various populations having serum antibodies.[344] A retrospective study of bovine carcasses submitted to a regional diagnostic laboratory in western Canada from 1970 to 1990 indicated that cases affected with the neurologic form of haemophilosis were decreasing, whereas cases with respiratory and/or myocardial disease caused by the organism were increasing.[335] The reason for the apparent shift in type of disease caused in cattle could not be determined from the study, and a similar study has not been repeated to see if the trend is continuing.

It is common for feedlot cattle to have measurable antibody titers to *H. somni* at feedlot entry,[187,297] indicating that cattle are commonly exposed on the farm of origin or in transit to the feedlot. Seroconversion is also common in the first few weeks after feedlot entry,[297,298] indicating that cattle also continue to be exposed to *H. somni* in the feedlot. Several Canadian reports have indicated that *H. somni* can be a significant contributor to the development of respiratory disease or undifferentiated fever in feedlot cattle,[297,345,346] although studies of feedlot respiratory disease do not always find the bacteria involved. A causative association is typically inferred either by the association of seroconversion with respiratory morbidity and mortality during the period of study or by the association of *H. somni* vaccination with decreased respiratory morbidity and mortality. By these measures it appears that most disease resulting from *H. somni* occurs within the first 2 months of the feeding period,[346] and perhaps even within the first 2 weeks.[298] In some cases the association of seroconversion or vaccination with all morbidity and mortality is also evaluated, but one study found that when causes of mortality were separated into those in which it was biologically plausible for *H. somni* to be involved and those in which it was not (e.g., cattle with musculoskeletal injuries), vaccination was associated with decreased mortality attributable to *H. somni* but not with a decrease in all causes of mortality.[346] A causative association for *H. somni* (or any respiratory pathogen) is sometimes assumed when animals with high antibody titers to the organism at feedlot entry ultimately have lower respiratory morbidity and mortality,[297] although the case has been made that this is not a reliable marker of causation.[298] A *decreasing* antibody titer to *H. somni* was associated with decreased likelihood of disease in one study[297] and increased likelihood of disease in another[187]; this demonstrates that it is not always easy to develop a unified theory regarding the role of infectious agents and the immune response from the available data. It is also noteworthy that high-quality field research on the role of *H. somni* in feedlot respiratory disease in recent years has come almost entirely from Canada; it is not clear whether this indicates that *H. somni* is a less significant contributor to disease in the United States or whether the research has just not been done.

H. somni is uncommonly isolated in surveys of the causes of pneumonia in young calves,[112,300] but it can cause bronchopneumonia that is significant; one necropsy survey found pneumonia in 12 of 15 calves under 8 weeks of age submitted because of disease resulting from *H. somni*, and in 8 of the 15 calves, pneumonia was the only lesion found.[335]

31.57.3.5

Necropsy Findings

H. somni produces lesions similar to that of *P. multocida*, and it may rarely produce lesions that resemble *M. haemolytica*, creating a fibrinous pleuropneumonia.[331,333,336] Grossly, plum or red to brown consolidated lobules are seen in the cranioventral lung (Fig. 31-59), sometimes with abscesses containing brown-red fluid material. Interlobular septa can be distended with edema and fibrin, and hemorrhage may be grossly visible.

333 Purulent material is seen within airways on the cut surface of lung. The surface of the pleura may be flecked with fibrin, or in some cases fibrin deposition may be extensive, with varying amounts of straw-colored fluid in the pleural cavity. Bronchial lymph nodes may be enlarged, with ecchymotic hemorrhages on the cut surface.

620

621

Fig. 31-59 Postmortem photograph of lungs from feedlot steer with bronchopneumonia caused by *Haemophilus somni*. Note extensive dark red, consolidated cranioventral lung. Laceration of caudoventral lung is iatrogenic and not relevant to the lesion. Photograph contributed by Feedlot Health Management Services, Okotoks, AB, Canada.

Histologically, inflammatory cells predominately made up of neutrophils infiltrate the alveoli and airways. Edema, hemorrhage, and fibrin can be seen in alveoli and interstitial spaces, and areas of coagulation necrosis

surrounded by inflammatory cells may be found. Interlobular septa are expanded with fibrin, and thrombi are seen in blood vessels.[333,336]

A massive fibrinous pleuritis with pleural effusion sometimes results from septicemic spread of *H. somni*. This condition can be differentiated from the fibrinous necrotizing lobar pleuropneumonia of shipping fever caused by *M. haemolytica* because the *H. somni* lesion involves only the pleural surface, not the lung.

31.57.3.6

Diagnosis

Bronchopneumonia or pleuropneumonia caused by *H. somni* is diagnosed as described for *M. haemolytica*. The bacteria can be difficult to isolate, so samples collected for culture should be transported to the diagnostic laboratory without delay, and the diagnostic bacteriology laboratory should be specifically requested to attempt to isolate *H. somni* if involvement of the agent is suspected. Samples are ideally taken from animals before antimicrobial treatment, as *H. somni* is susceptible to a wide variety of antimicrobials, and treatment makes it difficult to isolate the bacteria.[331] Serologic tests have been used to identify antibodies to *H. somni* for studies of the epidemiology of *H. somni* infection,[297,298] and seroconversion as measured via paired serology could be used to confirm infection in a group of cattle, but these assays may not be available at all diagnostic laboratories. IHC has been used to identify *H. somni* in association with lesions in formalin-fixed tissues,[347] and this may be an additional test available at some diagnostic laboratories.

31.57.3.7

Treatment and Prevention

H. somni is susceptible to a variety of antimicrobials, including tetracycline, penicillin, sulfonamides, and erythromycin, as well as more recently developed antimicrobials, many of which are labeled for use in the treatment of *H. somni* (see Table 31-10). In a feedlot with unusually high morbidity and mortality because of haemophilosis, prophylactic treatment with oxytetracycline was administered at different time points within the first 2 weeks of the feeding period in an effort to decrease haemophilosis morbidity or mortality, to no avail (although morbidity from all causes of respiratory disease was decreased).[348]

Several *H. somni* vaccines are commercially available; all are killed whole bacteria preparations (bacterins). Vaccination can prevent disease caused by experimental challenge; in one study, vaccination of 10-week-old calves with a commercial bacterin significantly decreased clinical signs and pulmonary pathology resulting from *H. somni* challenge.[333] Clinical trials of *H. somni* bacterins in the 1980s gave mixed results, with evidence that vaccination decreased respiratory morbidity and/or mortality in some trials but not in others[346,349,350]; and very little research has provided more information since then. In a cow-calf herd with a high incidence of calf pneumonia, vaccination of calves at 3 and 5 weeks of age with an *M. haemolytica* and *H. somni* bacterin in combination with a modified live BRSV vaccine led to decreased treatment rates as compared with calves not vaccinated or calves vaccinated with either the bacterin or the BRSV vaccine alone.[351] The decrease in treatment rates only tended toward statistical significance; this may have been because small numbers of calves were enrolled in the study. The specific influence of *H. somni* vaccination in this trial could not be determined. The same authors found that vaccination of cows with *M. haemolytica* and *H. somni* bacterin 4 weeks and/or 7 weeks prepartum increased antibody titers to both pathogens in the serum of their calves at 3 days and 1 month of age. Furthermore, calves vaccinated at 1 and 2 months in the face of maternal antibody had significantly higher titers at 4 and 6 months of age than unvaccinated calves.[352] The effect of

antibody titers on disease in the calves was not examined. A recent trial of the effect of vaccination on respiratory morbidity in feedlot cattle showed no effect of *H. somni* vaccination.[298]

The fact that *H. somni* vaccines induce cattle to produce IgE against the bacteria[342] indicates that vaccinated cattle may be at increased risk for a hypersensitivity reaction after a booster vaccine or infection. Although some older clinical trials showed a benefit associated with vaccination in terms of decreased respiratory morbidity and/or mortality, *H. somni* vaccination may also put cattle at risk for adverse reactions. Therefore it may be most prudent to recommend vaccination only for groups of cattle on operations in which significant morbidity or mortality caused by infection with *H. somni* has been confirmed.

As described for *M. haemolytica* and *P. multocida*, preventing primary injury to the respiratory tract by viral infection and limiting other causes of stress that suppress the host immune response are expected to help animals resist disease caused by *H. somni*.

31.57.4 Mycoplasma Bovis

31.57.4.1 Definition and Etiology

Mycoplasma bovis is a member of the genus *Mycoplasma* of the class Mollicutes, and as such it is among the smallest free living organisms. The first known mycoplasma, identified in 1898, was the causative agent of contagious bovine pleuropneumonia, *Mycoplasma mycoides* subsp. *mycoides*, small colony variant.[353] Mycoplasmas have since been recognized to cause disease in humans and a wide variety of animal and plant hosts. Mycoplasmas are small (approximately 200 nm) and pleomorphic, with a genome of only approximately 500 to 1000 kD.[354] They are bounded by a single membrane, and because they lack a cell wall they are naturally resistant to antimicrobials such as penicillins and cephalosporins that work by impairing cell wall synthesis. *Mycoplasma bovis* was first identified in 1961 in the United States, where it was isolated from a case of mastitis.[355] It has since spread worldwide. The bacterium was originally considered a subspecies of *Mycoplasma agalactiae*, and the two agents can be difficult to distinguish.[356] However, *M agalactiae* is a pathogen of sheep and goats and is rarely isolated in the United States, whereas *Mycoplasma bovis* is regularly isolated in cases of pneumonia, respiratory disease, arthritis, tenosynovitis, and other disorders of cattle. *Mycoplasma bovis* can cause disease in sheep, goats, and other species, but this is a rare occurrence.

31.57.4.2 Clinical Signs

Respiratory infection with *Mycoplasma bovis* causes fever, tachypnea, inappetence, and sometimes respiratory distress.[357] Coughing and nasal discharge are reported in some outbreaks.[358,359] Respiratory disease caused by *Mycoplasma bovis* can occur in outbreaks; in young dairy calves, a subset of calves affected often develops otitis, characterized by unilateral or bilateral drooping of ears with purulent aural discharge, possibly with facial paralysis caused by cranial nerve VII involvement, and vestibular signs such as head tilt, nystagmus, and ataxia.[358–361] In weaned beef calves and cattle entering feedlots, a subset of affected animals may develop arthritis and tenosynovitis[361–363]; this syndrome is sometimes referred to as *chronic pneumonia and polyarthritis syndrome* (CPPS).[363,364] Young dairy calves can also develop arthritis or tenosynovitis.[359] A typical complaint by the producer experiencing a respiratory disease outbreak involving *Mycoplasma bovis* is that cattle do not respond to therapy as expected, and a significant proportion of affected animals remain chronically ill and unthrifty for weeks after the onset of disease.[361,362,365] In addition to respiratory disease,

Mycoplasma bovis can also cause mastitis, arthritis and tenosynovitis, conjunctivitis, otitis, sinusitis, and myocarditis and/or pericarditis. The bacteria can also be isolated from aborted fetuses and from semen, linking the agent to reproductive failure.

The ability of *Mycoplasma bovis* to act as a primary respiratory pathogen has been debated. Classically the agent has been understood to be an opportunist, establishing itself after primary infection with viral pathogens or other bacteria. However, experimental challenge of gnotobiotic calves with *Mycoplasma bovis* alone induced respiratory disease with clinical signs of fever, tachypnea, and inappetence in four of seven calves and grossly evident lung lesions in all seven.[357] These findings indicate that *Mycoplasma bovis* can cause disease while acting alone, but, as for other bacterial respiratory pathogens described earlier, it is likely that natural disease often follows other primary insult. A recent survey of causes of death in cattle in Ontario feedlots identified caseonecrotic pneumonia caused by *Mycoplasma bovis* as a cause of more fatalities within the first 60 days of the feeding period than acute fibrinosuppurative pneumonia typical of disease caused by *M. haemolytica* or *H. somnus*.[188] This study indicates that *Mycoplasma bovis* is an important contributor to mortality in some feedlots, but more research is needed to determine whether the factors that predispose cattle to fatal disease resulting from *Mycoplasma bovis* are different from the factors known to predispose cattle to fibrinous bronchopneumonia caused by *M. haemolytica*.

31.57.4.3

Pathogenesis

Although *Mycoplasma bovis* has been recognized to cause respiratory disease in cattle for some time, very little is known about the mechanisms by which the agent causes disease. In disease caused by other mycoplasmas, attachment has been shown to be a key factor in pathogenesis. In vitro studies of *Mycoplasma bovis* suggest that pathogenicity is likewise associated with the ability to attach, as isolates from cases of clinical disease were better able to attach to embryonic bovine lung cells than were isolates from asymptomatic animals or high passage laboratory isolates.[366] Antibodies against several of the variable surface proteins (Vsps) expressed by *Mycoplasma bovis* were able to partially but not completely block attachment, indicating that the Vsps play a role in attachment.[366] Invasiveness is another pathogenic mechanism of *Mycoplasma bovis; Mycoplasma bovis* was found to be capable of migration between ciliated respiratory epithelial cells, whereas *Mycoplasma dispar*, another mycoplasma commonly isolated from cases of bovine pneumonia, remained attached to the surface of ciliated epithelial cells.[367] The ability of *Mycoplasma bovis* to invade allows the organism to cause disease in organs outside the respiratory tract, such as joints and tendon sheaths. *Mycoplasma bovis* produces a toxin that increases vascular permeability.[368] Certain strains of the agent have also been shown to be cytotoxic to mammalian cells[369]; it is not known whether this effect is related to the vascular toxin reported by Geary and colleagues.

Available data indicate that *Mycoplasma bovis* may cause disease in part through evading or impairing host immune function. Although not yet well characterized, a feature of *Mycoplasma bovis* that is likely important in enabling the bacteria to escape the host immune response is the expression of Vsps. The ability to vary surface protein expression has been shown to be an important pathogenic mechanism in certain mycoplasmas.[354] *Mycoplasma bovis* expresses at least three Vsps—VspA, VspB, and VspC—and isolates have been found that express some or all of these proteins.[370] A study of 50 *Mycoplasma bovis* isolates, including many field isolates, showed extensive variability in Vsps at both the genetic and antigenic level.

Evidence indicates that *Mycoplasma bovis* can directly impair the activity of neutrophils. In one study *Mycoplasma bovis* was found to adhere to bovine neutrophils, but adherence did not elicit an expected

activation response. Moreover, adherent *Mycoplasma bovis* inhibited normal neutrophil microbicidal activity.[371] The bacteria is also able to kill lymphocytes by inducing them to undergo apoptosis (programmed cell death).[372] Induction of proinflammatory cytokine production by the host may also contribute to disease caused by *Mycoplasma bovis*; an isolate of *Mycoplasma bovis* induced production of the proinflammatory cytokine TNF-α by bovine alveolar macrophages to a degree similar to that induced by *M. mycoides* subsp. *mycoides* (the cause of contagious bovine pleuropneumonia, a serious disease exotic to the United States) but in contrast to nonpathogenic mycoplasmas tested.[373]

Other research suggests that *Mycoplasma bovis* may induce an immune response that is not optimally protective. Vanden Bush and Rosenbusch showed that in calves experimentally infected with *Mycoplasma bovis*, serum titers of *Mycoplasma bovis*-specific IgG1 increased significantly after infection, whereas titers of antigen-specific IgG2 did not increase as markedly.[374] Because IgG2 is considered superior in opsonizing ability as compared with IgG1, the authors speculated that preferential induction of IgG1 by *Mycoplasma bovis* infection may be related to the apparent inability of the immune response to rapidly clear the organism, as evidenced by the common association of chronic pneumonia with *Mycoplasma bovis* infection.

31.57.4.4

Epidemiology

Mycoplasma bovis can be isolated from the respiratory tracts of normal cattle[188,375,376] and from cattle with respiratory disease.[208,365,377–380] Surveys of nasopharyngeal swabs taken from dairy calves with no clinical signs of respiratory disease found *Mycoplasma bovis* in 0% to 34% of the animals sampled.[376,380,381] A recent survey of multiple source weaned beef calves sampled soon after arrival at nine different backgrounding or stocker operations identified nasal shedding of *Mycoplasma bovis* in 0% to 6% of animals at each operation.[382] *Mycoplasma bovis* can also be found in bovine lungs without evidence of disease at postmortem examination.[188] The fact that *Mycoplasma bovis* can be isolated from animals with no clinical or pathologic signs of pneumonia has led some to question whether the agent is a true respiratory pathogen. However, a consistent association of *Mycoplasma bovis* with a clinical syndrome of chronic nonresponsive pneumonia with or without otitis, arthritis, or tenosynovitis,* and a pathologic syndrome of bronchopneumonia with multifocal caseous necrosis visible histologically and/or grossly,[362,364] has led to general acceptance that *Mycoplasma bovis* can contribute to significant morbidity and mortality in some situations.

622
623

Although more research is needed, currently available data support the concept that *Mycoplasma bovis* can spread from a few animals carrying the bacteria to others until a large proportion of a group is infected; transmission in these cases is most likely via respiratory infection by direct contact or short-distance aerosol.[361,362,375] Feeding milk infected with *Mycoplasma bovis* appears to be another important source of infection for dairy calves.[359–361] The fact that *Mycoplasma bovis* infection can be widespread in some populations was illustrated by a case-control study of cattle in the first 4 weeks after feedlot entry. Researchers used a protected BAL catheter to collect samples from the lower airways with minimal contamination from the nasal passages. Soon after arrival, these investigators found *Mycoplasma bovis* in the BALF of 52% of controls that were not treated for respiratory disease in the first 28 days, versus 61% of cases that were treated for respiratory disease within 28 days.[299] Two weeks later *Mycoplasma bovis* was found in BALF from over 80% of the controls and in 100% of animals who ultimately were treated for respiratory diseases by 28 days, indicating that colonization of the respiratory tract of all cattle sampled was widespread within a short period after feedlot entry.[375] Genetic characterization by arbitrarily primed PCR (AP-PCR) has been used to characterize *M. bovis* isolates associated with herd outbreaks of disease, with a single genetic lineage associated with disease in a

closed herd, and multiple genetic lineages associated with disease in a calf ranch where animals were frequently brought on site from multiple sources.[384]

Mycoplasma bovis has been isolated from both dairy calves and feedlot cattle with respiratory disease in multiple studies,* with particularly high prevalence occurring in animals with chronic pneumonia nonresponsive to antimicrobial therapy.[208,209,365,377] In a recent survey of cattle subjected to necropsy within 60 days of arrival at 72 feedlots, lung lesions were categorized as either fibrinosuppurative (typical lesion caused by *M. haemolytica* or *H. somni*) or caseonecrotic, which were characterized grossly by the presence of multiple foci of dry caseous material and histologically by areas of eosinophilic necrotic cellular debris (caseous necrosis) surrounded by inflammatory cells and fibrous tissue. *Mycoplasma bovis* was isolated in 53 of 54 cases (98%) with caseonecrotic lesions and in 52 of 58 of cases (89%) with fibrinosuppurative lesions; it was also isolated from 6 of 13 animals (46%) with normal lungs in this study.[188] In 49 chronically sick cattle from a single feedlot that were subjected to necropsy in 1 month, *Mycoplasma bovis* was identified in the lungs of 82% of the cases, and in the joints of 45% of the cases.[209] BVDV was also present in 39% of the cases from which *Mycoplasma bovis* was isolated. A later retrospective study by the same authors found BVDV in the lungs of 44% of cattle subjected to necropsy with a final diagnosis of pneumonia caused by *Mycoplasma bovis*; these data lead the authors to suggest that immunosuppression resulting from BVDV may predispose a subset of animals to chronic pneumonia and/or arthritis caused by *Mycoplasma bovis*. In contrast, Gagea and colleagues found that although BVDV infection was more common in feedlot cattle with bacterial pneumonia than in those with other diseases, it was not more common in cattle with caseonecrotic lesions typical of *Mycoplasma bovis* infection.[379]

* References 208, 209, 358, 359, 365, 377, 383.

* References 208, 262, 365, 377–379, 384.

31.57.4.5

Necropsy Findings

Grossly, lungs of cattle with pneumonia caused by *Mycoplasma bovis* have dark red, firm consolidated lobules of the cranioventral lung. Raised white to yellow, firm nodules that range from 0.5 to several centimeters in diameter are often but not invariably seen clustering in the cranioventral lung (Figs. 31-60 and 31-61).[357,364,379,385] These nodules may appear to be abscesses, but in most cases they are actually foci of coagulation necrosis.[357,379] Differential diagnoses for gross lesions of abscessing pneumonia in cattle include infection with *Arcanobacterium (Actinomyces) pyogenes* and *F. necrophorum* (both of which are more likely to cause a foul odor than *Mycoplasma bovis*) and *Mycobacterium bovis* (tuberculosis).[364] Other gross lesions include enlargement of interlobular septa by edema and fibrin; fibrinous or fibrous pleural adhesions are unusual but could be present if the animal is or has been co-infected with *M. haemolytica* or *H. somnus*. Animals with pneumonia typical of *Mycoplasma bovis* may also have arthritis in one or more joints characterized by abundant yellow fluid with fibrin and sometimes purulent material, and tenosynovitis characterized by extensive caseous exudate and pyogranuloma formation in the tendon sheaths.[362,364] Fibrin, purulent material, and caseous material may be present in the tympanic bullae.

Fig. 31-60 Postmortem photograph of lung from calf with bronchopneumonia caused by *Mycoplasma bovis*. Note extensive nodular abscessation of cranioventral lung. Photograph contributed by Dr. Tom Mullaney, Michigan State University, East Lansing Mich.

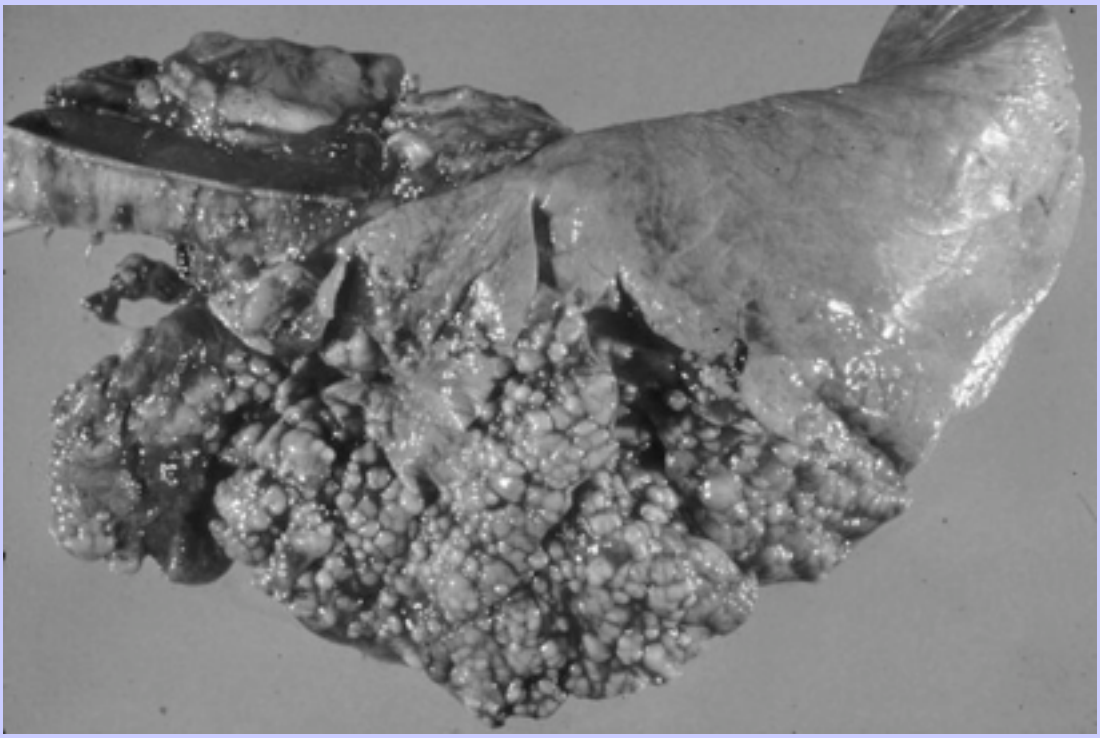

Fig. 31-61 Postmortem photograph of lung from calf with bronchopneumonia caused by *Mycoplasma bovis*. Note dark red consolidated cranioventral lung and white caseous material visible on cut surface. Photograph contributed by Dr. Ricardo Rosenbusch, Iowa State University, Ames Iowa.

Histologically there is purulent pneumonia and bronchiolitis, with extensive infiltration of neutrophils in airways, and peribronchiolar cuffing with lymphocytes and mononuclear cells. Foci of eosinophilic coagulation necrosis are surrounded by a rim of dark pyknotic inflammatory cells and, farther out, a region of primarily macrophages and some plasma cells.[357,364] Areas of coagulation necrosis may extensive, and ghostlike outlines of cells, alveolar walls, and alveoli may be seen.[357,364] Immunohistochemical staining for the organism often shows large numbers surrounding the periphery of areas of coagulation necrosis, as well as in association with bronchiolar and alveolar epithelial cells.[364,385] Histologic evaluation of joints, tendon sheaths, and the tympanic bullae and petrous temporal bone will reveal changes consistent with the gross lesions. Close inspection may also reveal foci of mononuclear cell accumulation with positive staining for *Mycoplasma bovis* by IHC in the liver and kidney[385] or in the pericardium.[347]

623
624

31.57.4.6

Diagnosis

Confirmation of disease caused by *Mycoplasma bovis* is best made by identification of the agent by culture or IHC in conjunction with gross and histopathologic lesions typical of disease attributed to the agent. Thus, in

order to reliably confirm a role for *Mycoplasma bovis* in an outbreak of bovine respiratory disease, postmortem of representative affected cases is necessary. It is important to request that the diagnostic laboratory specifically identify *Mycoplasma bovis*; in many cases diagnostic laboratories characterize agents only to the level of the genus by identification of typical organisms in culture. Because other mycoplasma such as *Mycoplasma bovirhinis, M. dispar*, and *Mycoplasma alkalescens* can also be isolated from the respiratory tract of cattle with pneumonia, a report of "*Mycoplasma* sp." is not equivalent to a diagnosis of disease caused by *Mycoplasma bovis*. Species-specific identification of *Mycoplasma bovis* can be made by antibody-based tests such as IHC or immunofluorescence (available at the Iowa State University Veterinary Diagnostic Laboratory, and possibly others) or PCR (available at many laboratories including the University of Georgia Athens Veterinary Diagnostic Laboratory).

Although available data suggest that *Mycoplasma bovis* is less commonly isolated from healthy cattle than other mycoplasmas are, because the organism can be found in nasal swabs and lung tissue of apparently normal animals, an isolation of the bacteria in the absence of evidence of disease is of uncertain significance. Nasal shedding has not been confirmed to be a reliable antemortem measure of the presence of pneumonia caused by *Mycoplasma bovis*; the agreement between the results of nasal swab culture and the presence of lung disease caused by *Mycoplasma bovis* was good in one study[378] and only moderate to poor in two other studies.[299,386] Serologic assays have been used to characterize seroconversion in epidemiologic studies, but the tests are not widely available, and their results have not been shown to reliably indicate active infection.[369] A recent report evaluated the agreement between the measurement of serum antibodies using a blocking ELISA and shedding of *Mycoplasma bovis* in the milk in a small number of cows; agreement was significant but only moderate ($\kappa = 0.44$).[387] If serology is attempted, paired serology with evidence of rising titers in association with outbreaks of respiratory and/or joint disease is likely to be more useful than measurement of titers on a single occasion.

31.57.4.7

Treatment and Prevention

Multiple authors report that cattle with pneumonia or arthritis caused by *Mycoplasma bovis* respond poorly to antimicrobial therapy.[209,362,363,369] Early studies indicated that tilmicosin had good effect against experimentally induced[388] disease caused by *Mycoplasma bovis* in cattle; however, recent studies of in vitro susceptibility profiles of panels of *Mycoplasma bovis* isolates reveal evidence of widespread evidence of resistance to tilmicosin, as well as erythromycin, ampicillin, and ceftiofur.[389,390] Susceptibility to oxytetracycline, chlortetracycline, and spectinomycin has been variable, although most isolates have been susceptible to fluoroquinolones such as enrofloxacin or danofloxacin.[390–392] However, no fluoroquinolone marketed in the United States is specifically labeled for treatment of cattle for disease caused by *Mycoplasma bovis*, and extralabel use of fluoroquinolones is illegal. A relatively new antimicrobial, tulathromycin, has shown good efficacy against experimentally induced *Mycoplasma bovis* infection; it is interesting to note that the response did not correlate with in vitro MIC data for the challenge isolate, which was high and predicted that the antimicrobial would not likely be effective.[393] Tulathromycin (Draxxin, Pfizer Animal Health) has recently been approved for treatment in the United States of respiratory disease caused by *Mycoplasma bovis*.

Although clinical trials and data from well-controlled experimental studies under conditions typical of U.S. cattle operations are lacking, reports suggest that in vitro MIC data may not always predict antimicrobial efficacy in the field.[369,394] If in vitro susceptibility tests do indeed fail to predict clinical efficacy, the reason for this failure is not certain. Because *Mycoplasma bovis* can be seen in association with foci of coagulation necrosis in lungs of affected cattle,[364,379,385] it may be that antimicrobials are not maximally effective in this

environment, or it may be that insufficient duration of treatment is carried out in at least some cases. Controlled trials indicating the duration of antimicrobial therapy needed for effective treatment of pneumonia caused by *Mycoplasma bovis* are lacking, but anecdotal reports suggest that early treatment is critical for success,[359,395] and that treatment should be continued for at least 7 to 10 days.[359] The high concentrations of tulathromycin found in bovine lung for 7 to 15 days after SC injection[393] make this a logical choice for prolonged treatment; a form of oxytetracycline that provides therapeutic blood levels for 7 days (Tetradure, Merial) may also be a good choice for treatment of some cases of disease caused by *Mycoplasma bovis*. Failure of antimicrobials that are predicted to be efficacious against *Mycoplasma bovis* may also be related to inability of the immune response to effectively clear the organism by mechanisms described previously. Some veterinarians report that outbreaks of *Mycoplasma bovis* cannot be stopped with any treatment, but that outbreaks are eventually terminated when chronically affected animals die or are shipped to slaughter.

Research indicates that vaccination can afford some protection against experimental challenge with *Mycoplasma bovis*.[396,397] Autogenous vaccines have been used for years, but no reports with large numbers of animals and appropriate controls are available to provide information about efficacy. Recently two *Mycoplasma bovis* vaccines have been licensed for sale in the United States. To my knowledge no studies have yet been reported in a peer-reviewed forum to provide unbiased evidence of efficacy for either product. Therefore, although small experimental studies suggest that vaccination might be an effective means of minimizing disease caused by *Mycoplasma bovis*, research in the clinical setting with currently available commercial vaccines is sorely needed to indicate whether vaccination can be recommended as an efficacious and cost-effective means of preventing morbidity associated with *Mycoplasma bovis*.

It is not yet clear why some animals develop chronic disease typical of *Mycoplasma bovis* and others do not when it can be found in the respiratory tracts of animals in both populations. Certainly the primary insults known to put ruminants at increased risk for infection with other bacterial respiratory pathogens, such as primary viral infection, mixing of animals from multiple sources, inadequate host immunity, and environmental stressors, may all play a role, but the relative importance of these and other factors in predisposing animals to disease caused by *Mycoplasma bovis* are not yet known. One group presented data suggesting that disease resulting from *Mycoplasma bovis* has increased in severity since the early 1980s,[379] so it may be that factors such as increasing virulence of currently circulating isolates or changes in certain management practices are involved. Because of the chronic nature of disease often associated with *Mycoplasma bovis*, the syndromes described warrant control from both a financial and an animal welfare perspective. Anecdotal reports indicate that some producers with at-risk cattle have more problems with chronic nonresponsive disease caused by *Mycoplasma bovis* than other producers with similarly at-risk cattle,[363] so it is hoped that future research will clarify the factors that put animals at specific risk for chronic disease associated with *Mycoplasma bovis* infection.

625

31.57.5 Mycoplasma Pneumonia of Goats

31.57.5.1 Definition and Etiology

Caprine pneumonias that are not contagious among adults are caused by several species of *Mycoplasma*. *Mycoplasma capricolum* has not been associated with disease in the United States since 1955, and *M. mycoides* subsp. *capri* has not been identified in the United States.[398] However, large colony type *M. mycoides* subsp. *mycoides* (Mmm) can be a very serious cause of mortality among goat kids and does in North America.[399,400]

31.57.5.2

Clinical Signs and Differential Diagnosis

In herds with Mmm infections, goat kids usually appear clinically normal until 2 to 8 weeks of age, when the following three clinical syndromes occur[399,400]:

1 A peracute illness characterized by high fevers (41.1° C to 42.2° C [105.8° F to 107.9° F]) and death within 12 to 24 hours

2 A CNS syndrome with opisthotonos and death within 24 to 72 hours

3 An acute to subacute syndrome with high fevers, multiple hot swollen joints, and pneumonia

The most common manifestations are swollen joints, lameness, and recumbency. About one half of affected kids have increased lung sounds on expiration and elevated respiratory rates. During an outbreak, 80% to 90% of kids die or are euthanized because of permanent recumbency. Mmm infection in adult does is also life-threatening. Forty-six does died in 1 week on a 600-goat dairy during an acute outbreak of arthritis and polyarthritis, mastitis, and interstitial pneumonia caused by Mmm infection.[401]

In the United States the main differential diagnosis of Mmm infection in goats is caprine arthritis-encephalitis (CAE), which is a chronic, sporadic disease. Animals with CAE are generally alert and nonfebrile and continue to eat well. Affected kids exhibit a CNS syndrome at 8 to 16 weeks of age characterized by ataxia and posterior paresis progressing to tetraparesis in 2 weeks to 2 months. They also have a progressive interstitial pneumonia that is usually inapparent. The arthritic form of CAE usually occurs in goats 1 to 2 years of age. In addition, the joints of animals with acute Mmm contain fibrinopurulent exudate, whereas mononuclear cells are present in the joint fluid of CAE cases.

31.57.5.3

Diagnosis

The definitive diagnosis of Mmm infection in individuals requires isolation of the agent from milk, joint fluid, blood, urine, or tissue. Infected goat herds can be readily identified by culturing bulk tank milk because infected does shed up to 10^{10} Mmm organisms per milliliter of milk.[399] Inapparent carriers can be identified by milk culturing, but false-negative results are a risk because organisms are shed intermittently. An ELISA to detect specific antibodies against Mmm has been developed but has not been evaluated for detection of carrier animals.[402]

31.57.5.4

Pathophysiology

Field cases of Mmm infection show evidence of widespread thrombosis, suggesting disseminated intravascular coagulation. A coagulopathy, indicated by increases in prothrombin and partial thromboplastin times and a decrease in number of platelets, has been demonstrated in experimental infections.[403] Mmm has been shown to cause direct damage to cultured endothelial cells and to activate complement.[404]

31.57.5.5

Epidemiology

Localization of Mmm in the udder with no overt signs of mastitis is a key feature of transmission of the disease. In other does, udder infections develop through contact with the organisms during milking, and their

kids become infected by ingestion of colostrum.[405] The localization of Mmm, often associated with mites in the external ear canal of asymptomatic goats, may also play a role in the epidemiologic process of Mmm infections.[406]

31.57.5.6

Necropsy Findings

The most common necropsy finding in goat kids that die of Mmm infections is a fibrinopurulent polyarthritis.[399,400] Approximately one half of field cases have pneumonia. One or more lung lobes have areas of patchy to diffuse red consolidation that is sometimes covered with a fibrinous exudate. Clear, golden yellow to serosanguineous fluid is found in the thorax in half of the cases. In some patients there are fibrinous adhesions between the lungs and thoracic wall. Affected lungs have microscopic evidence of bronchopneumonia or interstitial pneumonia. Other common lesions include pericarditis, peritonitis, and enlargement of the kidneys, liver, and spleen.

31.57.5.7

Treatment and Prognosis

Conventional antibiotic therapy for goats with Mmm infections is almost always unsuccessful.[399,400] Tylosin or tetracyclines are commonly used. A low percentage of kids make a clinical recovery from the septicemic illness but often have arthritis by the time they freshen. Does that recover from mastitis become chronic carriers.

31.57.5.8

Prevention and Control

Prevention is based on maintaining herds free of Mmm infection. Purchased does should originate only from herds that have no history of mortality in kids from arthritis and pneumonia and that have negative bulk tank cultures for Mmm. Purchased individuals should be held separate from the milking herd until they have an Mmm-negative milk culture result; treatment for ear mites may also be prudent. A vaccine is not commercially available; however, an experimental formalin-killed vaccine has been shown to be protective.[407]

Control of Mmm outbreaks is centered on prevention of the systemic infection in kids and mastitis in milking does. Rapid prevention of new cases in kids can be expected from a program of feeding heat-treated goat colostrum (56° C [132.4° F] for 1 hour) or cow colostrum at birth, pasteurized milk up to 1 month of age, and pasteurized milk or a high-quality milk replacer from 1 month to weaning.[399] All kids with swollen joints should be culled. Milking hygiene should be improved to prevent transmission of infection during milking. Udders should be dried with individual cloths or paper towels, teats should be dipped with an organic iodine base preparation, and teat cups should be backflushed. Milk samples from all does in the milking herd should be cultured to identify carrier does. Infected does should be kept in a separate string and milked last or culled, depending on production. Colostrum of dry does should be cultured as they freshen, and the does should be hand-milked separately until their milk is found to be free of Mmm. Monthly cultures of the bulk tank milk from the noninfected string should be performed to ensure that it is free of Mmm infection. The goal of control procedures is eradication of Mmm from the herd.

31.57.6 Other Mycoplasmas

Mycoplasmas are isolated, usually in combination with other pathogens, from 50% to 90% of beef and dairy cattle pneumonias.[111,112,408,409] Mycoplasmas have been associated with peribronchial and peribronchiolar lymphoid hyperplasia, which is sometimes referred to as a "cuffing pneumonia," a common lesion in calves that die or are euthanized because of ECP.[410,411] Mycoplasmas have also been recovered from lesions of acute and chronic bronchopneumonia in which a cuffing pneumonia was not apparent.

Other than *Mycoplasma bovis*, the species of mycoplasmas (see Box 31-4) prevalent in North America are generally considered to be mild respiratory pathogens, mainly causing subclinical infections unless coupled with environmental stresses or infections by other pathogens.[409] Tracheal bronchial aspiration performed on dairy calves at random found that calves with both *Mycoplasma* species and *Pasteurella* species present in the aspirate were at significantly greater risk of developing ECP than calves with only one organism or no organisms. A recent study of feedlot cattle found seroconversion to *M. alkalescens* to be significantly associated with undifferentiated fever, a clinical definition similar to undifferentiated respiratory disease.[297] Effects such as immunosuppression[412] and inhibition of the mucociliary transport mechanism,[413] which can be mediated by mycoplasmas, suggest that they may play an important contributory role in the pathogenesis of bovine pneumonia. *Mycoplasma ovipneumonia* is often isolated from pneumonic lungs of sheep and goats, usually accompanied by *M. haemolytica*. On its own, *M. ovipneumonia* is capable of causing mild, subacute to chronic bronchiolitis or bronchopneumonia that probably predisposes to *M. haemolytica* infections.

31.57.7 Arcanobacterium Pyogenes

Arcanobacterium pyogenes (formerly *Actinomyces pyogenes*, and before that, *Corynebacterium pyogenes*) is a gram-positive rod-shaped species of bacteria that is a common cause of internal or SC abscesses in ruminants. *Arcanobacterium pyogenes* is occasionally isolated from the lungs of ruminants with pneumonia, typically from animals that have chronic pneumonia, possibly from grossly visible abscesses.[111,410,414] This species is viewed as an opportunist that contributes to respiratory disease as a secondary or possibly "tertiary" invader after viral pathogens and other bacterial respiratory pathogens have become established. *Arcanobacterium pyogenes* has a variety of virulence factors including a cytolytic toxin termed *pyolysin*, as well as several molecules that aid in adherence to host cells.[415] Diagnosis of this pathogen is usually made as an incidental finding at necropsy of an animal with significant respiratory disease from other primary causes. Finding *Arcanobacterium pyogenes* during a respiratory necropsy should not induce efforts to directly treat or prevent this pathogen, but rather should induce efforts to prevent other primary or secondary causes of pneumonia and to treat animals in a timely manner with appropriate therapy for an adequate duration in order to prevent chronic pneumonia.

31.57.8 Other Bacteria Associated with Respiratory Disease in Ruminants

Bacteroides melaninogenicus and other anaerobic bacteria are considered opportunistic pathogens that become established after other primary or secondary respiratory pathogens induce lesions. Anaerobic bacteria are isolated from approximately one third of the lungs of cattle that die of bronchopneumonia.[416] These opportunists are believed to be inhaled with eructated ruminal gases. Other bacteria infrequently isolated from pneumonic bovine lungs are listed in Box 31-4. Isolation of these uncommon pathogens during a respiratory necropsy should signal a search for other underlying disease that put animals at risk for pneumonia caused by opportunistic pathogens; it

may also indicate a need for increase efforts to prevent and effectively treat other primary and secondary respiratory pathogens, which may have been present earlier and set the stage for these opportunists.

31.57.9 Chlamydial Agents (*Chlamydophila* Species)

Chlamydial agents are occasionally isolated from pneumonic ruminant lungs. These organisms are thought to produce only mild respiratory infections by themselves but may enhance the pathogenicity of concurrent infections. Research indicates that calves are infected with chlamydial agents relatively early in life and that crowding enhances the likelihood of a high proportion of animals being infected.[417] Experimental challenge of calves with a combination of chlamydia and *M. haemolytica* results in clinical disease more severe than either agent produces alone.[418]

31.58 APPROACH TO DIAGNOSIS AND TREATMENT OF RESPIRATORY DISEASE OF UNDETERMINED CAUSE (UNDIFFERENTIATED RESPIRATORY DISEASE OF RUMINANTS)

Information regarding diagnosis and treatment of individual infectious agents that can cause ruminant respiratory disease was described earlier. However, it is most common for one or more of these agents to be involved when a group of cattle, sheep, or goats has an outbreak of respiratory disease. Moreover, when a veterinarian is called to make an initial evaluation of a group of ruminants with respiratory disease, the exact causative diagnosis is not known. The term *undifferentiated respiratory disease* has been applied to respiratory disease of uncertain cause.[419] Thinking of an outbreak as “undifferentiated respiratory disease” before a causative diagnosis is confirmed is helpful to ensure that the veterinarian considers all possible infectious agents and management factors that may be contributing to disease in the animals in question, rather than immediately focusing on one agent or factor that is guessed to be of importance. A plan to diagnose and treat the current problem and prevent future respiratory disease can then be made by administering treatments and instituting management changes appropriate for any of the agents likely to affect the class of animals involved.

31.58.1 Clinical Signs

626
627

Successful intervention with an outbreak of undifferentiated respiratory disease is based on identification and alteration of the risk factors associated with the outbreak. An investigation begins with collection of a thorough history of the problem and is followed by examination of affected animals and the environment. The history questions are directed to management practices that predispose to pneumonia (see later). It is important to observe personally as many management practices as possible to ensure that what is described is actually implemented. Examination of the environment includes evaluation of the nutrition program to determine whether any of the dietary factors that predispose to pneumonia are present.

Once a thorough history is collected, several animals involved in the outbreak should be examined. Because infectious respiratory disease is so common in ruminants, producers may assume that any illness not obviously occurring in another body system is a result of respiratory disease. However, to ensure rational use of antimicrobials and vaccines and to make properly focused management changes, confirmation of the clinical diagnosis of respiratory disease is necessary.

Ruminants affected by bronchopneumonia exhibit signs of respiratory tract inflammation and, sometimes, toxemia. In early stages, animals stand off by themselves and do not approach feed. They hold their heads and

ears low, appear depressed, and move slowly. Respirations become rapid and shallow, there is frequent licking of the muzzle, and a moist cough is often present. Animals may have a fever of 40° C to 41° C (104° F to 105.8° F) and as the disease progresses they appear gaunt, have deep labored respirations, and may hold the head extended. Dyspnea may be both inspiratory and expiratory. Ocular and nasal discharges progress from serous to mucopurulent. Normal lung sounds are difficult to hear except in calves, goats, and sheep. Sheep normally have harsh inspiratory sounds. The heavy chest wall of larger cattle makes it difficult to hear normal airway sounds. The first auscultable lung changes are increased harshness of inspiratory sounds. By the time expiratory sounds are as loud as or louder than inspiratory sounds, severe bronchopneumonia exists. In the most severe cases, auscultation of the anterior ventral lung fields reveals crackles and wheezes and an increase in bronchial sounds, especially on inspiration. When ventral consolidation occurs, harsh tracheal breathing is still audible ventrally, but percussion reveals ventral dullness. Percussion is best accomplished on young calves and goats of any age. Recently shorn sheep can be readily percussed, but heavy wool makes percussion difficult. Animals in which a fibrinous pleuritis develops are reluctant to move because of pain, have shallow respirations, and sometimes have pleural friction rubs detectable on auscultation. Nasal discharge, dyspnea, abnormal lung sounds, cough, and high fevers are cardinal signs of bronchopneumonia. Other respiratory tract conditions that must be considered as differential diagnoses include acute bovine pulmonary edema and emphysema (ABPEE), interstitial pneumonia, pulmonary edema, pleuritis, laryngitis, tracheitis, and lungworms. Rare conditions include thoracic neoplasia and diaphragmatic hernia. Systemic conditions that result in respiratory signs include septicemia, heart failure, acid-base imbalances, and poisonings such as nitrate toxicity. An important feature that separates systemic conditions from bronchopneumonia is that, in addition to signs of pulmonary dysfunction, systemic conditions often are manifested by clinical signs of damage to other organ systems. In sheep and goats, ovine progressive pneumonia (OPP), CAE, and lung or mediastinal abscesses caused by *C. pseudotuberculosis* or other bacterial invaders are additional differential diagnoses.

Clinical signs associated with specific viral infections of the respiratory tract have previously been presented. In general the clinical signs observed are dependent on the stage of the disease and particularly on whether secondary bacterial pneumonia has been superimposed. In the early stages of viral pneumonia common clinical features include mild depression and anorexia, often marked elevation in body temperature, serous to mucopurulent lacrimal and nasal discharges, cough, and elevated respiratory rates. On auscultation of the lungs there may be an increase in breath sounds. In the presence of secondary bacterial pneumonia, the severity of clinical signs becomes more pronounced.

31.58.2 Diagnostic Workup of Undifferentiated Ruminant Respiratory Disease

If clinical examination of a group of cattle, sheep, or goats indicates that respiratory disease is present, it is not always necessary to immediately submit diagnostic tests. Occasional outbreaks of respiratory disease occur in groups of ruminants, and such occasional outbreaks can often be managed successfully with administrative symptomatic therapy alone (described later). However, if recurrent outbreaks occur, or if animals do not respond appropriately to symptomatic therapy, then diagnostic tests are warranted so that more information is available to better characterize the nature of the problem. In such situations a careful evaluation of management practices and facility design is also warranted to ensure that all practices possible are maximizing the ability of animals to resist respiratory infection. Management practices important to minimizing respiratory infection are described later (p. 638).

31.58.3 Clinical Pathology and Assessment of Immune Status

CBCs or serum biochemical analyses are rarely of much value in diagnosis of respiratory disease in ruminants. Some viruses, such as BVDV, may cause leukopenia, but when bacterial pneumonia is superimposed the WBC count is most often in the high-normal range to mildly elevated with a left shift. Animals with bacterial pneumonia may have an inflammatory leukogram characterized by a leukocytosis with a mature neutrophilia, possibly with a left shift; hyperfibrinogenemia is likely to occur. Animals with chronic pneumonia may have a normal WBC count even when there is significant pulmonary pathology.

Failure of passive transfer is a major risk factor for pneumonia in calves, so investigation of outbreaks in calves should include an evaluation of passive transfer status by measurement of immunoglobulins in the serum of calves 1 to 7 days of age. The zinc sulfate turbidity test, sodium sulfite test, and measurement of total serum protein with a refractometer are practical, satisfactory procedures for estimation of serum immunoglobulin concentrations.

31.58.4 Necropsy Findings

The value of necropsy findings to confirm the cause of death, particularly in animals that die unexpectedly, cannot be overemphasized. If producers can be encouraged to allow all animals that die to be subjected to necropsy, much valuable information may be gained before a disease outbreak causes excessive mortality. It is unfortunately common for veterinarians to be contacted only after several animals have died without any having been subjected to necropsy, and thus much valuable information that could have helped prevent further disease and death has been lost. Establishing a practice of subjecting all animals that die to at least gross necropsy can aid greatly in maintaining management practices that limit animal disease and death; this is because the actual cause of death identified at necropsy can sometimes be unexpected. For example, if an animal is assumed to have died of pneumonia, but it actually died of acute enterocolitis, then control measures may be undertaken that are inappropriate for the true problem.

627

628

The cost of having animals sent to the local diagnostic laboratory for full necropsy may dissuade some owners from allowing necropsies. However, much useful information can be gained simply by gross necropsy evaluation performed on the farm by the local veterinarian. With some practice veterinarians can develop confidence in identifying the major differentiating gross features of common diseases, and they can thus ensure that management is aimed at control of disease of the correct organ system. Moreover, there are some identifiable characteristics typical of the major infectious causes of bronchopneumonia. Gross necropsy can help the veterinarian make a more accurate list of differential diagnoses for outbreaks of bronchopneumonia, allowing the development of a more logical plan for treatment and prevention.

A respiratory necropsy should include assessment of the upper airways and trachea. Fibrinopurulent material in the larynx is evident in cattle with necrotic laryngitis (see Fig. 31-50). Infection with BHV-1 (IBR) causes generalized reddening (congestion) and small raised, red or pale plaques on the mucosa of the nasal passages and trachea; more severe cases have dark red, hemorrhagic changes, possibly with yellow-brown exudate adherent to the mucosa (fibrinopurulent tracheitis) (see Fig. 31-53).

Bronchopneumonia in recently transported cattle (shipping fever pneumonia) is most commonly a fibrinopurulent bronchopneumonia. The infection is aerogenous; it begins in the bronchioles and extends through their walls into the surrounding parenchyma. The cranioventral areas of affected lungs are swollen, dark red to gray-brown in color, firm, and heavy. Bronchial lymph nodes are swollen, wet, and dark red. The inflamed lung

and parietal pleura are sometimes covered with variable amounts of yellow fibrin, and the pleural cavity may contain straw-colored fluid (see Fig. 31-56). Fibrinous pleuritis usually indicates the presence of *M. haemolytica* or *H. somnus*. These species can also cause necrosis of lung, which will be firm and brown to gray (see Fig. 31-57), or dark red wedge-shaped lesions (infarcts) that are caused by thrombosis of an artery supplying the region (see Fig. 31-58). The dorsal regions of the caudal lobes often are mottled by interspersed patches of inflammation and normal parenchyma. In up to one third of bronchopneumonia cases, forced respirations result in vesicular to bullous pockets of emphysema in the dorsal areas of the caudal lobe (see Fig. 31-54). These changes can also be seen with primary BRSV infections or with AIP. Focal or multifocal areas of firm white to yellow material that look like abscesses may actually be caseous necrosis caused by *Mycoplasma bovis* (see Figs. 31-60 and 31-61); the chronic phase of pneumonia resulting from *M. haemolytica* may also cause similar lesions. Abscesses containing caseous or liquid purulent material may also be caused by *Arcanobacterium (Actinomyces) pyogenes* or anaerobic bacteria. Lambs that die of bronchopneumonia caused by *M. haemolytica* have swollen lungs with reddish purple anterior ventral consolidation. An extensive fibrinous pleuritis with large amounts of straw-colored exudate is often present. Chronic cases have multiple abscesses and pleural adhesions. As much as 60% to 80% of the lung tissue is usually involved in fatal cases of severe bacterial pneumonia.

Bronchopneumonia in housed dairy calves (ECP) is less often fibrinous, but rather is characterized by the presence of firm, collapsed, dark red lobules in the cranioventral or caudal ventral lung (Fig. 31-62); in severe cases whole lobes of the lung may be affected. Firm dark red lobules without fibrin on the pleura are common in pneumonia caused by *P. multocida, Mycoplasma bovis*, or other mycoplasmas. Infection with BRSV and PI3 can also cause lobular consolidation of the ventral lung (see Fig. 31-55). Less commonly *M. haemolytica* or *H. somnus* organisms are isolated from such lesions without fibrinous pleuritis.

Fig. 31-62 Postmortem photograph of lung lesions typical of enzootic calf pneumonia. Note scattered collapsed, dark red lobules in the cranioventral lung. This type of lesion could be caused by BRSV, PI3, *Pasteurella multocida*, or various mycoplasmas. Photograph contributed by Dr. Amelia Woolums, University of Georgia, Athens, Ga.
